A DICTIONARY

OF

MACHINES, MECHANICS, ENGINE-WORK, AND ENGINEERING.

HACKLE OR HAX. A kind of comb or brush made of iron spikes; used for combing or pulling the fibres of wool or flax, so as to reduce them from a tangled to a smooth state.

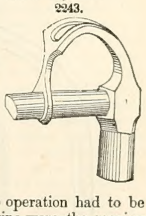
HADE. In mining, the underlay or inclination of the vein.

HALF-TIMBERED HOUSES. Buildings in which the foundations and principal supports were of stout timber, and the interstices of the fronts were filled with plaster.

HALLIARDS. In navigation, the ropes or tackles usually employed to hoist or lower any sail.

HAMMER. A well known carpenter's tool. Fig. 2243 represents a modification known as *Anderson's Patent Hammer.* In this hammer, the claw, as will be seen by the cut, extends to the handle and clasps it with a strong ring, which makes it impossible, in drawing nails, for the handle to give way, draw out, or become loose. The face of the patent hammer will thus always remain true, it being kept at the same angle with the handle. Six different sizes are now made, weighing from half a pound to one and a half pounds.

2243.



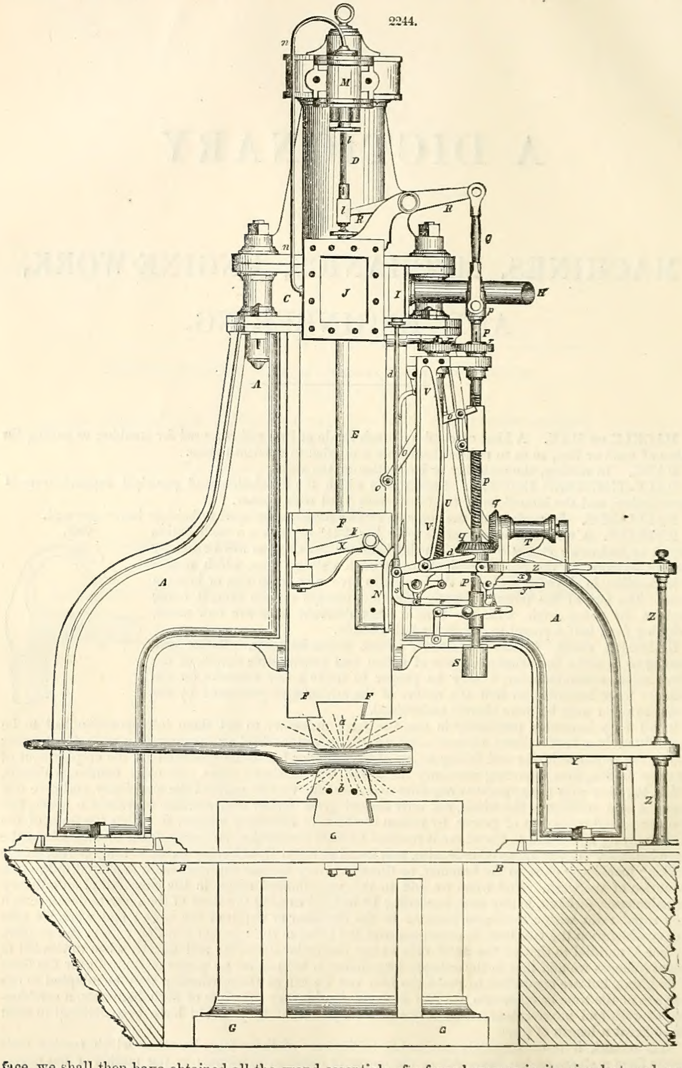
HAMMER, *steam.* JAMES NASMYTH'S patent steam-hammer. Before proceeding to describe the principle, mode of action, and constructive details of the direct-action steam-hammer, it may be proper to make a few remarks on the ordinary forge-hammers, so that the nature of the advantages possessed by the steam-hammer may be more clearly understood.

In all forge-hammers previously in use, the force necessary to set them into operation had to be transmitted in a very indirect manner,—for whether a water-wheel or steam-engine were the moving power, the requisite lifting and falling action of the hammer had to be produced by the employment of rotatory motion, thus rendering necessary the use of wheels, shafts, cams, and other cumbrous details, which, together with the apparatus requisite to connect the various parts of the machinery, and give due strength and solidity to the whole, not only caused great outlay and sacrifice of valuable space, but also occasioned much loss of power, by reason of the very circuitous manner in which the force of the prime moving agent had to travel ere it reached its final destination, and came forth in blows from the forge-hammer. Great inconvenience, also, was found to result from having a considerable portion of the working machinery close to the hammer, as thereby a very serious impediment was offered to the free execution of the work. And when we add to this very limited range in the clear fall of an ordinary forge-hammer, (seldom, in any case, exceeding 18 inches,) causing the force of the blow to decrease in a very rapid ratio, with a moderate increase in the diameter or depth of the work; and when we take into consideration the fact that, in consequence of the helve of the hammer working on a centre or joint, its face is parallel to that of the anvil only at one particular distance; and finally, when to this list of inconveniences we add that in the ordinary forge-hammer we possess no power or control over the force of its blows, but are compelled to make the best use we can of them, whether they be adapted to our purpose at the time or otherwise, we find inherent in the very principle of such hammers, a combination of evils and inconveniences that only excite surprise that they should have been suffered to exist for so great a length of time.

This remark is most strikingly applicable in the case of those forge-hammers which receive their power from a steam-engine, inasmuch as the power in question originates in the motion of the piston, in the very state and condition in which, for the purpose of hammering, we desire it ultimately to be, namely, as a straight up and down motion; so that instead of causing this reciprocating action of the piston-rod to pass through all the complex media of beam, connecting-rod, crank and cam shaft, for no

other purpose than to cause it to act in the same manner as at first,—if we dispense with all this mass of intermediate machinery, and simply invert the steam cylinder so as to bring its piston-rod out at the bottom of the cylinder, and attach it *directly* to a block of iron working in guides right over the anvil

2244.



face, we shall then have obtained all the grand essentials of a forge-hammer in its simplest and most obvious, and, at the same time, as experience has demonstrated, in its most perfect and efficient form. Such is the Direct-Action Steam-Hammer, and such considerations as the preceding led to the invention of this machine.

Some idea of its efficiency in shingling puddled balls may be formed from the fact, that one of 3C cwt., which has been for nearly two years in constant operation at the Gartness Works of the Monkland Iron Company, in the West of Scotland, works off with perfect ease the constant produce of from 18 to 20 puddling furnaces. For this duty the steam-hammer is found to be peculiarly adapted, as it can be made to act for the first few strokes as a *squeezer*, to bring the puddled ball to a neat cubical form; after which it may be made to deal out upon it such energetic blows as secures the entire expulsion of all cinder and other non-metallic impurities, the absence of which, to a greater or less extent, mainly determines the quality of wrought-iron. In short, in every process where either blows of the most enormous energy, or slight taps of the utmost gentleness are required, either continuously or in all grades of variation from the one extreme to the other, the steam-hammer offers facilities which have never hitherto been obtained from any mechanical contrivance for such purposes.

Fig. 2244 represents a side elevation of the steam-hammer, exhibited in full operation, the hammer-block, valve-geer, and other working parts being disposed in the positions which they occupy at the termination of a stroke. Fig. 2245 is a general plan corresponding to the above.

Fig. 2246 is an end elevation, and Fig. 2247 a vertical transverse section of the machine.

Fig. 2248 is a sectional elevation of a portion of the machine, showing the positions of the hammer-block, valve-geer, and other working parts when the hammer is raised for a fresh stroke.

The framing of the steam-hammer consists of two strong cast-iron standards A A, bolted and further secured by keys to a broad base-plate B B, embedded in the solid masonry forming part of the floor of the forge. The standards are surmounted, and their upper extremities united by a species of entablature C, in which the steam-passages and valve-face are formed, and to the upper surface of which the steam cylinder D is bolted. The piston-rod E is fitted to work vertically through a stuffing-box in the centre of this entablature, and its lower extremity is directly attached to the mass of cast-iron F, forming the hammer-block, which is guided to a strictly vertical and rectilinear course by being made to work freely in planed guides formed on the interior surfaces of the standards A A. The hammer *a* itself is inserted into a dovetail recess in the bottom of the block F, where it is retained by wooden packing and iron wedges; while the anvil *b* is in a similar manner secured to the anvil-block G, which is a mass of cast-iron of such weight as effectually to oppose, by its inertia, the momentum of the hammer, and prevent the force of the blows from being dissipated.

Such are the main features of this machine; from which it will be at once understood that, if we can provide the means of rapidly raising the hammer-block to a sufficient elevation, and then as rapidly letting it fall down upon, and so give a blow to the work placed upon the anvil, we have all that is requisite to produce a forge-hammer in its simplest, and, at the same time, its most powerful and per fect form.

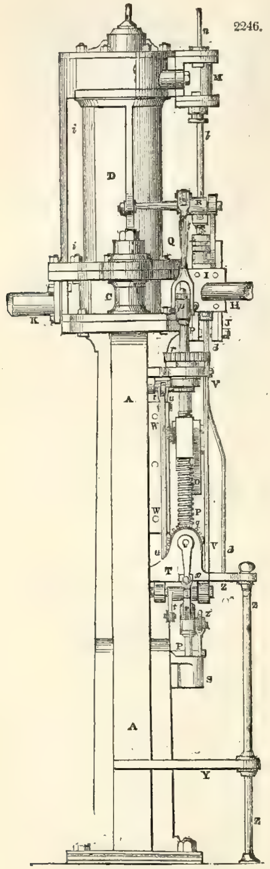
The duty above adverted to, of raising the hammer-block, is performed by the direct application of the elastic force of steam. For this purpose, the steam is led on to the machine by the steam-pipe H, communicating with a neighboring high-pressure boiler; a throttle, or shut-off valve *c*, inclosed within the valve-box I, being situated close to its junction with the main steam-valve chest J, and brought within the control of the attendant workman by means of the rod and lever *d d*. The alternate admission of the steam into the cylinder by the port *f*, and its escape therefrom by the passage *g*, and waste steam-pipe K, are regulated by means of the slide-valve *e*, which may either be worked by hand, or, through the intervention of the self-acting mechanism to be hereafter specified, by the action of the machine itself. The piston L, which is strongly constructed of malleable iron, and fitted with a single packing ring, works steam-tight within the cylinder D; and being directly attached by the piston-rod E to the hammer-block F, it will be obvious that, on the admission of steam of sufficient elastic force beneath the piston, we are supplied with the means of raising the hammer-block to any required height within the range of the machine; while by opening the communication between the under side of the piston and the external atmosphere, the action of gravity will be unimpeded, and the hammer will descend upon the work placed on the anvil, and discharge a blow upon it, energetic in proportion to the weight of the hammer-block, and the height from which it has fallen.

And as, by these simple means, there is no practical inconvenience in supplying the power to raise a hammer-block of 5 or 6 tons weight to an elevation of 7 or 8 feet above the anvil, some idea may be formed of the vast energy of the blows given out by such a mass of iron falling rapidly through so great a space, and discharging *the whole* of its momentum upon the work placed below on the anvil to receive it. In the case of the old system of forge or helve hammers, about one-third only of the total weight of the hammer was effective, the other two-thirds resting on the pivot-standards; so that, in this point of view, the proportion between the blow of a steam-hammer and that of a helve-hammer is nearly 3 to 1 in favor of the former.

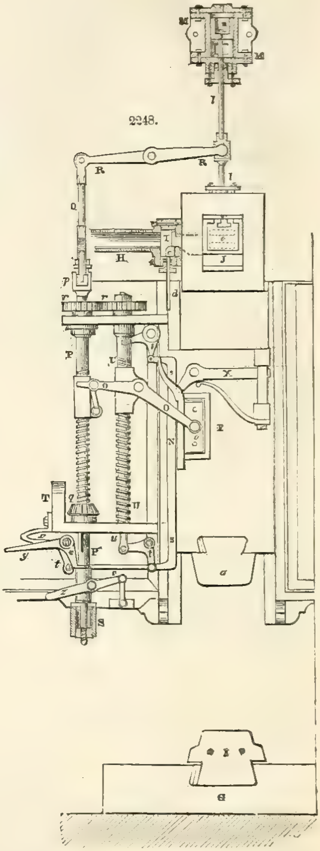
It will be seen, further, that the anvil-face and hammer-face are at all times parallel to each other, whatever be the height or distance between them. The practical value and importance of this property, which is inherent in the principle of the steam-hammer, has been duly appreciated by all who have had experience of the working of this machine.

With a view to prevent any risk of the piston striking the cylinder-cover when working to the full, or very highest stroke of the hammer, a very simple but effective air or steam recoil spring is provided, by having the cylinder-cover screwed down quite air-tight, so that as soon as the piston passes, in its upward motion, the holes *h h*, the air or steam remaining above is shut up in the upper chamber; and as it has no means of escape, it acts as a most perfect spring in arresting any further rise of the piston; and has, besides, the important advantage of converting into increased *downward* velocity of action the undue upward action, which might otherwise have proved not only useless, but destructive. The increase of energy in the blows which can be obtained by this simple means is a point of considerable importance. It is scarcely necessary to remark that, in the emergency above adverted to, the apertures *h h* act as safety-valves for the issue of the main body of the steam, which escapes through the passage *i i*, into the exhaust or waste steam-pipe K.

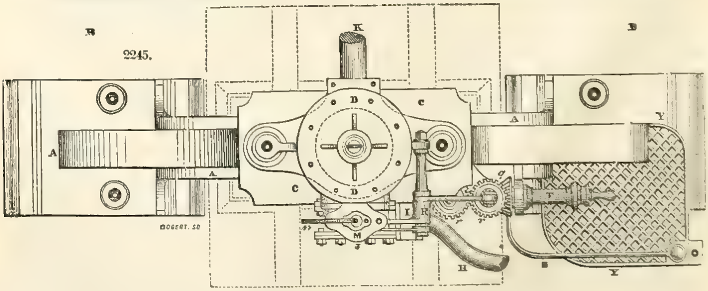
2246.



2248.

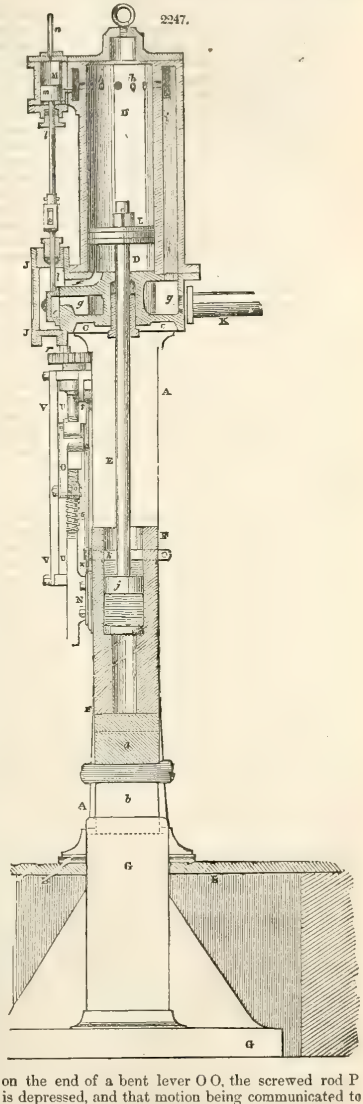


2245.



Plan of Fig. 2244 on preceding page.

Another point of constructive detail worthy of special notice is, the peculiar mode adopted for connecting the piston-rod to the hammer-block. This is one of the most important details in the entire invention, and without which no practical success would have attended it. Had the piston-rod been attached to the hammer in the ordinary mode of attaching pistons to the machinery of a steam-engine or such like, namely, by a cotter, or by screwing the rod into the hammer, or such other solid, unyielding mode, the effect of the blow or fall, at each stroke of the hammer, would have been that the piston-rod and piston (being composed of a considerable *mass* of materials) would have themselves acted *as a hammer*, and would have discharged their momentum upon the means of fastening, and this with such destructive effect as to break through all such *solid, unyielding means of resistance*, after a few blows.



This was foreseen from the first as an action to be prevented, and accordingly, in my original drawing, already adverted to, a remedy was provided, which experience has proved to be entirely effectual.

This contrivance consists in placing, in a cylindrical recess formed in the body of the hammer-block, and under the knob *i*, on the end of the piston-rod, a series of pieces of hard wood, or other *slightly* elastic material, as in Fig. 2246. The effect of this arrangement is to allow the momentum of the piston and piston-rod to deposit itself in such a comparatively gradual manner as to cause the concussion arising from the most severe and energetic blows of the hammer to have not the slightest evil effects on the piston and rod; it is, in fact, the very same expedient to which nature has had recourse for the purpose of obviating those unpleasant and destructive shocks and vibrations which we should experience at every step or stamp of the foot, had no cartilage been provided between the joints of our bones. It is surprising to observe by how small an amount of elasticity, from the employment of such compressible material, the evil effect of violent shocks may be removed. The connection of the piston-rod and hammer-block is secured by means of the two keys *k k*, driven very firmly *above* the knob or button *j*, a layer or two of the elastic material being interposed for the purpose of neutralizing any shock in the contrary direction.

We shall now proceed to describe the mechanism by which the height of the fall of the hammer, and consequent intensity of the blow, may be modified according to circumstances, and the machine made perfectly self-acting.

The requisite alternating motion of the steam-valve *e* is produced in the following manner:— The valve-spindle *l* is prolonged upwards and attached to a small solid piston *m*, working within a short cylinder M, bolted to the main steam cylinder D. A small portion of steam is supplied above the piston *m*, by a slender copper tube *n*, communicating with the steam valve-chest J; by this arrangement it will be seen that, unless counteracted by some superior force, the pressure of the steam upon the piston *m* will tend to keep the valve *e* constantly depressed, in which position the steam-port *f* is full open. This counteracting force is supplied by the action of the hammer itself; for, by means of the tappet N, (which is bolted to the hammer-block,) coming into sliding contact, when the latter is raised, with the small friction-roller *o*, mounted on the end of a bent lever O O, the screwed rod P which is jointed to the opposite end of that lever, is depressed, and that motion being communicated to the valve-spindle *l*, through the intervention of the connecting-rod Q and valve-lever R, the steam-

valve e is raised, thus cutting off all further ingress of steam under the piston, and almost at the same instant permitting the escape of that which had served to raise the hammer. By this simple contrivance the upward motion of the hammer is made the agent for its own control in that respect. By comparing the relative positions of the parts referred to, as exhibited in Figs. 2244 and 2248, the nature of the motion above described will be at once most fully understood. To obviate the injurious effects of the shock of the tappet N against the lever O, a connection is provided at p, on a similar principle to that formerly described in reference to the connection of the piston-rod and the hammer-block; and in order to restrict the downward travel of the valve to the proper point, a check or *buffer-box* S is provided, consisting of a small cylinder bolted firmly to the framing of the machine, within which a circular nut, screwed on the lower end of the rod P, works as a piston, a few leather washers being interposed between the latter and the close or upper end of the cylinder.

It may be here remarked, that it is by no means necessary to continue the admission of steam under the piston until the termination of the upward stroke, or *lift* of the hammer, seeing that the velocity which the hammer-block has acquired in its upward motion makes it continue to ascend after the further ingress of the steam has been arrested. This circumstance is a source of considerable economy of steam, as we have by such action (as well as by that due to the expansive energy of the steam) an effect as to height of lift of the hammer, greater than that which is due to the actual expenditure of steam at its original pressure. It is worthy of remark, also, that as the *over-running* action above alluded to will necessarily increase in proportion to the velocity of ascent of the hammer-block, this circumstance will, to a considerable extent, compensate for the increased expenditure of steam due to that increased velocity.

From the above description it will be obvious, that the lift of the hammer, and consequent intensity of the blows, depends simply upon the position of the lever O, in relation to that of the hammer-block when at its lowest point. Therefore, if we can provide the means of altering the distance between these two points, we shall have it in our power to modify permanently the force of the blows to any required extent within the range of the machine. This condition is most completely satisfied by the arrangement of mechanism employed by me, and which is clearly represented in the figures.

The rod P which conveys the action of the lever O to the valve-lever R, is screwed throughout the greater part of its length, and is so adjusted in its bearings, as to be susceptible of rotatory as well as vertical motion. This motion of rotation is imparted to it by means of a handle fixed to a short axis, working in a bracket T bolted to the framing, and actuating a pair of small bevel-wheels $q\ q$. The nut through which the screw works forms the point of attachment between the rod P and the lever O, the connection being effected by means of a short intermediate rod for the sake of insuring parallelism of motion. A pair of small spur-wheels $r\ r$, (through the first of which the rod P works by means of a sunk feather,) serve to transmit the angular motion of the rod P to a similar screwed-rod U, situated parallel to and at a short distance from the former; the nut of the screw U forms the fulcrum or centre of motion of the lever O, and the pitch of the threads of both screws being equal, though formed in contrary directions to each other, it is obvious that, on turning the handle, the lever O and all its appendages will be simultaneously raised or depressed, and consequently the lift of the hammer regulated to any required extent, and its amount altered with the utmost ease and precision. The pin which forms the centre of motion of the lever O is protected and secured from lateral strains by the cast-iron guides V and W, seen most distinctly in the sectional plan, Fig. 2245.

A most essential part of the self-acting geer remains yet to be noticed. It is obvious that, were no provision made for the retention of the steam-valve in the position into which it is thrown by the upward motion of the hammer-block, the latter would not be permitted to have its due effect in the accomplishment of its work; for, as soon as it descended so far as to relieve the end of the lever O from contact with the tappet N, the valve would resume the position into which it is constantly solicited by the action of the *steam-spring* at M, and the descent of the blow would be impeded by the return of the steam into the cylinder, before the hammer had completed its fall. To obviate this inconvenience, a simple but most effectual contrivance has been applied. Towards the lower extremity of the valve-screw P a shoulder is formed, against which a short lever w, called the *trigger*, is constantly pressed by the spring x, so that when the rod P is depressed by the action of the lever O, it is arrested by the trigger and retained in that position until the blow has been struck. This delicate and most important part of the mechanism is very carefully constructed, the point of the trigger, and the shoulder against which it acts, being formed of steel, and hardened to resist wear.

To release the valve-screw from the trigger, and so permit the return of the valve into the position requisite for effecting a fresh stroke, the following mechanism has been adopted: on the front of the hammer-block, Figs. 2244 and 2248, a lever X, called the *latch-lever*, is fitted to work freely on a pin passing through the body of the hammer-block. That portion of the latch-lever which is most remote from the valve-geer is considerably heavier than the opposite end, and is constantly pressed upwards by means of a spring. The lighter end is brought into contact with a long bar $s\ s$, called the *parallel bar*, the extremities of which are suspended upon two small bell-cranks $t\ t$, whose other arms are connected by means of a slender rod u, Fig 2247, forming a species of parallel motion, for the purpose of adapting this geer to come into efficient operation, at whatever point in the range of the hammer its blow may be arrested. A small connecting-rod v, between the lower bell-crank and a short lever on the axis of the trigger w, completes this part of the mechanism.

The action of this geer is of a very peculiar nature, and is admirably adapted to fulfil the object intended. At the instant the hammer gives a blow to the work upon the anvil, the effect of the concussion is to cause the momentum of the heavy end of the lever X to overcome the upward pressure of the spring, and thereby to protrude its opposite end against the edge of the parallel bar s, which motion, though but slight in amount, is yet adequate, through the arrangements above described, to throw back the trigger from contact with the valve-screw, and leave the latter free to obey the impulse of the steam-spring in the readjustment of the valve into its original position.

These various movements, which have taken so long to describe, are all performed in less than half a second, and consequently the action of the hammer is proportionally rapid.

The construction of the self-acting geer is so arranged as to admit of advantage being taken, when circumstances render it desirable, of the very action to obviate which the trigger *w* is introduced. When it is desired to strike a gentle blow, such as is frequently required during particular stages in the progress of a piece of work, it is not requisite, for this purpose, to change the position of the valve-lever O. All that has to be done is to hold back the point of the trigger *w*, by its handle *y*; this permits the valve to reopen and let the steam in under the piston L, at the instant the tappet N has fallen away from contact with the lever O. The effect of this is, that a quantity of steam is admitted into the cylinder under the piston, which serves as a cushion, by which the violent fall of the hammer is arrested, and its momentum modified to any extent, or at the pleasure of the person in charge of the handles. The handle *z*, is for the purpose of placing the steam-valve also under his control, and, for his further convenience in the management of the hammer, a platform Y and hand-rail Z are erected against the framing of the machine.

A modification of the frame of this machine has been made at the Washington Navy Yard, one support only being used, by which means access is had to the anvil on all sides except that occupied by the support.

HAMMER, *Tilt or Trip.* See TILTING.

HARVESTER. An agricultural machine for reaping and gathering in grain, much used in the western country. There are many forms of them, known in this part of the country as REAPERS, which see.

HAT-MAKING embraces two distinct kinds of manufacture, felted and covered hats; the covering of the latter being sometimes silk, and at other times cotton.

Felted hats comprehend two classes, differing chiefly in the materials used in making, the process being nearly identical. The lower class is marked by inferior ingredients, unmixed with beaver, and embraces *wool*, *plated*, and *short-nap* hats.

Wool hats are made entirely of coarse native wool and hair stiffened with glue. *Plates* have a *nap* or pile rather finer than their body, and are sometimes *water-proof* stiffened. *Short naps* are distinguished from plates by additional kinds of wool, viz. hare's back, seal, neuter, musquash, (Muscovy cat,) and are all water-proof stiffened.

The second class may be said to comprehend two orders, called stuff and beaver hats. The first includes mottled and stuff bodies. The latter term is not used generally, as all *stuffs* are understood to be of this sort when *mottled* is not expressed. *Mottled bodies* are made chiefly of fine wool, and inferior rabbit down or coney wool. *Stuff bodies* consist of the best hare, Saxony, and red wools, mixed with Cashmere hair and silk. *Stuff hats* are *napped*, that is, covered with pile of mixed seal, neuter, hare-back, inferior beaver, and musquash. *Beaver hats* are, or ought to be, napped with beaver only; the lower priced qualities with *brown wooms* taken from the back; the more valuable kinds with *cheek* and *white wooms*, being the finest parts of the fur found on the belly and cheeks of the beaver.

The apparatus and terms used in making felted hats, which it is necessary to describe briefly, are the bow, basket, hurdle, battery, and planks.

The *bow* is about six feet long, usually made of ash, thick enough not to be elastic. The handle is called the *stang*. The *bow-string* is a strong catgut cord tensely fastened.

The *hurdle* is a fixed bench, with three enclosing sides, to prevent the stuff being flittered off in bowing.

The *basket* is of light wicker-work, about twenty by twenty-two inches in size.

The *battery* consists of the kettle and the planks, which are inclined planes, usually eight in number, one only being appropriated to each workman. The half of each plank next the kettle is lead, the upper half is mahogany.

The first process in hat-making is *bowing* the stuff or furs, which are weighed out to a proportionate scale, and laid on the hurdle, immediately under the bow, which is suspended by a pulley. The bow is held firmly with the left hand, rather towards the *breech-end*, not edgewise, but on its side, with the string in contact with the stuff, the clotted and adherent portions of which are separated into single fibres, and attain a loose, flocky, mixed condition by the continued vibration of the bow-string, caused by a very rapid succession of touches with the bow-stick. It is then divided as nearly as possible, and one-half laid aside, whilst the other is again bowed. In this second operation, partly by the bowing, but chiefly by the *gathering*, or patting use of the basket, the stuff is loosely matted into a conical figure, about fifty by thirty-six inches, called a *bat*. In this formation care is taken to work about two-thirds of the wools down towards what is intended for the brim, which being effected, greater density is induced by gentle pressure with the basket. It is then covered with a wettish linen cloth, upon which is laid the *hardening skin*, a piece of dry half-tanned horse-hide. On this the workman presses or bakes for seven or eight minutes, until the stuff shall have adhered closely to the damp cloth, in which it is then doubled up, freely pressed with the hand, and laid aside. By this process, called basoning, (from a metal plate or *bason*, used for like purposes in making *wool* hats,) the bat has become compactly felted and thinned towards the sides and point. The other half of the flocked stuff is next subjected to precisely the same proceedings, after which, a cone-shaped slip of stiff paper is laid on its surface, and the sides of the bat folded over its edges to its form and size. It is then laid paper-side downward upon the first bat, which is now replaced on the hurdle, and its edges transversely doubled over the introverted side-lays of the second bat, thus giving equal thickness to the whole *body*. In this condition it is reintroduced between folds of damp linen cloth, and again hardened, so as to unite both halves, the knitting together of which is quickly effected. The paper is now withdrawn, and the body being folded into three plies, is removed to the plank or battery-room.

In the battery the *liquor* is scalding heat, composed of pure soft water, with about half a gill of oil of vitriol as an astringent. Herein the body is imbrued, and withdrawn to the plank to partly

cool and drain, when it is unfolded, rolled gently with a pin tapering towards the ends like a liquor horse, turned, and worked with in every direction, to toughen, shrink, and at the same time prevent adhesion of its sides. *Stopping* or thickening the thin spots which now appear on looking through the body, is carefully performed, by additional stuff daubed on by successive supplies of the hot liquor from a brush frequently dipped into the kettle, until the body be shrunk sufficiently, (about one-half,) and thoroughly equalized. When quite dried, *stiffening* is performed with a brush dipped into a glutinous pulpy composition, and rubbed into the body; the surface intended for the inside having much more imposed than the outer, while the brim is made to absorb many times the quantity applied to any other part. This viscous matter contains *proofing*, or those ingredients which render the hat waterproof.

On being again dried, the body is ready to be *covered*, and is once more taken to the battery. The first cover of beaver or napping, which has been previously *bowed*, is equally strewed on the body, and patted upon with the brush charged with the hot liquor, until incorporated; the *cut* ends only being the points which naturally intrude. Here the body is put into a coarse hair-cloth dipped and rolled in the hot liquor, until the beaver is quite worked in. This is called *rolling off*, or ruffing. A stripe for the brim round the edge of the inside, is treated in like manner, and is thus prepared for the second cover, which is applied and inworked in like manner; the rolling, &c., being continued until the whole has become incorporated, and a clean, regular, close, and well-felted *hood* is the result. The dry hood, after having the nap beat up and freed, is clipped to the length which may be thought best, by means of common shears. A clipping machine, invented nearly four years ago in Scotland, is now very generally preferred, and doubtless will soon everywhere supersede the ordinary process; much greater regularity, speed, and certainty being secured by it. When the nap is thus disposed of, the hood is soaked in the battery kettle, and then *drawn down* on a block to the size and shape wanted, firmly tied at the bottom with a cord, around which the brim is left in a frilled condition.

Dyeing is the next step. A *suit*, or six dozen, are put into the dye-kettle at a time, all on the crown-blocks already mentioned, and allowed to remain three-quarters of an hour in the liquor, which is kept as near as possible one degree below the boiling point. These being taken out and set in the yard to cool, another suit is introduced for a like period, and the various suits are so treated at least twelve times in successive order. Each of the first four introgressions of every suit is accompanied by about seven pounds of copperas, and two pounds of verdigris. The body is then washed and brushed out in changes of hot water, until no coloring can be recognized in it. When thus thoroughly cleansed, it is steamed on a block shaped as the hat is wished to be when complete; and in the finishing shop by neavy (21-pound) heated irons and moisture, the frilled brim is shrunk until rendered quite level, the nap gently raised all over with a fine wire card, and brushed and ironed smooth in the uniform directions. The tip, a thin lath-sheet, is then fitted and stuck to the inside of the crown, and *robbined* or secured all round the edges by stripes of prepared paper. When thus *got down*, it is sent to the *picker*, who, with tweezers, extracts the *kemps*, or "gray hairs," which are a few of those thick fibres peculiar to the fur of amphibious animals, that have escaped the search of the machine used in blowing the beaver, so as to separate them from its fine parts. This being carefully accomplished, it is transferred to the finisher, who, with a plush cushion, a brush, and hot iron, imparts to it that bright sleeky lustre. The *shaper* then rounds the brim with a knife and notched segment to the breadth wanted; and shapes it in varied styles by means of a hot iron and damp, with about a foot length of rope, over which the *curl* is laid. The *trimming* is next done, when the *tipper-off* corrects the twists, smooths the ruffled nap caused by trimming, and *papers* it up with tissue and cartridge, which completes it for the retailer.

Silk hats are made upon bodies of wool, stuff, willow, straw, and Leghorn plait, and cambric and woollen cloth, although chiefly on felted wool bodies, which are dipped in glue size, wrung out, blocked, and dried. The *tip* is then fitted and robbined, when a flour-box, charged with powdered shell-lac and rosin in like quantities, is used to strew equally its grainy mixture on the external surface of the *shell*, so called from being the frame-work. This is burned in by hot irons, first on the top, which passes through to the lath-tip within; then on the upper brim, the sides, and, finally, the under brim. When this is hardened it is coated with thick ordinary flour-paste, which is dried, and the shell again blocked and smoothed; then once more glue-sized outside, dried, and varnished, which prepares it for *covering*. The shag for the sides is cut across the web, in a ratio of obliquity increased by inferiority. This cross part is sown to a circular piece for the crown, whilst the brims are singly patched together. These preparations being completed, the *top-side* or upper brim is first stuck, then the crown, next the sides, and, finally, the under brim. *Sticking* is effected simply by the heat of the iron passing through the covering and melting the varnished surface. In the finish of this manufacture, the most particular part is the *side-seam*, which is disposed of thus: The selvidge end is cut perpendicularly from top to brim, by a sharpened pallet-knife, the nap having been previously brushed clear off its edge. The other selvidge end is then stuck and cut with the utmost nicety, in close parallel with the other. It is then finished very much in the same manner as a beaver hat.

The above-mentioned method of making hat-bodies is now mostly superseded in this part of the country by the adoption of machinery, the manual labor being confined to the getting up the hat, and is a distinct business; the hatter for the most part purchasing his hat-bodies far cheaper than he can make them.

The machinery is very simple. The fur or hair of which the felt is to be made, after being cleaned and lightly beat up, by passing through a kind of winnowing machine, is delivered to a boy, who spreads the fur very lightly and in small quantities on an endless web before him, which, passing between rollers, carries the fur into the body of the machine, where it encounters a cylindrical brush in rapid motion, which separates the hair or fur completely, throwing it towards a contracted opening in the sides of the cylinder-case. This opening, about an inch wide at top and nearly three inches at bottom, is in height equal to the cone of the hat-body. Immediately in front, and close to this opening,

is placed a perforated copper cone, the perforations so small, and in such number, as almost to render the surface of the cone, from base to apex, a wire-gauze surface. This cone is open at the bottom and placed on an opening equal to its base, which opening is in communication with a fan or blast, so arranged as to exhaust the interior, or "suck," so to speak, the air through the meshes of the copper cone. The hair or fur in its divided state, thrown towards this opening in the cylinder case, is brought under the influence of the powerful draught towards and through the cone; the latter at the same time slowly revolving on its axis, exposes all its sides to the opening, and the hair is driven against it with such force as to adhere for the time, and receive and retain on all sides, as it revolves, the fine particles of hair as they are drawn from the cone. In the space of half a minute a dry hat-body is formed on the copper cone; this is immediately enveloped by a wetted felt, and the whole immediately removed, and its place supplied by a fresh copper while the first is being stripped of its now wet felt. The whole operation is performed with wonderful dispatch, the hat-body resulting from it being exceedingly light and uniform in texture, and requires but little labor before it is in condition to be transferred to the hands of the hatter for working up. In this manner any form of felt may be made. The opening in the cylinder case being of flexible metal, admits of adjustment to the wants of the particular form of the felt to be constructed. The application of this principle is universal in the manufacture of felt.

HEART-WHEEL. A cam for converting a uniform circular into a uniform rectilinear motion.

HEAT. Heat in the ordinary application of the word, implies the sensation experienced upon touching a body hotter or of a higher temperature. *Caloric*, the principle or cause of the sensation of heat. On touching a hot body, caloric passes from it, and excites the feeling of warmth: when we touch a body having a lower temperature than our hand, caloric passes from the hand to it, and thus arises the sensation of cold.

Caloric is usually treated of as if it were a material substance; but, like light and electricity, its true nature has yet to be determined.

Caloric passes through different bodies with different degrees of velocity. This has led to the division of bodies into *conductors* and *non-conductors* of caloric: the former includes such bodies as metals which allow caloric to pass freely through their substance, and the latter comprises those that do not give an easy passage to it, such as stones, glass, wood, charcoal, &c.

Table of the relative Conducting Power of different Bodies.

Gold	1000	Platinum	981
Silver	973	Copper	898
Iron	374	Zinc	363
Tin	304	Lead	180
Marble	24	Porcelain	12·2
Fire-brick	11	Fire-clay	11·4

With Water as the Standard.

Water	10	Elm	32
Pine	39	Ash	31
Lime	39	Apple	28
Oak	33	Ebony	22

Relative Conducting Power of different Substances compared with each other.

Hares' fur	1·315	Cotton	1·046
Eider-down	1·305	Lint	1·032
Beavers' fur	1·296	Charcoal	·937
Raw silk	1·284	Ashes (wood)	·927
Wool	1·118	Sewing-silk	·917
Lamp-black	1·117	Air	·576

Relative Conducting Power of Fluids.

Mercury	1·000	Proof spirit	·312
Water	·357	Alcohol (pure)	·232

Radiation of caloric.—When heated bodies are exposed to the air, they lose portions of their heat, by projection in right lines into space, from all parts of their surface.

Bodies which radiate heat best, absorb it best.

Radiation is affected by the nature of the surface of the body; thus, black and rough surfaces radiate and absorb more heat than light and polished surfaces.

Table of the Radiating Power of different Bodies.

Water	100	Blackened tin	100
Lamp-black	100	Clean "	12
Writing-paper	100	Scraped "	16
Glass	90	Ice	85
India-ink	88	Mercury	20
Bright lead	19	Polished iron	15
Silver	12	Copper	12

Reflection of caloric differs from radiation, as the caloric is in this case reflected from the surface without entering the substance of the body: hence the body which radiates, and consequently absorbs most caloric, reflects the least, and *vice versâ*.

Latent caloric is that which is insensible to the touch, or incapable of being detected by the thermometer. The quantity of heat necessary to enable ice to assume the fluid state is equal to that which

would raise the temperature of the same weight of water 140°; and an equal quantity of heat is set free from water when it assumes the solid form.

If 5½ lbs. of water, at the temperature of 32°, be placed in a vessel communicating with another one, (in which water is kept constantly boiling at the temperature of 212°,) until the former reaches this temperature of the latter quantity, then let it be weighed, and it will be found to weigh 6½ lbs., showing that 1 lb. of water has been received in the form of steam through the communication, and reconverted into water by the lower temperature in the vessel.

Now this pound of water, received in the form of steam, had, when in that form, a temperature of 212°. It is now converted into the liquid form, and still retains the same temperature of 212°, but it has caused 5½ lbs. of water to rise from the temperature of 32° to 212°, and this without losing any temperature of itself. It follows, then, that in returning to the liquid state, it has parted with 5½ times the number of degrees of temperature between 32° and 212°, which are equal 180°, and $180° \times 5\frac{1}{2} = 990°$. Now this heat was combined with the steam; but as it was then not sensible to a thermometer, it was called *Latent.*

It is manifest, then, that a pound of water, in passing from a liquid at 212° to steam at 212°, receives as much heat as would be sufficient to raise it through 990 thermometric degrees, if that heat, instead of becoming latent, had been *sensible.*

The sum of the sensible and latent heat of steam is always the same at any one temperature; thus, $990° + 212° = 1202°$.

If to a pound of newly fallen snow were added a pound of water at 172°, the snow would be melted, and 32° will be the resulting temperature, 138° of heat becoming latent in the melted snow.

Latent Heat of various Substances.

Fluids.		Vapors.	
Ice	140°	Steam	990°
Sulphur	144	Vinegar	875
Lead	162	Ammonia	860
Beeswax	175	Alcohol	442
Zinc	493	Ether	302

Sensible caloric is free and uncombined, passing from one substance to another, affecting the senses in its passage, determining the height of the thermometer, and giving rise to all the results which are attributed to this active principle. See Steam.

It is frequently desirable to convert the degrees of heat, as indicated by one thermometer, into its equivalent as denoted by another. The following rules will serve this purpose for the thermometers in general use:—

To reduce the degrees of a Fahrenheit thermometer to those of Reaumur and of the centigrade; the zero of the Reaumur scale being at the freezing point, and 80° at the boiling point, whilst the zero of the centigrade is at the freezing point, and 100° at the boiling. See Thermometer.

Fahrenheit to Reaumur.—Rule.—Multiply the number of degrees above or below the freezing point by 4, and divide by 9.

Thus, $212° - 32 = 180 \times 4 = 720 \div 9 = 80$, *Ans.*
$+24° - 32 = \quad 8 \times 4 = \quad 32 \div 9 = 3{\cdot}5$, *Ans.*

or 3·5 below zero.

Fahrenheit to centigrade.—Rule.—Multiply the number of degrees above or below the freezing point by 5, and divide by 9.

Thus, $212° - 32 = 180 \times 5 = 900 \div 9 = 100$, *Ans.*

Or multiply the degrees of Fahrenheit by ·444 for reducing them to Reaumur, and by ·555 for reducing them to centigrade.

Medium heat of the globe is placed at 50°; at the torrid zone, 75°; at moderate climates, 50°; near the polar regions, 36°.

The extremes of *natural heat* are from 70° to 120°; of *artificial heat,* from 91° to 36,000°.

Evaporation produces cold, because caloric must be absorbed in the formation of vapor, a large quantity of it passing from a sensible to a latent state, the capacity for heat of the vapor formed being greater than that of the fluid from which it proceeds.

Evaporation proceeds only from the surface of the fluids, and therefore, *other things equal,* must depend upon the extent of surface exposed.

When a liquid is covered by a stratum of dry air, evaporation is rapid, even when the temperature is low.

Table of Effects upon Bodies by Heat.

	Fahrenheit.		Fahrenheit.
Cast-iron, thoroughly smelted	2754°	Lead, melts	594°
Fine gold, melts	1983	Bismuth, melts	476
Fine silver, melts	1850	Tin, melts	421
Copper, melts	2160	Tin and bismuth, equal parts, melt	283

Melting Point of Alloys.

Lead 2 parts,	tin 3 parts,	bismuth 5 parts,	melts at	212°
" 1 "	" 4 "	" 5 "	melts at	246
	" 1 "	" 1 "	melts at	286
	" 2 "	" 1 "	melts at	336
" 2 "	" 3 "		melts at	334
	" 8 "	" 1 "	melts at	392
" 2 "	" 1 "	common solder,	melts at	475
" 1 "	" 2 "	soft solder,	melts at	360

Boiling points.—The boiling point of water, from 27 to 31 inches of the mercurial column, varies 1·65° for every inch, being at 30 inches 212°; and on this variation is founded the apparatus for determining altitudes.

Comparative Heat from various Fuels.

1 lb. of tolerably good coal will raise the temperature of 60 lbs. of water from 32° to 212°.
1 lb. of kiln or perfectly dried wood will effect the same on 35 lbs.
1 lb. of wood simply dried in the air " " 26 lbs.
1 lb. charcoal " " 79 lbs.

Turf of good quality yields as much heat for equal weights as wood, and the heat it gives out by radiation whilst burning has been considered even greater than that of wood.

For the various methods of applying heat to the warming of buildings, see article Warming.

HEDDLES, *Machine for making Weavers'.* This machine is the invention of Mr. Kassimir Vogel, of Lowell, Massachusetts.

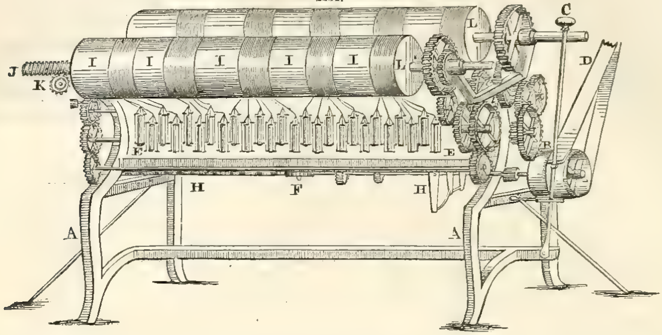
The object of the machine is to make weavers' heddles from the thread, casting the loop by braiding instead of knotting, and performing triple the amount of work, and better than can be done by hand. A patent is also secured for the peculiar eye of the heddle, so that both machine and its results are protected.

Description.—Fig. 2251 is a perspective view, and shows gangs of different heddles winding on the beams. A A is the iron framing. B are the driving and slack pulleys. C is the lever to geer and ungeer. E E are the bobbins, with the thread to make the heddles. There is a small shaft under the bed of E, which, by small cog-wheels on the same, operate and revolve the bobbins by geering into F. I I are the heddles after the eye is formed, winding up on the beams L L. The gang of wheels at the left are for the purpose of connecting the shafts of the beams to be driven by the main shaft below. The number of eyes to the foot in the heddles can be increased or diminished by the geering of these small wheels. K is a small bearing for the shaft of L, and J is the shaft with a screw cut on part of it. This is for winding the heddle gradually along the beam, and as K is a grooved and wormed faced pulley driven slowly by the small gang of wheels at the right, the shaft J is wormed slowly through its bearings, carrying the beam to let the heddles wind one after another on the same. The heddles are formed of a double cord, which is twisted by the bobbins revolving, and the eyes or loops are formed by the bobbins being interlocked, braiding the two strands at the two points which form the eye of the heddles. The section views will explain the operations better in detail.

As the same letters indicate like parts on all the following engravings, we shall describe them collectively. Fig. 2252 is a side elevation. Fig. 2253 is a top view of the revolving tables and spindles. Fig. 2254 is an end elevation. Fig. 2255 is a view of the under side of the machine, showing the geering by which the tables that carry the spindles are made to revolve.

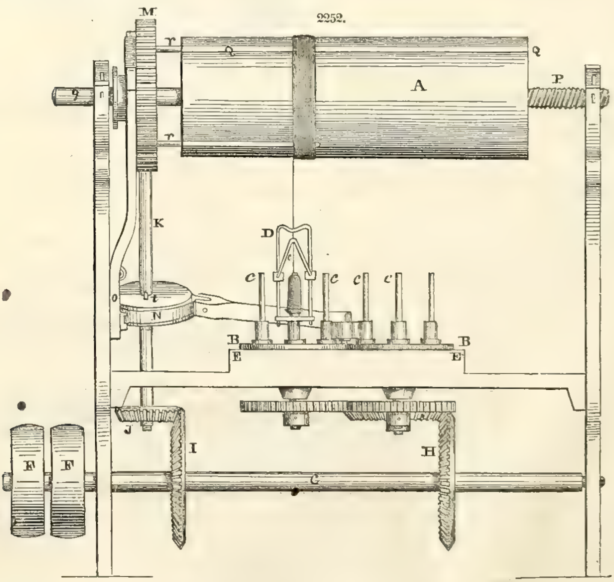
A is the heddle-beam. B B B B are revolving spool-frames or tables. C represents the spool-spindles. *a* are slots in the spool-tables. Each table has six slots or spindle recesses, but only three are occupied at once with the spindles. As the tables revolve, three slots are occupied with spindles and three are empty alternately, and an occupied slot in one is brought opposite to an empty recess in its

2251.



fellow-table, as seen in Fig. 2253. The tables B B constitute one pair, and the tables B 2, B 3, another, forming two distinct harness, one on each side on two beams, but driven by the same geering. The yarn is put on the spindles C, and passes through a hole in the top of the flyers D, or over a depression, Fig. 2252, to hold it in its place, and then passes under *c*, a recurved wire, that has a perforated weight

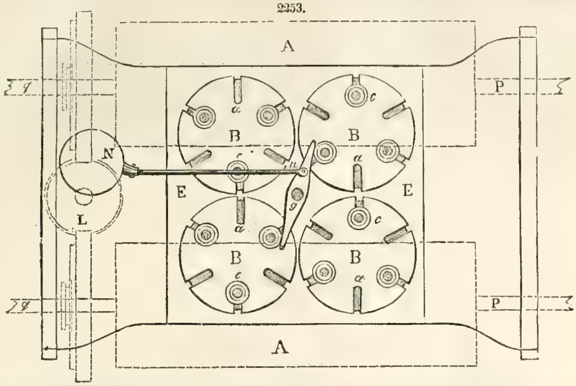
2252.



2 *a* at each end. The flyers pass through these holes, and the legs serve as guides to the weights. This is to take up the slack of the yarn. The spindles have each a groove in their lower parts, adapted to slide into the recesses of the tables when the recesses coincide. The platform E E has circular cavities for the lower ends of the spindles. F F, Fig. 2252, are fast and loose pulleys to drive the

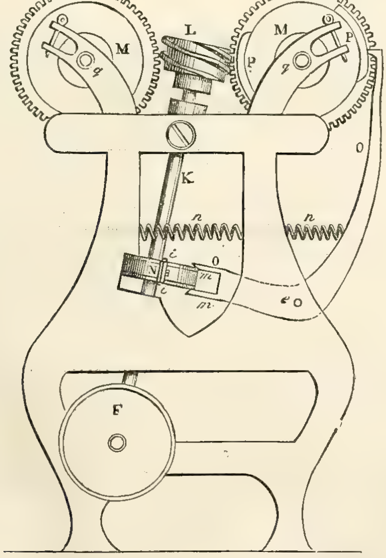
shaft G. A bevel-wheel H, on G, gives motion to the revolving spool-tables by toothed wheels, as seen at Fig. 2255. The bevel-wheel I, Fig. 2252, gives motion to the heddle-beams by geering into J, on the shaft K. This shaft carries a worm-wheel, which geers into M to drive A. N is an eccentric on K

2253.



to vibrate g, a shipper, which shifts the spindles from one table to another; the opposite ends of g operate on two pairs of tables. A connecting-rod with N vibrates the shippers. N is connected with K, and turns with it by clutch-pins, and when these are not engaged the shafts turn without N. $i\ i$, Fig. 2254, is a pin that passes through N, projecting out above and below, nearly in contact with K. There

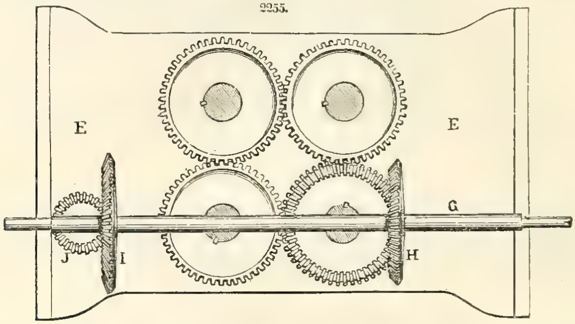
2254.



are two clutch-pins on K, either of which may be brought in contact with i, as the eccentric-wheel is made to slide up and down on the shaft. O, Figs. 2252 and 2254, is a forked lever with its fulcrum at e Its fork ends $m\ m$ embrace N, the eccentric, and raise and lower it at proper times. $n\ n$ is a spiral spring attached to the forked lever, serving to draw it inwards to depress the eccentric and make it

clutch with the lever clutch-pin. On the wheel M are cams or lifting pieces $p\,p$, which, when they come in contact with the end of O, force it out and raise N, the eccentric, so as to engage with the upper clutch-pin at the required time, as will be understood by Fig. 2254. The axis of A is P, a screw Fig. 2252, tapped into the frame of the machine and moves A endwise as it revolves, to wind the heddles, as they are made spirally on the beams. q is the smooth axis of A, on which the beam slides, moved by the screw on the guide-rods $r\,r$. Q Q are rods that may be inserted in grooves in A. The semi-diameter of A must be of the length of the heddles. After the number of heddles for a harness have been made, grooved pieces may be slipped over Q and glued upon them to embrace the twisted strands, or any other mode may be adopted. The shipper connecting-rod h, (which looks like an n,) Figs. 2252 and 2253, has a hinge-joint t, to allow it to be lifted from the shipper g. The small bevel-wheel J, on the shaft K, is one-third of the diameter of the driving-wheels, when there are three spindles on the table, and therefore makes the changes of the spindles in the recesses in one revolution of the revolving spool-tables. If there were four spindles in the table, the wheel J would be one-fourth the diameter of the driving-wheel, &c.

2255.



To explain its operation, Fig. 2251 exhibits a different arrangement of mechanical parts from the section views, but they are just the mechanical equivalents to accomplish the same thing. Heddle or harness making is the formation of *eyes* by two *cords* being knotted together. These eyes must be formed at regular distances on the harness. This machine forms two cords by B B, revolving and twisting the yarn on the three spindles, one by each table revolving, the cord winding at the same time as it is twisted on the beam A. Now to form four eyes on the heddles every revolution of the beam, look at Fig. 2253. If the strands that make the two cords were interlocked at certain periods, eight times during the revolution of A, that four eyes would be formed by the strands of the two cords being thus at certain points braided into one another. This is the way this machine does its work, and this can be done by the forked lever in Fig. 2254 shifting the shipper, or by cams on the inside of the upper geer-wheel of Fig. 2251. To make the spindles in c interlock to braid the eyes. The cams or clutch operate the shipper g, so that instead of vibrating from side to side, as now seen in Fig. 2253, touching the spindles outside, it is (the shipper) stopped by the resting of the eccentric one-sixth of the revolution of the tables, and then it will be easily perceived that the shipper will take into the inside of the spindle e and throw it into the empty recess a of the other table, which coincides, thus interlocking the threads and braiding the two cords together into one, forming an eye of the heddle by braiding instead of knotting. It will be observed, too, that the clutch can be changed by cams, to operate the shipper, to make as large or as many eyes in a foot as may be desired; but the changing or passing of the spindles from one table to another must be performed by the shipper twice for one eye, according to the length of the eye, and they are not shifted again until A has revolved the distance wanted to form the base of a new eye for the harness.

HELIOTROPE *Reflecting Lantern*, used by Major J. D. GRAHAM as meridian marks for great distances, in 1841, while tracing the due north line from the monument at the source of the river St. Croix.

The lantern was constructed by Messrs. Henry N. Hooper & Co. of Boston, under Maj. G.'s directions. It was similar in form to the Parabolic Reflector Lantern, sometimes used in light-houses, but much smaller, so as to be portable.

The burner was of the argand character, with a cylindrical wick, whose transverse section was half an inch in diameter, supplied with oil in the ordinary manner. This was placed in the focus of a paraboloid reflector, or paraboloid, of sheet-copper, lined inside with silver about 1-20th of an inch in thickness, polished very smooth and bright. The dimensions were as follows:

	Inches.
Diameter of the base of frustrum of reflector	16·
Distance of vertex from base	3·75
Distance of focus from vertex	2·25
Diameter of cylindrical burner	·50
Diameter of a larger burner which was never used, but which, by an adapting piece, could be easily substituted	1·25

The instrument answered the purpose for which it was intended admirably well, and was of great use in tracing the due north line. While it occupied the station at Park's Hill, 15 feet above the surface of the ground, or 828 feet above the sea, in the latter part of September and early part of October, 1841, the light from it was distinctly seen with the naked eye at night, when the weather was clear from Blue Hill, whose summit, where crossed by the meridian line, is 1071 feet above the sea, the intervening country averaging about 500 feet above the sea, and the stations being 36 miles apart. The light appeared to the naked eye, at that distance, as bright, and of about the same magnitude, as the planet Venus.

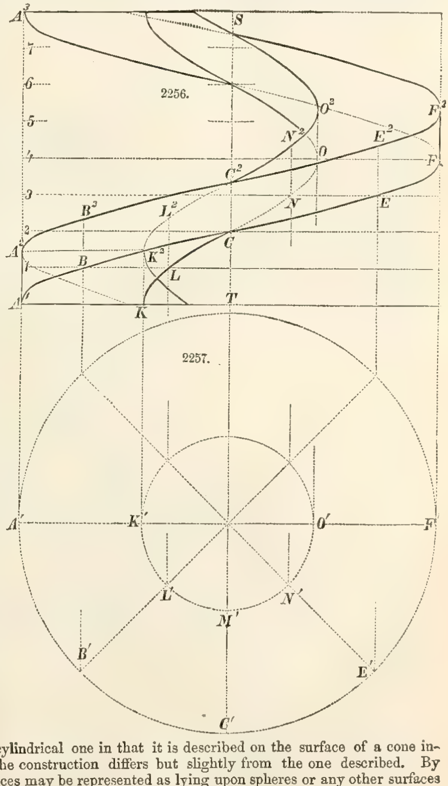
The wick employed by Major G. was considerably smaller than that usually made, even for parlor lamps; and to this cause is attributed, in a great measure, the perfection with which the parallel rays were transmitted from the reflecting parabolic surface, so as to make them visible at so great a distance. Though a greater quantity of light is generated by a larger wick, the portion of rays reflected in a direction parallel to the axis, and which alone come to the eye, is the smaller as the flame transcends the focal limit. The size of wick most advantageous for use may easily be determined by experiment. The smaller is its transvere section, provided it is only large enough to escape being choked up by the charred particles, even one-third, or perhaps less, the further the light would be visible.

The heliotrope, which is employed in the day time, was made by order of Mr. Hassler, at the instrument shop of the coast survey office. It was a rectangular parallelogram of good German plate-glass, 1 4-5ths by 1 1-5th inch in size, giving an area of reflecting surface of $2\frac{16}{100}$ square inches. This also was seen at the distance of 36 miles.

HELIX. A spiral curve. The cylindrical or screw helix is the curve described upon the surface of a cylinder by a point revolving round it, and at the same time moving parallel to its axis by a certain invariable distance during each revolution.

Figs. 2256 and 2257, to construct the helical curve described by the point A upon a cylinder projected horizontally in the circle A′ C′ F′, the pitch being represented by the line A′ A³. Divide the pitch A′ A³ into any number of equal parts, say eight; and through each point of division, 1, 2, 3, &c., draw straight lines parallel to the ground line. Then divide the circumference A′ C′ F′ into the same number of parts; the points of division B′, C′, E′, F′, &c., will be the horizontal projections of the different positions of the given point during its motion round the cylinder. Thus, when the point is at B′ in the plan, its vertical projection will be the point of intersection B of the perpendicular drawn through B′ and the horizontal drawn through the first point of division. Also when the point arrives at C′ in the plan, its vertical projection is the point C, where the perpendicular drawn from C′ cuts the horizontal passing through the second point of division, and so on for all the remaining points. The curve A B C F A³ drawn through all the points thus obtained, is the helix required.

A helical surface is generated by the revolution of a straight line round the axis of a cylinder; its outer end moving in a helix, and the line itself forming with the axis a constant and invariable angle.



The conical helix differs from the cylindrical one in that it is described on the surface of a cone instead of on that of a cylinder; but the construction differs but slightly from the one described. By following out the same principles, helices may be represented as lying upon spheres or any other surfaces of revolution. In the arts are to be found numerous practical applications of the helical curve, as wood and machine screws, geers and staircases.

HEPTAGON. A figure having seven equal angles and sides.

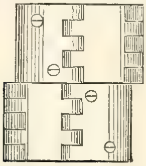
HEXAEDRON, *the Cube*. One of the five regular or Platonic bodies, and so called from its having six faces. The square of the side or edge of a hexaedron is one-third of the square of the diameter of the circumscribing sphere; and hence the diameter of a sphere is to the side of its inscribed hexaedron as $\sqrt{3}$ to 1.

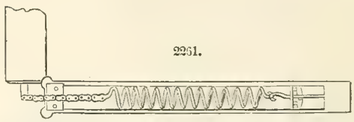
HEXAGON. A figure of six sides and angles. Angle at the centre $= 60°$; angle at the circumference $= 120°$; area to side, $1 = 2{\cdot}5980762$; area to any side, $(S) = 3^2 \times 2{\cdot}5980762$.

HIGH-PRESSURE ENGINE. The simplest form of the steam engine is the non-condensing, or high-pressure engine. In this engine the condensing apparatus is dispensed with, and steam being admitted into the cylinder, at a high temperature, and consequently high pressure, and having acted on the piston, is allowed to escape into the open air. A part of the force of the steam is of course expended in overcoming the pressure of the atmosphere, and it is only that portion of the steam's elastic force that exceeds 15 pounds to the square inch that is effective in moving the engine. The surplus pressure is usually from 30 to 40 pounds on the circular inch. See STATIONARY ENGINES, AND ENGINES VARIETIES OF.

HINGE, TAFT'S *double-jointed hinge and door-spring*, Figs. 2260 and 2261. This hinge is so constructed that it admits of the opening of the door, or gate, in either direction, and in combination with it is a spring connected by a chain with the casing, whereby the door is held close to it as well as made to close itself. Each hinge employed in this improvement may consist of four or more pieces, two of which are

2260.





2261.

side plates with knuckles attached thereto. The connecting plates with their knuckles are connected by pivots to those of the plates, and each connects the plate to the other, so that when the hinge is opened in the opposite direction the connecting plate changes sides and folds upon the plate, so that the hinge presents the same appearance in either position.

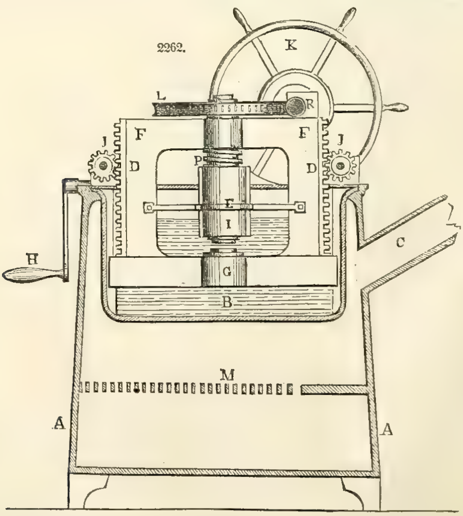
HINGES. The joints on which doors, gates, &c., turn.

HIP. The external angle formed by the meeting of the sloping sides of roofs which have their wall-plates running in different directions.

HORN. See ANIMAL MATTER USED IN THE ARTS.

HORN, *machine for pressing*. Horn, tortoise-shell, and many other animal substances, are capable of being softened by heat and moulded by pressure into any shape and with any design in the sharpest

2262.



and most delicate relief. A screw press has usually been employed for this purpose, but the one represented by Fig. 2262, which is a section through its centre, is far superior.

A A is a box of cast-iron. B is a copper to contain the hot water, and M is a grate for the fire to heat the same. C is the smoke-pipe. F F G is the press, made of strong cast-iron, and capable of being drawn up and let down in the water at pleasure, by means of racks, D D, at each side, actuated by pinions J J. The axles of these pinions cross the machine and have each a wheel at the end, moved by two arms, or screws cut upon the axis and turned by the handle H. The press is guided in the ascent or descent by grooves in the side of the boiler. When raised up out of the water, the moulds, with the horn or tortoise-shell between them, are put beneath the presser, and a severe pressure is produced by turning the wheel K. This wheel has an endless screw R upon its axis, which works the teeth of a large wheel L, fixed on the top of the screw P. The screw is received into an interior screw formed within the box or presser I, which is guided and prevented turning round by the cross-bar E, through which the presser is fitted; by this means, when the screw P is turned round by the wheel L and endless screw, the horn or tortoise-shell is pressed between the moulds; the press is then lowered again into the water of the boiler, in order to be still further softened by the boiling; but when the press is down in the boiler, the screw can be screwed tighter by turning the wheel K until the desired impression is obtained. By turning the handle H, the press is then raised up out of the boiler, and by turning back the wheel K the pressure is released and the moulds can be removed.

HORSE. *The power of a horse* when applied to draw loads, as well as when made the standard of comparison for determining the value of other powers, has been variously stated.

The relative strength of men and horses depends, of course, upon the manner in which their strength is applied. Thus, the worst way of applying the strength of a horse is to make him carry a weight up a steep hill, while the organization of the man fits him very well for that kind of labor. And three men, climbing up a steep hill, with each 100 lbs. on his shoulders, will proceed faster than most horses with 300 lbs.

It is highly useful to load the back of a drawing horse to a certain extent; though this, on a slight consideration, might be thought to augment unnecessarily the fatigue of the animal: but it must be recollected that the mass with which the horse is charged vertically is added in part to the effort which he makes in the direction of traction, and thus dispenses with the necessity of his inclining so much forward as he must otherwise do: and may, therefore, under this point of view, relieve the draught more than to compensate for the additional fatigue occasioned by the vertical pressure. Carmen, and wagoners in general, are well aware of this, and are commonly very careful to dispose of the load in such a manner that the shafts shall throw a due proportion of the weight on the back of the shaft horse.

The best disposition of the traces during the time a horse is drawing is to be perpendicular to the position of the collar upon his breast and shoulders: when the horse stands at ease, this position of the traces is rather inclined upwards from the direction of the road; but when he leans forward to draw the load, the traces should then become nearly parallel to the plane over which the carriage is to be drawn; or, if he be employed in drawing a sledge, or any thing without wheels, the inclination of the traces to the road should be about $18\frac{1}{2}°$, when the friction is one-third of the pressure.

When a horse is made to move in a circular path, as is often practised in mills and other machines moved by horses, it will be necessary to give the circles which the animal has to walk round the greatest diameter that will comport with the local and other conditions to which the motion must be subjected. It is obvious, indeed, that, since a rectilinear motion is the most easy for the horse, the less the line in which he moves is curved, with the greater facility he will walk over it, and the less he need recline from a vertical position: and besides this, with equal velocity the centrifugal force will be less in the greatest circle, which will proportionally diminish the friction of the cylindrical part of the trunnions, and the labor of moving the machine. And, further, the greater the diameter of the horse-walk, the nearer the chord of the circle in which the horse draws is to coincidence with the tangent, which is the most advantageous position of the line of traction. On these accounts it is that, although a horse *may* draw in a circular walk of 18 feet diameter, yet in general it is advisable that the diameter of such a walk should not be less than 25 or 30 feet; and in many instances 40 feet would be preferable to either.

It has been stated by Desaguliers and some others, that a horse employed daily in drawing nearly horizontally can move, during eight hours in the day, about 200 lbs. at the rate of $2\frac{1}{2}$ miles per hour, or $3\frac{2}{3}$ feet per second. If the weight be augmented to about 240 or 250 lbs., the horse cannot work more than six hours a day, and that with a less velocity. And, in both cases, if he carry some weight, he will draw better than if he carried none. M. Sauveur estimates the mean effort of a horse at 175 French, or 189 avoird. pounds, with a velocity of rather more than three feet per second. But all these are probably too high to be continued for eight hours, day after day. In another place Desaguliers states the mean work of a horse as equivalent to the raising a hogshead full of water (or 550 lbs.) 50 feet high in a minute. But Mr. Smeaton, to whose authority much is due, asserts, from a number of experiments, that the greatest effect is the raising 550 lbs. forty feet high in a minute. And, from some experiments made by the Society for the Encouragement of Arts, it was concluded, that a horse moving at the rate of three miles an hour can exert a force of 80 lbs. The proper estimate would be that which measures the weight that a horse would draw up out of a well; the animal acting by a horizontal line of traction turned into the vertical direction by a simple pulley, or roller, whose friction should be reduced as much as possible.

Tredgold has directed his attention to the subject of "*horse-power.*" His expression for the power of a horse is $250\, v \left(1 - \frac{v}{\text{v}}\right)$; and $\frac{250\, d v \left(1 - \frac{v}{\text{v}}\right)}{1 + n}$ for the day's work in lbs. raised one mile; d being the hours which the horse works in a day, and the weight of the carriage to that of the load as $n : 1$. He also gives $\frac{14{\cdot}7}{\sqrt{d}}$, for the greatest speed in miles per hour, when the horse is unloaded.

He gives the following table of the comparison of duration of a horse's daily labor and maximum velocity unloaded:—

Duration of labor. Hours.	Maximum velocity unloaded in miles per hour.	Duration of labor. Hours.	Maximum velocity unloaded in miles per hour.
1	14·7	6	6·
2	10·4	7	5·5
3	8·5	8	5·2
4	7·3	9	4·9
5	6·6	10	4·6

Taking the hours of labor at 6 per diem, the utmost he would recommend, the maximum of useful effect he assigns at 125 lbs., moving at the rate of three miles per hour; and regarding the expense of carriage in that case as unity, then,

Miles per hour.	Proportional expense.	Moving force or traction.
2	1·125	166 lbs.
3	1·	125 "
$3\frac{1}{2}$	1·0285	104 "
4	1·125	83 "
$4\frac{1}{2}$	1·333	$62\frac{1}{2}$ "
5	1·8	41 "
$5\frac{1}{8}$	2·	$36\frac{1}{2}$ "

That is, the expense of carrying goods at 3 miles per hour being 1, the expense at $4\frac{1}{2}$ miles per hour will be $1\frac{1}{3}$; the expense being doubled when the speed is $5\frac{1}{8}$ miles per hour.

Various estimates have been made of a horse's power by Desaguliers, Smeaton, and others; but the estimate now generally adopted as a standard for measuring the power of steam-engines, is that of Mr. Watt, whose computation is about the average of those given by the other writers. The measure of a horse's power, according to Mr. Watt, is, that he can raise a weight of 33,000 pounds to the height of one foot in a minute.

Horse-power, as the measure of the force of steam-engines.—It is by this nominal power that engines are usually bought and sold and always spoken of, unless when the contrary is expressly stated.

The following is Boulton and Watt's rule for determining the nominal horses' power.

Let D = the diameter of the cylinder in inches.

V = half the velocity of the piston in feet per minute.

Then $\frac{(D^2 - 4\ D)\ V}{2650}$ = the number of nominal horses' power.

But in order to determine V before the engine has been made, Boulton and Watt fixed upon an empirical velocity for each different length of stroke. The several velocities are as follow:

Stroke. ft. in.	Velocity. ft.	Stroke. ft. in.	Velocity. ft.
2 0	160	4 0	200
2 6	170	4 6	210
3 0	180	5 0	220
3 6	190		

And so on, with 10 feet of additional velocity for every 6 inches of additional stroke. The original engines of the Thames and Shannon, constructed by Boulton and Watt, were rated at 80 horse-power, the cylinders being $47\frac{1}{2}$ inches in diameter, and the length of stroke 4 feet 6 inches, $(47{\cdot}5)^2 - 4\ (47{\cdot}5) = 2066{\cdot}25 \times 105 = 217930 \div 2650 = 83$ horse-power nearly, instead of 80. Land engines of $43\frac{1}{2}$ inches diameter of cylinder and 8 feet stroke, making 16 double strokes in a minute, were rated by Boulton and Watt at 80 horse-power. The average effective pressure on the piston is rated at barely 7 lbs. per square inch, and the power may be thus computed, $(43\frac{1}{2})^2 \times {\cdot}7854 = 1486{\cdot}2 \times$ by 7 and 266, and $\div$ by $33{,}000 =$ about 80 horse-power. In marine engines a greater area of piston is allowed to represent a horse-power than in land engines, because the motion of the piston is supposed to be slower, but the effective force is calculated a little higher, or at 7·3 per square inch.

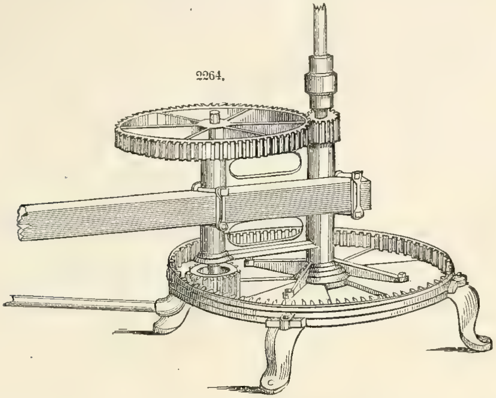
HORSE-POWER, Bogardus's. This improvement in the horse-power for driving machinery is based on the principle of the well-known sun and planet motion, and consists of a base-frame having cogs in the inner periphery of the rim into which mash the cogs of a pinion on the lower end of the arbor of the planet-wheel, the cogs of which drive a pinion on a central shaft that carries the driving-pulley, the arbor of the planet-wheel being adapted to turn in a sleeve, in a travelling wing to which the horse-beam is secured; and the said wing having another and parallel sleeve that turns on a central hollow standard of the frame through which the shaft of the central pinion and driving-pulley passes, and in which it turns.

The base-frame is cast in one piece, consisting of the central hub, and the outer ring connected by radial arms, and standing on legs. The central hub is cast with a hollow standard properly turned with a slight taper, to which is fitted a sleeve that turns thereon freely but accurately, and resting on the upper surface of the hub; and likewise with this sleeve, and making part thereof, is cast a wing, to which is secured by bolts the horse-beam or lever, by which the whole is operated. The other end of the wing is also provided with another sleeve cast therewith, and parallel to the other, to which is fitted accurately (but yet to admit of turning freely) the arbor of the planet-wheel and planet-wheel pinion, the former being at the top and the latter at the bottom. One of these, either the wheel or the pinion, can be permanently attached to the arbor, and the other keyed on after it has been inserted in the

sleeve. The cogs of the pinion of the planet-wheel take into the cogs formed in the inner periphery of the rim of the base-frame, and which may be called the master-wheel; and the cogs of the planet-wheel take into the cogs of and drive the central pinion on the upper end of a vertical shaft that passes through and turns freely but accurately in the central hollow standard, which is adapted to it, the driving-pulley being keyed on the lower end and below the hub.

A band from the driving-pulley can be carried under the frame and between the legs, to any place required in the usual manner to drive any piece of machinery; but if desired, the driving-pulley can be attached to the central shaft above the central pinion, Fig. 2264. The arbor of the planet-wheel is oiled through a hole in the wheel which delivers it at the junction of the sleeve and arbor; and in like manner the central shaft and the sleeve that turns on the central standard are oiled by pouring the oil through a hole in the central pinion, which delivers it on the upper end of the hollow standard, and which is grooved to direct the oil to its inner and outer periphery.

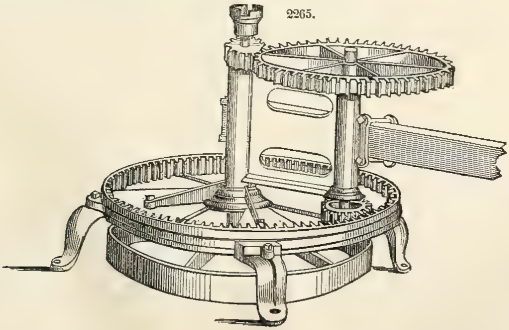
2264.



Arranged to carry the belt from the horizontal pulley under the foot-path on which the horse walks.

The whole apparatus is made light and portable, rests on the case-frame, and turns on the central standard, which makes part of the base-frame, without supports or bearings at the top. The whole can be taken apart for transportation, and can be again put together with ease. The whole strain comes on and is supported by the hollow standard, which being cast with the base-frame will resist any strain that can be applied to it by the horses employed to drive the machine. The sleeves of the wing and the inside of the central standard are or may be laid with soft metal.

2265.



Arranged to carry a shaft under the foot-path, or an upright shaft to the floor above.

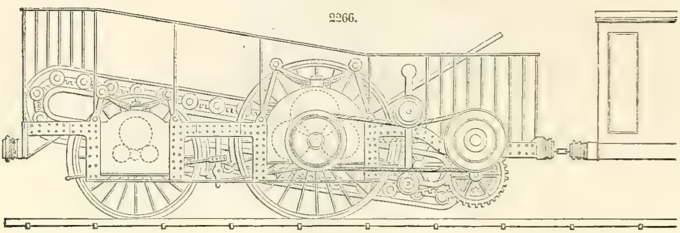
In some ferry-boats and machines, horses are placed on a revolving platform, which passes backward under the feet whenever the horse exerts his strength in drawing against a fixed resistance, so that the horse propels the machinery without moving from his place. A horse may act within still narrower limits, if he is made to stand on the circumference of a large vertical wheel, or upon a bridge supported

by endless chains which pass round two drums, and are otherwise supported by friction-wheels. Various other methods have been practised for applying the force of animals, but most of them are attended with great loss of power, either from friction, or from the unfavorable position of the animal.

For agricultural purposes, the movable-platform horse-power is probably the best, and is coming very much into use. It consists of an inclined platform, or endless chain, provided with slats of wood upon which the horse treads, giving motion to a horizontal shaft by means of teeth in the chain or rack, working into a pinion on the shaft. It has very lately been patented in Italy under the name of *impulsoria*, and is in experimental use on the Southwestern Railway in England, and is thus described in a late number of the *London News*:—

The patent impulsoria, for railways, consists in introducing the animals into a kind of coach, called impulsoria, by which they transmit their acting power to the leading wheels. This transmission is conveyed by a very simple means, rendering useful both the driving power of the animals and their own weight. The horse being thus introduced into the impulsoria, is placed upon a perfect rectilinear, artificial ground, or platform, turning so easily that the animal, which is yoked to the shafts, when it walks, does not itself advance, but, what amounts to the same thing, the platform itself is pushed backward, as shown in Fig. 2266. By this artificial ground platform, called by the patentee *pedivella*, is moved an axle, armed with a pulley, from which, by means of a rope, the motion is conveyed to the axletree of the leading wheels. The varying proportions between the diameters of the pulleys give different degrees of speed. The horses are to be worked always at their usual pace, whilst the new locomotive will be able to run at any requisite speed, without ever altering the usual walking pace of the horses, which are inside the impulsoria, as on the floor of a room, sheltered from the weather.

2266.



The importance of introducing the horses into the carriage in order to get more speed from the surplus of the acting power, had been long thought of, and the principle has been several times attempted in England, France, and Italy, but hitherto without success.

The new machine (whose inventor is Signor Clemente Masserano, from Pignerol, Piedmont) has been brought from Italy to England, and deposited at the Nine-elms terminus of the Southwestern Railway, where it may be seen working on the line. It has been made for two horses only, and they work it very well on the *pedivella*. More than thirty wagons have been already experimentally drawn by it up the very inclined line of the station. For working it up and down the station, a wagon is fastened to it when it attains a speed of seven miles an hour. In the experiment to be made on the great line, it is expected to gain a speed of from fifteen to twenty miles an hour. The impulsoria runs either way, like the steam-engine; but the driving horses do not change direction or movement. They can instantly be stopped, without stopping the machine; and the machine can likewise be stopped while the horses continue to walk on the *pedivella*, without transmitting motion to the leading wheels.

By the simple manner in which the horses exercise their moving power on the new machine, they can work easily the usual time, commonly about eight hours a day.

Such economy is of the utmost importance to the numerous interests engaged in the railways subject to enormous working expenses. The principal advantage of the new machine will be to afford very cheap locomotion on all branch lines, thus extending the advantage of the railway to localities hitherto impracticable from the expensive moving power.

The directors of the Southwestern Railway were the first to receive the impulsoria on their line where they have granted every facility to its ingenious inventor.

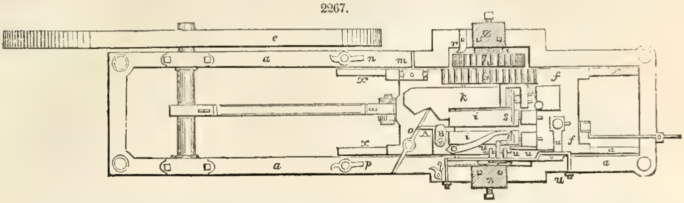
HORSE-SHOE, Burden's Patent Machine for making. From the specifications of the patents we extract the following description of the machine and its operation.

Fig. 2267, section and plan of the machine for rolling, drawing, and shaping horse-shoes; *a a a a* stationary or outside frame; *b b b b* feet which support the same; *c* the fly-wheel; *d* the connecting-rod *e e* the crank; *f f* the moving-frame; *g* the rack, having cogs in it, which is bolted into the moving-frame, and which mashes or fits into the segment *h*, having long cogs, as seen at *h*, the lower or under segment which is fastened into the roller *i*, as seen at *i*. Fig. 2269, K the moving-jaw; *l l* the side steels or iron, between which the piece of iron is confined and the sides, while it is drawn or rolled by the swedges D D having steels or swedges E E the exact thickness of the shoe intended.

It will be observed that one of these side steels or irons is fastened into the moving-jaw *k* or K, by means of screw-bolts, while the other is similarly fastened into the moving-frame *f f*. *m* a button, or cam, which, when the moving-frame *f f* is moved or drawn backwards and forwards by the crank *e*, through the connecting-rod *d*, it strikes against the pin or stop *n*, which permits the button or cam *o* to push back or open the moving-jaw *k*, when it strikes against the pin or stop *p* on the other side of the stationary frame, by which means the piece of iron which may be between the side steels or irons, and which is

drawn or rolled to the shape desired, is permitted to drop out. *q*, a pin or stop, which, when the cam *o* strikes against it on the moving-frame's return motion, permits the cam *m*, when it strikes against the pin or stop *r*, to close the moving-jaw *k*. It will be observed that when the moving-frame *f f* has performed its forward motion, then the cam *m* strikes against the stop *n*, which permits the cam *o* to open the moving-jaw *k* by striking against the stop *p*, which allows the piece of iron, which may have been rolled or shaped to a horse-shoe, to drop from between the side steels or irons *l l*. *s*, a chisel fastened by screw-bolts on the top of the side steel or iron *l*; *t*, a chisel fastened by screw-bolts in the chisel box *u u u*.

2267.



It will be observed that the box *u u u* turns on a pin in the moving-frame, which, when the crank pushes back the moving-frame, the head or box part strikes against the pin or piece of iron *w*, and presses up the chisel *t* against the chisel *s*, and cuts off the piece of iron to the length intended for a horse-shoe. *v*, a piece of iron intended to draw back the chisel-box *u u u*, as seen at Fig. 2268; *x x x x*, brasses on which the moving-frame slides backwards and forwards; *y*, a piece of iron to lay the bar on as a guide while in the act of feeding into the machine. Z Z end view and section of the posts through which the rollers *i i* are fastened and revolve; A, piece of iron or stop which graduates the length of shoe; B, piece of iron having a hole in it, through which the iron or stop A passes, which graduates the length of shoe; C, the piece of iron which prevents the shoe from being drawn back by the chisel or the side steel *l*, previous to the swedges pressing it between them.

2268.

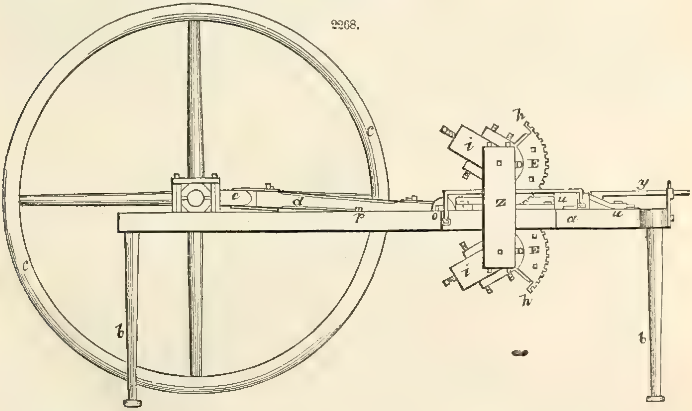


Fig. 2268, section and elevation of machine. *h*, segments which are fastened into the rollers *i i*; C, the rack which mashes or works into the upper segment *h*, the cogs of which being twice the length of the under segment *h* permits the rack to operate into it, which, when pushed backwards and forwards by the moving-frame *f f*, the whole is put in motion. *i i*, the rollers into which the segments, with cogs *h h* and swedges D D, with pieces or swedges E E, are fastened. *k* the moving-jaw; *l l* the side steels or irons between which the piece of iron is held, while it is rolled or drawn by the vertical swedges D D and the steels or swedges E E to the desired shape of shoe. It will be perceived that the rollers *i i* revolve on gudgeons. Z Z, posts or stationary frame, into which the rollers *i i* are fastened and revolve.

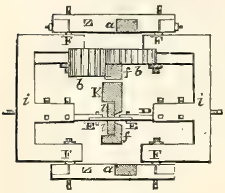
Fig. 2271, sectional elevation of part of the machine. *i i*, the rollers in which the swedges with the pieces of steel or swedges E E are fastened. *l l*, one of the side steels or irons. H represents a piece of iron as being formed into a horse-shoe. It will readily be perceived that by grinding the steels or swedges E E, any shape or taper required can be given to the piece of iron or shoe marked H. It will be observed that the four views or figures, as above described, represents the part or parts of machinery for cutting off, rolling, or drawing the iron into the shape required for horse-shoes, and that Fig. 2267 is a

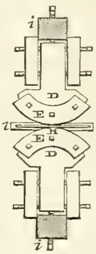
section, having the upper roller *i* removed for the purpose of showing more distinctly the interioı arrangements of the machine.

Fig. 2270, sectional elevation of part of the machine. *i i* the rollers. D D the swedges: the under one, which is cast-iron, or may be fitted with steel swedge similar to those used for rolling or shaping the shoe, as seen at D D, E E, the edge of which being similar to the flat side of a horse-shoe. The upper one is also of cast-iron, so constructed as to fasten in two pieces of steel under the covers or caps *i i*. These pieces of steel are so shaped at their edges as to groove and punch the holes at one operation. They are graduated as to depth by the four screws which pass through the *flanch* above *l l*, one of the side steels. H represents a horse-shoe in the act of being grooved and punched.

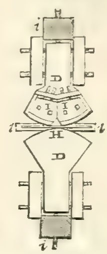
2269.



2270.



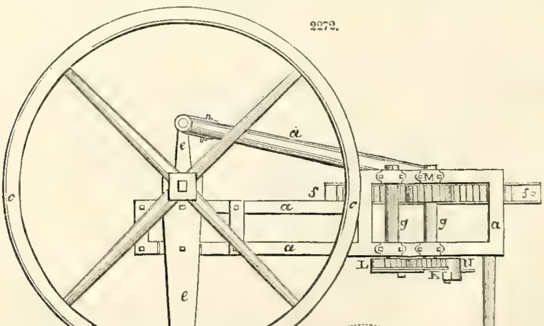
2271.



The machine for grooving and punching is precisely as the one for rolling or drawing the shoe to the required shape, with the exception of the upper swedge, as described above.

Fig. 2272, elevation of machine for bending horse-shoes. *a a a* the frame. *b b* the feet which support the same. *c c* the fly-wheel. *d* the connecting-rod. E the crank-shaft. *f f* the rack. *g g* the two shafts. K the piece of iron round which the shoe is bent, having cogs on its edges shaped so as to fit and mash into the piece K, while they revolve round on their respective shafts *g g*. M the wheel which mashes and fits into the rack *f f*, and which communicates motion to the shafts *g g* and pieces of iron K and L. N a button or nipper which takes hold at the end of the horse-shoe, in consequence of its coming in contact with the piece of iron L, and holds it fast while it is in the act of bending; and when bent, said button or nipper strikes against the other side of piece L, which opens and lets the shoe drop. It will be observed that the shafts *g g* and pieces of iron K and L do not make a full revolution

2272.



2273.

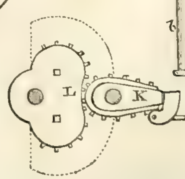


Fig 2274, plan of machine for bending horse-shoes. *a a* the frame. *c* the fly-wheel. *e* the crank-shaft. *d* the connecting-rod. *f* a rack. M a wheel, whose cog mashes or fits into the cogs of the rack *f*. L the eccentric piece of iron which fits into the piece K, on which the shoe is formed, as seen at Figs

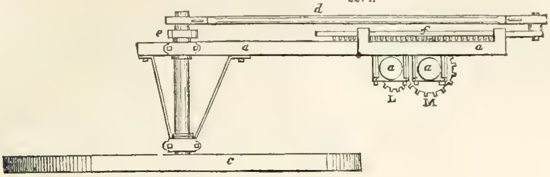
2272 and 2273. O, cap which confines the piece of iron while in the act of bending around the piece K, as represented by the dotted lines at Fig. 2273.

Fig. 2273, section of the irons K and L. These two pieces, K and L, are fastened on the shaft *g g* with their reversed sides up from what they appear in the drawing. The dotted lines represent a cap, which is fastened on the piece of iron L with screw-bolts. This cap is about one inch thick, and serves the purpose of keeping the iron close up while in the operation of bending around the piece of iron K.

2274.



The nature of the operation is as follows:—

Firstly: Fig. 2267 represents a section of the machine, having the upper roller *i* removed, so as to show more distinctly the interior arrangement of the machine. Supposing a pulley of about four feet diameter were bolted to the arms of the fly-wheel *c*, (which is omitted in the drawing,) and to which motion were communicated by a leather strap or belt from a corresponding pulley on a shaft connected with a water-wheel or other power; it is evident that every revolution of the fly-wheel *c* would move the carriage or moving-frame *f f* backwards and forwards, giving motion to the different parts of the machine, as described and shown above.

And supposing the crank *e e*, by the connecting-rod *d*, had pulled or drawn the moving-frame *f f* forward so as to cause the button or cam *m* to strike against the stop *n*, the cam *o* would also strike against the stop *p*, and consequently push back or open the moving-jaw *k*, which turns on a pivot at the other end. And supposing the moving-frame *f f* were pushed back on the brasses *x x*, and towards the last part of the motion a hot piece of iron (previously rolled to the desired size) were introduced between the side steels or irons *l l*, it is evident that the cutter-box *u u u* would strike against the stop *w* and press up the chisel *t* against the chisel *s*, cutting off the necessary length of iron to make the shoe; and should the moving-frame be drawn forward by the crank *e*, the piece of iron, being confined by the side steels or irons *l l* on the sides, would be rolled or shaped by the vertical steels or swedges E E, when the cam *m* would strike against the stop *n* and permit *o* to open the jaw *k* and let the piece drop; the appearance and shape of which may be seen as represented by H, are so ground or shaped as to roll or taper the piece H at each end intended for the heels of the shoe; but it is found by experiment that by using the iron square, and so grinding the steel or swedges E E as to flatten or roll down the middle of the piece, leaving the ends square for the heels of the shoe, makes the best shoe.

Secondly: Having explained the process of cutting the bar or rod into suitable lengths, and rolling or shaping the same suitable for horse-shoes, it remains to describe the method of punching and grooving them. And having already stated that the machine for grooving and punching is precisely the same as the one above described for rolling or shaping the shoe, with the exception of the upper swedge, which is substituted for the swedge represented in Fig. 2271: supposing in a machine every way similar to the one for rolling or shaping the shoe, as described under the first head, (with the exception of the upper swedge, in lieu of which the one represented by Fig. 2270 was substituted,) the piece of iron which came from the first machine were introduced between the side steels or irons *l l*, and the machine set in motion, it is evident it would be grooved and punched and drop out of the machine on the moving-jaw K being opened in the same manner as the piece dropped out from the first machine, as described under the first head.

Thirdly: Having described the manner in which the piece is grooved and punched, it remains to show how it is bent, which is the last operation. The piece of iron being now rolled or shaped as may be desired for a horse-shoe, as also grooved and punched, is introduced into the machine, as shown and described in Figs. 2272 to 2274.

We here copy Mr. Burden's claim:

"First: I claim the machine for rolling, drawing, or shaping horse-shoes, as described and represented by Figs. 2267 to 2272, *as a whole as there arranged;* namely, those parts called side steels or irons *l l*, which confine the piece of iron intended for a horse-shoe, on the sides, while it is rolled or shaped by the vertical swedges E E. I also claim the vibrating or reciprocating motion of moving-frame *f f*, which gives motion to all the other parts of the machine, which enables the operator to feed up the iron intended for horse-shoes to the stop A, cutting it off accurately, and rolling and shaping them at the same time.

And I claim the above-named reciprocating motion, whether it be by side steels or swedges, as above named, or whether it be merely a pair of common grooved rollers, the one having a groove or channel turned or cut the shape of the shoe, the other having a tongue so shaped as to fit the groove exactly, the periphery of said tongue being so shaped as to roll the shoe thinner at some parts than at others, as may be desired.

It will be observed that if *two* rollers, as aboved named, were connected together at the end by two pinions, and on the other end of one were fastened a wheel similar to the wheel M on one of the shafts *z* of the bending machine, having a rack operating into said wheel, connected to a crank in every respect

similar to the bending machine, it is evident that said rollers would move backwards and forwards, making such part of a revolution as the length of the crank might give them. I therefore claim said reciprocating motion when applied to rolling or shaping horse-shoes by rollers. I do not claim the use of *solid rollers* in rolling horse-shoes; for I believe this has been done, or, rather, *attempted to be done*, and has universally proved a failure, in consequence of not having reciprocating motion to enable the operator to feed up the iron to a stop so as to insure the piece of iron intended for a horse-shoe being always in the proper place to receive the impression from the roller.

Another reason why rolling horse-shoes by solid rollers has failed, is, that the tongue of the one and socket of the other are liable to wear, and consequently have to be laid aside. Whereas, my method of having the tongue or swedges, as also the socket, divided into sections, allows the whole being ground, repaired, and moved at pleasure by screws, so as to insure the sides of the socket fitting close to the tongue, as also having one side of the socket movable, to allow the shoes being discharged. I also claim the method of having those parts of the machine which confine the iron on the sides, represented as side steels, marked *l l*, movable, so as to permit their being ground, when worn, at the same time moving them close up to the swedges E E by screws. I also claim the plan of making the rollers *i i*, with an open mortise, so as to permit the swedges D D being moved. In fine, I claim the method of dividing the working parts which roll or shape the shoe into such sections as enables me to grind, replace, and remove them at pleasure; in lieu of solid rollers, which, when worn, have to be laid aside altogether. I wish it to be particularly understood that I do not confine myself to the precise method of operating the machine for rolling or shaping horse-shoes, as represented by the drawing hereunto annexed; as, in lieu of the frame *f f* being moved, it may be made stationary, and the rollers *i i* moved backwards and forwards in slides, with corresponding movements given to the other parts, which would give analogous results.

Secondly: I claim the machine for grooving and punching horse-shoes, as represented by the figures and descriptions thereof. That is to say, I claim the manner of confining the piece of iron intended for a horse-shoe, between the side steels *l l*, while in the act of grooving and punching, by the upper swedge D having the pieces of steel fastened under the caps *i i*. I also claim the vibrating or reciprocating motion of the machine in grooving and punching, for the same reasons as set forth in my claim to the machine for rolling or shaping. I claim the manner of so shaping the edge of the steels as to leave projections for the heads of the nails, as in all cases, even when made by hand, the groove is first made, then the holes; but by my plan I make both at once, which serves the double purpose of adding strength to the punches, by being formed and composing part of the steel which forms the groove or channel, as also performing both operations at once. I also claim the method of fastening the two pieces of steel which groove and punch the shoe under the caps *i i*, which permits their being screwed down by four screws, when necessary, in consequence of their becoming short by filing or other causes. And as I deem the discovery of forming the projections or punches on the same piece of steel which grooves or channels the shoe of great importance, I shall describe the manner in which it is done. Take a piece of cast or other steel, previously rolled or hammered to about one-fourth of an inch in thickness, about four inches wide, and as long as necessary, to form the groove on one side of the shoe. Then grind or reduce the edge by a file to the proper shape to form the groove: then mark the projections or punches, filing down the spaces between the projections so as to give them sufficient length to form the holes, which adds great strength to the punches, compared with the method of inserting small pieces of steel into a roller to form punches.

Thirdly: I claim the machine for bending horse-shoes, as represented and described by the drawings thereof, in *every particular as there arranged.* And in addition to which, I claim any other method of bending horse-shoes, so long as the piece is taken hold of by one end, while the other is bent round the mould, no matter whether the mould revolve round or is stationary, and the piece of iron is pulled or bent round it.

I also claim, in a particular manner, the placing of the face of the mould downwards, so as to permit the shoe to drop or discharge itself. I also claim the using of a piece of flat iron, as represented by the dotted lines in Fig. 2273, for the purpose of keeping the shoe close up to the mould while in the act of bending. I also claim the *nipper* or *button*, which closes and holds fast the end of the horse-shoe by striking against the piece L while in the act of bending round the shoe shape K, and which opens in consequence of its coming in contact with the other side of the piece L, and lets the shoe drop.

I also claim the manner of making the geering or wheels connected with the pieces of iron K and L eccentric, or so shaped as to have the pitched line describe the same circle as the shoe.

HYDRAULIC RAM. See Ram.

HYDRODYNAMICS, is that branch of general mechanics which treats of the equilibrium and motion of fluids. The terms *hydrostatics* and *hydrodynamics* have corresponding signification to the *statics* and *dynamics* in the mechanics of solid bodies; viz., hydrostatics is that division of the science which treats of the equilibrium of fluids, and hydrodynamics that which relates to their forces and motion. It is, however, very usual to include the whole doctrine of the mechanics of fluids under the general term of hydrodynamics, and to denote the divisions relative to their equilibrium and motion by the terms HYDROSTATICS and HYDRAULICS. We adopt the latter division, and shall confine ourselves to a few of the most usually received theoretical deductions, and state those rules which have been the result of a judicious application of theory to experiment, as the subject itself is the one the least advanced of any branch of mechanics, and we are as yet far from being in possession of the requisite data for a rigorous solution of the problems which arise. Very many excellent treatises have been written, to which we refer the scientific reader; but the extent of the subject forbids the introduction of any of them into this work, further than to select the best practical rules for the use of the mechanic.

Hydrostatics comprises the doctrine of the pressure and the equilibrium of non-elastic fluids, as water mercury, &c., and that of the weight and pressure of solids immersed in them.

1. Fluids press *equally in all directions*, upwards, downwards, aslant or laterally

This constitutes one essential difference between fluids and solids, solids pressing only *downwards* or in the direction of gravity.

2. The upper surface of a gravitating fluid at rest is horizontal.

3. The pressure of a fluid on every particle of the vessel containing it, or of any other surface, real or imaginary, in contact with it, is equal to the weight of a column of the fluid, whose base is equal to that particle, and whose height is equal to its depth below the upper surface of the fluid.

4. If, therefore, any portion of the upper part of a fluid be replaced by a part of the vessel, the pressure against this from below will be the same which before supported the weight of the fluid removed, and every part remaining in equilibrium, the pressure on the bottom will be the same as it would if the vessel were a prism or a cylinder.

5. Hence, the smallest given quantity of a fluid may be made to produce a pressure capable of sustaining any proposed weight, either by diminishing the diameter of the column and increasing its height, or by increasing the surface which supports the weight. It is upon this principle that the hydrostatic press is made to operate. See HYDROSTATIC PRESS.

6. The pressure of a fluid on any surface, whether vertical, oblique, or horizontal, is equal to the weight of a column of the fluid whose base is equal to the surface pressed, and height equal to the distance of the centre of gravity of that surface below the upper horizontal surface of the fluid.

7. Fluids of different specific gravities that do not mix, will counterbalance each other in a bent tube when their heights above the surface of junction are inversely as their specific gravities.

A portion of fluid will be quiescent in a bent tube, when the upper surface in both branches of the tube is in the same horizontal plane, or is equidistant from the earth's centre. And water poured down one branch of such a tube, (whether it be of uniform bore throughout or not,) will rise to its own level in the other branch.

Thus, water may be conveyed by pipes from a spring on the side of a hill, to a reservoir of equal height on another hill.

8. The ascent of a body in a fluid of greater specific gravity than itself, arises from the pressure of the fluid upwards against the under surface of the body.

The *centre of pressure* is that point of a surface against which any fluid presses, to which if a force equal to the whole pressure were applied, it would keep the surface at rest, or balance its tendency to turn or move in any direction.

The centre of pressure of a parallelogram, whose upper side is in the plane of the horizontal level of the liquid, is at $\frac{2}{3}$ of the line (measuring downwards) that joins the middles of the two horizontal sides of the parallelogram.

If the base of a triangular plane coincides with the upper surface of the water, then *the centre of pressure is at the middle of the line drawn from the middle of the base to the vertex of the triangle.* But, if the vertex of the triangle be in the upper surface of the water, while its base is horizontal, *the centre of pressure is at $\frac{3}{4}$ of the line drawn from the vertex to bisect the base.*

If b the breadth and d the depth of a rectangular gate, or other surface, exposed to the pressure of water from top to bottom, then the entire pressure is equal to the weight of a prism of water whose content is $\frac{1}{2}\,b\,d^2$. Or, if b and d be in feet, then the whole pressure $= 31\frac{1}{4}\,b\,d^2$, in pounds.

If the gate be in form of a trapezoid, widest at top, then, if B and b be the breadths at the top and bottom respectively, and d the depth,

$$\text{Whole pressure in pounds} = 31\tfrac{1}{4}\,[\tfrac{1}{3}\,(B - b) + b]\,d^2.$$

Floating bodies.—If any body float on a fluid, it displaces a quantity of the fluid equal to itself in weight.

Also, the centres of gravity of the body and of the fluid displaced, must, when the body is at rest, be in the same vertical line.

If a vessel contain two fluids that will not mix, (as water and mercury,) and a solid of some intermediate specific gravity be immersed under the surface of the lighter fluid and float on the heavier, the part of the solid immersed in the heavier fluid, is to the whole solid as the difference between the specific gravities of the solid and the lighter fluid is to the difference between the specific gravities of the two fluids.

The buoyancy of casks, or the load which they will carry without sinking, may be estimated by reckoning 10 pounds avoirdupois to the ale gallon.

The buoyancy of *pontoons* may be estimated at about *half a hundred weight* for each cubic foot.

Thus a pontoon which contained 96 cubic feet, would sustain a load of 48 cwt. before it would sink. This is an approximation, in which the difference between $\frac{6}{11}$ and $\frac{1}{2}$, that is, $\frac{1}{22}$ of the whole weight, is allowed for that of the pontoon itself.

This property has been successfully employed in pulling up piles in a river where the tide ebbs and flows. A barge of considerable dimensions is brought over a pile as the water begins to rise; a strong chain which has been previously fixed to the pile by a ring, &c., is made to gird the barge, and is then fastened. As the tide rises the vessel rises too, and by means of its buoyant force draws up the pile with it.

In an actual case, a barge 50 feet long, 12 feet wide, 6 deep, and drawing 2 feet of water, was employed. Here, $50 \times 12 \times (6 - 2) \times \frac{4}{7} = \dfrac{50 \times 12 \times 16}{7} = 192 \times 7\frac{1}{7} = 1344 + 27\frac{3}{7} = 1371\frac{3}{7}$ cwt. $=$ $66\frac{1}{2}$ tons, nearly, the measure of the force with which the barge acted upon the pile.

Specific gravities.—If a body float on a fluid, the part immersed is to the whole body as the specific gravity of the body to the specific gravity of the fluid. (See GRAVITY and SPECIFIC GRAVITY.)

Hydraulics is that part of mechanical science which relates to the motion of non-elastic fluids, and the forces with which they act upon bodies.

Motion and effluence of liquids.—1. A jet of water, issuing from an orifice of a proper form, and directed upwards, rises, under favorable circumstances, nearly to the height of the head of water in the reservoir; and since the particles of such a stream are but little influenced by the neighboring ones, they may be considered as independent bodies, moving initially with the velocity which would be acquired in falling from the height of the reservoir. And the velocity of the jet will be the same whatever may be its direction.

2. Hence, if a jet issue horizontally from any part of the side of a vessel standing on a horizontal plane, and a circle be described having the whole height of the fluid for its diameter, the fluid will reach the plane at a distance from the vessel, equal to that chord of the circle in which the jet initially moves.

3. When a cylindrical or prismatic vessel empties itself by a small orifice, the velocity at the surface is uniformly retarded; and in the time of emptying itself, twice the quantity would be discharged if it were kept full by a new supply.

4. But the quantity discharged is by no means equal to what would fill the whole orifice, with this velocity. If the aperture is made simply in a thin plate, the lateral motion of the particles towards it tends to obstruct the direct motion, and to contract the stream which has left the orifice, nearly in the ratio of two to three. So that in order to find the quantity discharged, the section of the orifice must be supposed to be diminished from 100 to 62 for a simple aperture, to 82 for a pipe of which the length is twice the diameter, and in other ratios according to circumstances.

5. When a siphon, or bent tube, is filled with a fluid, and its orifices immersed in the fluids of different vessels, if both surfaces of the fluids are in the same level, the whole remains at rest; but if otherwise, the longer column of fluid in the siphon preponderates, and the pressure of the atmosphere forces up the fluid from the higher vessel, until the equilibrium is restored; and the motion is the more rapid as the difference of levels is greater: provided that the greatest height of the tube above the upper surface be not more than a counterpoise to the pressure of the atmosphere.

6. If a notch or sluice in form of a rectangle be cut in the vertical side of a vessel full of water, or any other fluid, the quantity flowing through it will be $\frac{2}{3}$ of the quantity which would flow through an equal orifice placed horizontally at the whole depth, in the same time, the vessel being kept constantly full.

7. If a short pipe, elevated in any direction from an aperture in a conduit, throw the water in a parabolic curve to the distance or range R, on a horizontal plane passing through the orifice, and the greatest height of the spouting fluid above that plane be H, then the height of the *head* of water above that conduit pipe may be found, *nearly:* viz., by taking, first, $2 \cot E = \frac{R}{2H}$; and, secondly, the altitude of the head $A = \frac{1}{2} R \times \operatorname{cosec} 2E$.

Ex. Suppose that $R = 40$ feet, and $H = 18$ feet. Then $\frac{R}{2H} = \frac{40}{36} = 1{\cdot}1111111 = 2 \cot 60° 57'$: and $A = \frac{1}{2} R \times \operatorname{cosec} 2E = 20 \times \operatorname{cosec} 121° 54' = 20 \times 1{\cdot}177896 = 23{\cdot}55792$ feet, height required.

Note. This result of theory will usually be found about 4-5ths of that which is furnished by experiment.

Motion of water in conduit pipes and open canals, over weirs, &c.—1. When the water from a reservoir is conveyed in long horizontal pipes of the same aperture, the discharges made in equal times are nearly in the inverse ratio of the square roots of the lengths.

It is supposed that the lengths of the pipes to which this rule is applied are not very unequal. It is an approximation not deduced from principle, but derived immediately from experiment.

2. Water running in open canals, or in rivers, is accelerated in consequence of its depth, and of the declivity on which it runs, till the resistance increasing with the velocity, becomes equal to the acceleration, when the motion of the stream becomes uniform.

It is evident that the amount of the resisting forces can hardly be determined by principles already known, and therefore nothing remains but to ascertain, by experiment, the velocity corresponding to different declivities, and different depths of water, and to try, by multiplying and extending these experiments, to find out the law which is common to them all.

The Chevalier Du Buat has given a formula for computing the velocity of running water, whether in close pipes, open canals, or rivers, which, though it may be called *empirical,* is extremely useful in practice.

Let V be the velocity of the stream, measured by the inches it moves over in a second; R a constant quantity, viz., the quotient obtained by dividing the area of the transverse section of the stream, expressed in square inches, by the boundary or perimeter of that section, *minus* the superficial breadth of the stream expressed in linear inches.

The mean velocity is that with which, if all the particles were to move, the discharge would be the same with the actual discharge.

The line R is called by Du Buat the *radius,* and by Dr. Robison the *hydraulic mean depth.* As its affinity to the radius of a circle seems greater than to the depth of a river, we shall call it, with the former, the *radius of the section.*

Lastly, let S be the denominator of a fraction which expresses the slope, the numerator being unity, that is, let it be the quotient obtained by dividing the length of the stream, supposing it extended in a straight line, by the difference of level of its two extremities; or, which is nearly the same, let it be the co-tangent of the inclination or slope.

The above denominations being understood, and the section, as well as the velocity, being supposed uniform, V in English feet,

$$= \frac{307 \sqrt{(R - \frac{1}{10})}}{S^{\frac{1}{2}} - \frac{1}{2} \log.(S + \frac{16}{10})} - \frac{3}{10} \sqrt{(R - \frac{1}{10})};$$

$$\text{or } v = \sqrt{R - ^1}\left(\frac{307}{s^{\frac{1}{2}} - \frac{1}{2}\log.(s + \frac{16}{10})} - \frac{3}{10}\right)$$

When R and s are very great,

$$v = R^{\frac{1}{2}}\left(\frac{307}{s^{\frac{1}{2}} - \frac{1}{2}\log. s} - \frac{3}{10}\right) \text{ nearly.}$$

The logarithms understood here are the hyperbolic, and are found by multiplying the common logarithms by 2·3025851.

The slope remaining the same, the velocities are as $\sqrt{R - \frac{1}{10}}$.

The velocities of two rivers that have the same declivity, are as the square roots of the radii of their sections.

If R is so small, that $\sqrt{R - \frac{1}{10}} = 0$, or $R = \frac{1}{10}$, the velocity will be nothing, which is agreeable to experience; for in a cylindric tube $R = \frac{1}{2}$ the radius; the radius, therefore, equal two-tenths; so that the tube is nearly capillary, and the fluid will not flow through it.

The velocity may also become nothing by the declivity becoming so small, that

$$\frac{307}{s^{\frac{1}{2}} - \frac{1}{2}\log.(s + \frac{16}{10})} - \frac{3}{10} = 0; \text{ but}$$

if $\frac{1}{s}$ is less than $\frac{1}{500000}$, or than $\frac{1}{10}$ of an inch to an English mile, the water will have sensible motion.

In a river, the greatest velocity is at the surface, and in the middle of the stream, from which it diminishes towards the bottom and the sides, where it is least. It has been found by experiment, that, if from the square root of the velocity in the middle of the stream, expressed in inches per second, unity be subtracted, the square of the remainder is the velocity at the bottom.

Hence, if the former velocity be $= v$, the velocity at the bottom $= v - 2\sqrt{v} + 1$. (A.)

The mean velocity, or that with which, were the whole stream to move, the discharge would be the same with the real discharge, is equal to half the sum of the greatest and least velocities, as computed in the last proposition.

The mean velocity is, therefore, $= v - \sqrt{v} + \frac{1}{2}$. (B.)

This is also proved by the experiments of Du Buat.

When the water in a river receives a permanent increase, the depth and the velocity, as in the example above, are the first things that are augmented. The increase of the velocity increases the action on the sides and bottom, in consequence of which the width is augmented, and sometimes also, but more rarely, the depth. The velocity is thus diminished, till the tenacity of the soil, or the hardness of the rock, afford a sufficient resistance to the force of the water. The bed of the river then changes only by insensible degrees, and, in the ordinary language of hydraulics, is said to be permanent, though in strictness this epithet is not applicable to the course of any river.

When the sections of a river vary, the quantity of water remaining the same, the mean velocities are inversely as the areas of the sections.

This must happen, in order to preserve the same quantity of discharge.

The following table, abridged from Du Buat, serves at once to compare the surface, bottom, and mean velocities in rivers, according to the formulæ (A) and (B).

VELOCITY IN INCHES.			VELOCITY IN INCHES.		
Surface.	Bottom.	Mean.	Surface.	Bottom.	Mean.
4	1·	2·5	56	42·016	49·008
8	3·342	5·67	60	45·509	52·754
12	6·071	9·036	64	49·	56·5
16	9·	12·5	68	52·505	60·252
20	12·055	16·027	72	56·025	64·012
24	15·194	19·597	76	59·568	67·784
28	18·421	23·210	80	63·107	71·553
32	21·678	26·839	84	66·651	75·325
36	25·	30·5	88	70·224	79·112
40	28·345	34·172	92	73·788	82·894
44	31·742	37·871	96	77·370	86·685
48	35·151	41·570	100	81·	90·5
52	38·564	45·282			

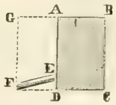
The knowledge of the velocity at the bottom is of the greatest use for enabling us to judge of the action of the stream on its bed.

Every kind of soil has a certain velocity consistent with the stability of the channel. A greater velocity would enable the waters to tear it up, and a smaller velocity would permit the deposition of more movable materials from above. It is not enough, then, for the stability of a river, that the accel-

erating forces are so adjusted to the size and figure of its channel that the current may be in train: it must also be in equilibrio with the tenacity of the channel.

We learn from the observations of Du Buat, and others, that a velocity of three inches per second at the bottom will just begin to work upon the fine clay fit for pottery, and however firm and compact it may be, it will tear it up. Yet no beds are more stable than clay, when the velocities do not exceed this; for the water soon takes away the impalpable particles of the superficial clay, leaving the particles of sand sticking by their lower half in the rest of the clay, which they now protect, making a very permanent bottom, if the stream does not bring down gravel or coarse sand, which will rub off this very thin crust, and allow another layer to be worn off. A velocity of six inches will lift fine sand; eight inches will lift sand as coarse as linseed; twelve inches will sweep along fine gravel; twenty-four inches will roll along rounded pebbles an inch diameter; and it requires three feet per second at the bottom to sweep along angular stones of the size of an egg. (*Robison on Rivers.*)

Eytelwein, a German mathematician, has devoted much time to inquiries in hydrodynamics. His formulæ apply to the motion of water; 1st, in a cylindric tube; 2d, in an open canal.



Let d be the diameter of the cylindric tube E F, h the total height F G of the head of water in the reservoir above the middle of the orifice F, and l the length E F of the tube, all in inches; then the velocity in inches with which the fluid will issue from the orifice F will be

$$v = 23\tfrac{1}{3}\sqrt{\frac{57\,h\,d}{l + 57\,d}}:$$

this multiplied into the area of the orifice will give the quantity per second.

Let d = diameter of the pipe in inches, Q = the quantity of water in cubic feet discharged through the pipe per minute, l = the length of the pipe in feet, and h = the difference of level between the surface of the water in the reservoir and at the end of the pipe or the head; then, any three of these quantities being given, the fourth may be determined from the following formulæ:—

$$d = 5\sqrt{\frac{\cdot 0448\,Q^2\,(l + 4\cdot 2\,d}{h}}$$

$$Q = \sqrt{\frac{h\,d^2}{\cdot 0448\,(l + 4\cdot 2\,d)}}$$

$$l = \frac{h\,d^5}{\cdot 0448\,Q^2} - 4\cdot 2\,d \qquad h = \frac{\cdot 0448\,Q^2\,(l + 4\cdot 2\,d)}{d^5}$$

These formulæ are more convenient expressed logarithmically, thus—

$$\text{Log. } d = \tfrac{1}{5}\left\{2 \text{ log. } Q + \bar{2}\cdot 6515 + \text{log. } (l + 4\cdot 2\,d) - \text{log. } h\right\}.$$

$$\text{Log. } Q = \tfrac{1}{2}\left\{\text{log. } h + 5 \text{ log. } d - \bar{2}\cdot 6515 - \text{log. } (l + 4\cdot 2\,d)\right\}.$$

$$\text{Log. } l = \text{log. } h + \text{log. } d - \bar{2}\cdot 6515 - 2 \text{ log. } Q \text{ (neglecting } - 4\cdot 2\,d).$$

$$\text{Log. } h = 2 \text{ log. } Q + \bar{2}\cdot 6515 + \text{log. } (l + 4\cdot 2\,d) - 5 \text{ log. } d.$$

When a pipe is bent in one or more places, then if the squares of the sines of the several changes of direction be added into one sum s, the velocity v will be found by the formula

$$v = \sqrt{\frac{548\,d\,h}{d + \frac{1}{45}\,l + \frac{1}{6}\,d\,s}}$$

l, h, d, and v, being all in inches.

Prouy gives a very safe formula for calculating the velocity of water in pipes, and it is very convenient for use, and is reliable.

V = velocity in feet per second.

D = diameter of pipe in feet.

H = the head, from surface of water in reservoir to the surface of water above the mouth of pipe.

L = the length of pipe.

$S = \frac{H}{L}$. Then $V = 48\cdot 5254\sqrt{D\,S}$. The measures are all in feet.

For open canals.—Let v be the mean velocity of the current in feet, a area of the vertical section of the stream, p perimeter of the section, or sum of the bottom and two sides, l length of the bed of the canal corresponding to the fall h, all in feet: then

$$v = \sqrt{9582\,\frac{a\,h}{p\,l} + 0\cdot 0111} - 0\cdot 109.$$

The experiments of M. Bidone, on the motion of water in canals, agree within the 80th part of the results of computations from the preceding formulæ.

We have used the following formula of Eytelwein, taken from the Edinburgh Encyclopedia, article *Hydrodynamics*, for ascertaining the velocity of water in an open canal, and the results have been satisfactory.

d = *hydraulic mean depth*, or *mean radius* in inches, called R in preceding formulæ of Du Buat.

f = fall in two mile of canal, in inches.

V = velocity in inches per second.

Then, $V = 0\cdot 91\sqrt{f\,d}$.

For apertures in the sides or bottom of vessels.—If q equal the quantity of water discharged in cubic feet per minute, v the velocity of the affluent water in feet per second through the aperture, a the area of the aperture in square inches, and h the height from its centre to the surface of the water, we have

$$v = c\sqrt{h}; \text{ and } q = \cdot 4167\, a\, c\sqrt{h};$$

in which c is a constant quantity, depending upon the nature of the aperture, and the value of which, for several different forms, is contained in the following table:—

Nature of the Orifices employed.	Ratio between the theoretical and real discharges.	Coefficients for finding the velocities in Eng. ft.
For the whole velocity due to the height	1 to 1·00	8·04
For wide openings whose bottom is on a level with that of the reservoir	1 to 0·961	7·7
For sluices with walls in a line with the orifice	1 to 0·961	7·7
For bridges with pointed piers	1 to 0·961	7·7
For narrow openings whose bottom is on a level with that of the reservoir	1 to 0·861	6·9
For smaller openings in a sluice with side walls	1 to 0·861	6·9
For abrupt projections and square piers of bridges	1 to 0·861	6·9
For openings in sluices without side walls	1 to 0·635	5·1
For an orifice in a thin plate	1 to 0·621	5·0

The following table of Smeaton is mainly the result of experiments.

TABLE, *abridged from one by Mr. Smeaton, for showing the height of head necessary to overcome the friction of water in horizontal pipes.*

Velocities per second of water in the pipes.										Bore of the pipes.
Ft. in. 0 6	Ft. in. 1 0	Ft. in. 1 6	Ft. in. 2 0	Ft. in. 2 6	Ft. in. 3 0	Ft. in. 3 6	Ft. in. 4 0	Ft. in. 4 6	Ft. in. 5 0

Look for the velocity of water in the pipe in the upper row, and in the column below it, and opposite to the given diameter of the pipe standing in the last column, will be found the perpendicular height of a column or head, in feet, inches, and tenths, requisite to overcome the friction of such pipe for 100 feet in length, and obtain the given velocity.

From the present standard work, *Lowell Hydraulic Experiments*, by Jas. B. Francis, Esq., we extract the following on weirs:

The formula proposed for weirs of considerable length in proportion to the depth upon them, and having complete contraction, (as first suggested to the author by Mr. Boyden in 1846,) is

$$Q = C\,(l - b\,n\,h)\,h^{a};$$

in which

$Q =$ the quantity discharged in cubic feet per second.
$C =$ a constant coefficient.
$l =$ the total length of the weir in feet.
$b =$ a constant coefficient.
$n =$ the number of end contractions. In a single weir having complete contraction, n always equals 2, and when the length of the weir is equal to the width of the canal leading to it, $n = 0$.
$h =$ the depth of water flowing over the weir, taken far enough upstream from the weir, to be unaffected by the curvature in the surface caused by the discharge.
$a =$ a constant power.

By experiments the numerical values were determined as follows:

$$Q = 3.33\,(L - 0.1\,n\,H)\,H^{\frac{3}{2}}:$$

the English foot being the unit of measure.

This formula is only applicable to rectangular weirs, made in the side of a dam, which is vertical on the upstream side, the crest of the weir being horizontal, and the ends vertical; also, the edges of the orifice presented to the current must be sharp; for, if bevelled or rounded off in any perceptible degree, a material effect will be produced on the discharge; it is essential, moreover, that the stream should touch the orifice only at these edges, after passing which it should be discharged through the air, in the same manner as if the orifice was cut in a thin plate. The formula is not applicable to cases in which the depth on the weir exceeds one third of the length; nor to very small depths. There seems no reason why it should not be applied with safety to any depths between 6 inches and 24 inches.

The height of the surface of the water in the canal, above the crest of the weir, is to be taken for the depth upon the weir; this height should be taken at a point far enough from the weir to be unaffected by the curvature caused by the discharge; if more convenient, it may be taken by means of a pipe opening near the bottom of the canal near the upstream side of the weir, which pipe may be made to communicate with a box placed in any convenient situation; and if the box and pipe do not leak, the height may be observed in this manner, very correctly. However the depth may be observed, it may require to be corrected for the velocity of the water approaching the weir.

The end contraction must either be complete, or entirely suppressed; the necessary distance from the side of the canal or reservoir to the end of the weir, in order that the end contraction may be complete, is not definitely determined. In cases where there is end contraction, we may assume a distance from the side of the canal to the end of the weir equal to the depth on the weir, as the least admissible, in order that the proposed formula may apply.

As to the fall below the weir, requisite to give a free discharge to the water, it is not definitely determined; it appears that when the sheet, passing the weir, falls into water of considerable depth, the depth on the weir being about 0.85 feet, no difference is perceptible in the discharge, whether the water is 1.05 feet or 0.235 feet below the crest of the weir; it is very essential, however, in all cases, that the air under the sheet should have free communication with the external atmosphere. With this precaution it appears that, if the fall below the crest of the weir is not less than half the depth upon the weir, the discharge over the weir will not be perceptibly obstructed. If the sheet is of very great length, however, more fall will be necessary, unless some special arrangement is made to supply air to the space under the sheet at the places that would otherwise not have a free communication with the atmosphere.

In respect to the depth of the canal leading to the weir, experiments show that, with a depth as small as three times that on the weir, the proposed formula agrees with experiment, within less than one per cent.; this proportion may be taken as the least admissible, when an accurate gauging is required.

It not unfrequently happens that, in consequence of the particular form of the canal leading to the weir, or from other causes, the velocity of the water in the canal is not uniform in all parts of the section; this is a frequent cause of serious error, and is often entirely overlooked. If great irregularities exist, they should be removed by causing the water to pass through one or more gratings, presenting numerous small apertures equally distributed, or otherwise, as the case may require, through which the water may pass under a small head; these gratings should be placed as far from the weir as practicable.

If the canal leading to the weir has a suitable depth, it will be requisite only when great precision is required, to correct the depth upon the weir for the velocity of the water in the canal by the formula (*D*).

h being the head due to the velocity with which the water approaches the weir: —

$$H' = \left[(H+h)^{\frac{3}{2}} - h^{\frac{3}{2}}\right]^{\frac{2}{3}}$$

Substituting H' for H in the previous formula, we obtain the flow increased for the velocity with which the water approaches the weir.

Of gauging the flow of water in open canals of uniform rectangular section.—It has been frequently found convenient at Lowell, to gauge large streams of water by causing them to flow through short rectangular canals of uniform section, and a particular method of obtaining the mean velocity has been practised, which will now be described.

A convenient part of the feeding canal is selected and lined with timbers and planks, so as to make a smooth and uniform rectangular channel; this is called a flume. The mean velocity is obtained by means of tubes, loaded at one end, so that they may float in nearly a perpendicular position, the lower ends just clearing the bottom of the flume; these tubes are put in near the upper end of the flume, and from the observed paths and velocities that they assume through a defined portion of the length of the flume, a mean velocity is deduced. The times of the transits are observed by the same chronometer, the signals being made by an electric telegraph erected for the purpose. The telegraph used for this purpose is a very simple apparatus; the circuit is formed by an insulated copper wire, about $\frac{1}{30}$ of an inch in diameter, and the electric current is maintained by a small galvanic battery. Whenever the circuit is broken, a small electro-magnet becomes demagnetized, which causes a slight blow to be struck on a vertical glass plate, placed near the observer, who notes the times of the transits. The tubes are cylinders, made of tinned plate, about two inches in diameter, and of a length usually a little exceeding the depth of the water in the flume. By a comparison of the results obtained by gauging, by the floats and by weir, the error in assuming the average velocity of the floats for that of the stream, was found to be correct within a trifling per centage.

Contrivances to measure the velocity of running waters.—For these purposes, various contrivances have been proposed, of which two or three may be here described.

Suppose it be the velocity of the water in a river that is required; or, indeed, both the velocity and the quantity which flows down it in a given time. Observe a place where the banks of the river are steep and nearly parallel, so as to make a kind of trough for the water to run through, and by taking the depth at various places in crossing make a true section of the river. Stretch a string at right angles over it, and at a small distance another parallel to the first. Then take an apple, an orange, or other small ball, just so much lighter than water as to swim in it, or a pint or quart bottle partly filled with water, and throw it into the water above the strings. Observe when it comes under the first string, by means of a quarter second pendulum, a stop-watch, or any other proper instrument; and observe likewise when it arrives at the second string. By this means the velocity of the upper surface will be obtained. And the section of the river at the second string must be ascertained by taking various depths, as before. If this section be the same as the former, it may be taken for the mean section: if not, add both together, and take half the sum for the mean section. Then the area of the mean section in square feet being multiplied by the distance between the strings in feet, will give the contents of the water in solid feet, which passed from one string to the other during the time of observation; and this by the rule of three may be adapted to any other portion of time. The operation may often be greatly abridged by taking notice of the arrival of the floating body opposite two stations on the shore, especially when it is not convenient to stretch a string across.

M. Pitot invented a stream measurer of a simple construction, by means of which the velocity of any part of a stream may readily be found. This instrument is composed of two long tubes of glass open at both ends: one of these tubes is cylindrical throughout; the other has one of its extremities bent into nearly a right angle, and gradually enlarges like a funnel, or the mouth of a trumpet: these tubes are both fixed in grooves in a triangular prism of wood; so that their lower extremities are both on the same level, standing thus one by the side of the other, and tolerably well preserved from accidents. The frame in which these tubes stand is graduated, close by the side of them, into divisions of inches and lines.

To use this instrument, plunge it perpendicularly into the water, in such manner that the opening of the funnel at the bottom of one of the tubes shall be completely opposed to the direction of the current, and the water pass freely through the funnel up into the tube. Then observe to what height the water rises in each tube, and note the difference of the sides; for this difference will be the height due to the velocity of the stream. It is manifest, that the water in the cylindrical tube will be raised to the same height as the surface of the stream, by the hydrostatic pressure: while the water entering from the current by the funnel into the other tube, will be compelled to rise above that surface by a space at which it will be sustained by the impulse of the moving fluid: that is, the momentum of the stream will be in equilibrio with the column of water sustained in one tube above the surface of that in the other. In estimating the velocity by means of this instrument, we must have recourse to theory as corrected by experiments. Thus, if h, the height of the column sustained by the stream, or the difference of heights in the two tubes, be in feet, we shall have $v = 6{\cdot}5 \sqrt{h}$, nearly, the velocity, per second, of the stream; if h be in inches, then $v = 22{\cdot}47 \sqrt{h}$, nearly: or further experiments made with the instrument itself may a little modify these coefficients.

Note. In an example like this, it is a good approximation, *to multiply continually together, the area of the orifice, the number* 336, ($336 = 5{\cdot}6 \times 66$,) *and the square root of the depth in feet of the middle of the orifice.*

Thus, in the preceding example, it will be $\frac{1}{2} \times \frac{1}{2} \times 336 \times \sqrt{4{\cdot}25} = \frac{1}{4} \times 336 \times 2{\cdot}062 = 173{\cdot}2$ cubic feet.

The less the height of the orifice compared with its depth under the water, the nearer will the result thus obtained approach to the truth. If the height of the orifice be such as to require consideration, the principle of Art. 6, page 17, may be blended with this rule.

Thus, applying this rule to *Ex.* 2, we shall have area $\times \sqrt{}$ depth $\times 336 \times \frac{2}{3} = 9 \times 3 \times 224 = 6048$, for the cubic feet discharged. This is less than the former result by about its 900th part. It is, therefore, a good approximation, considering its simplicity: it may, in many cases, supersede the necessity of recurrence to tables.

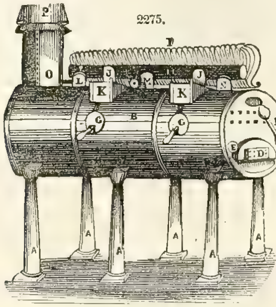
HYDRO-ELECTRICAL MACHINE. The production of electricity by the passage of steam through a small jet, was unknown till 1840. It is now generally concluded that it is the effect of the friction of globules of water against the sides of the opening, urged forward by the rapid passage of the steam; the effect of this is to render the steam or water positive, and the pipes from which it issues negative.

Fig. 2275 represents this machine, as manufactured by Benjamin Pike, Jr., of 294 Broadway, New York, in which A A, &c., are six green glass supports, three feet long; B is a cylindrical tubular boiler of rolled iron-plate, $\frac{3}{8}$ inch thick; its extreme length is seven feet six inches, one foot of which is occupied by the smoke-chamber, making the actual length of the boiler six and a half feet; its diameter three and a half feet. The furnace D and ash-hole C are contained within the boiler, and are furnished with a metal screen to be applied for the purpose of excluding the light during the progress of one class of experiments; F is the water-gage; E the feed-valve; J J are two tubes leading from the valves K K to the two tubes H; A and I are forty-six bent iron tubes, terminating in jets, either half or the whole of which may be opened by means of the lever G G; L is a valve for liberating steam during the existence of the maximum pressure; M is the safety-valve; N is a cap covering a jet, that is employed for illustrating a certain mechanical action of a jet of steam; O is the first portion of the funnel; P the second portion, which slides into itself by a telescope joint, so that the boiler may be insulated when the experiments commence. The boiler is cased in wood.

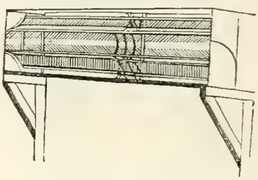
Fig. 2276, which may be called the prime conductor, but which is not used for the purpose, is a zinc case, furnished with four rows of points. It is placed in front of the jets, in order to collect the elec

tricity from the ejected vapor, and thus prevent its returning to restore the equilibrium of the boiler The maximum pressure at the commencement of the experiments is 80 pounds, which gradually gets reduced to 40 pounds, or lower. The portion of the apparatus which is peculiarly connected with the generation of the electricity, is a series of bent tubes with their attached jets. Each jet consists of a brass socket, containing a cylindrical piece of partridge-wood, with a circular hole or passage through it, $\frac{1}{8}$ of an inch in diameter, into which the steam is admitted through an aperture. The peculiar shape of this aperture appears to derive its efficacy from the tendency it gives the steam to spread out in the form of a cup, on entering the wooden pipe, and by that means to bring it and the particles of water of which it is the carrier, into very forcible collision with the rubbing surface of the wood.

2275.



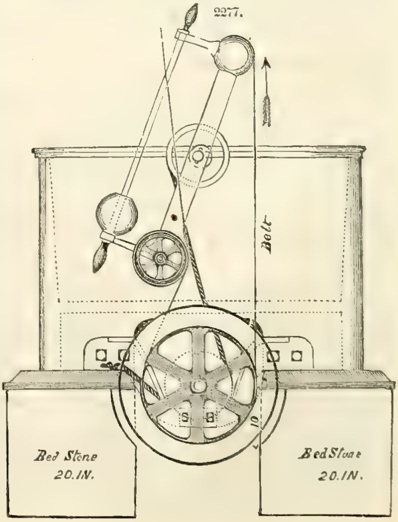
2276.



The electricity produced by this engine is not so remarkable for its high intensity, as for its enormous quantity. In no case, antecedent to this, has the electricity of tension taken so rapid a stride towards assimilating with galvanic electricity. Mr. Faraday's experiments on the identity of the electricities had shown how small was the quantity obtained from the best machines; and had given good reason to expect that chemical effects would be exalted when the quantity could be increased. And such is the case here; a very remarkable experiment in illustration of this is, that not only is gunpowder ignited by the passage of the spark, but even paper and wood shavings will be inflamed when placed in the course of the spark passing between two points—such an effect was never before produced with common electricity. In like manner, chemical decompositions are effected much more readily by means of the hydro-electric, than by that from the common machine.

HYDRO-EXTRACTOR. An apparatus for removing liquids or moisture from yarns or cloths in the process of manufacture. The main feature or principle of the machine is extremely simple, consisting merely of a circular open wire-basket, in which the wet cloths are placed as uniformly as possible, and which is then made to revolve with such rapidity that the moisture is thrown out by the centrifugal force through the interstices of the basket. As the vis inertiæ prevents the instant communication of a sufficient velocity to the basket loaded with heavy goods, various expedients have been resorted to to make communicated velocity progressive. The contrivances for this purpose, on the original English patent, are extremely complicated; but the arrangement shown in Fig. 2277, (which is an exterior view of the machine and the driving apparatus,) is much more simple, and perfectly effective. It is the invention of M. C. Bryant, of Lowell, Massachusetts. The whole machine rests on two square bed-stones; the outside of the case, or tub, is only shown in the figure, within which the wire-basket, open at the top for the reception of the goods, revolves on a vertical shaft; to this shaft motion is communicated from the horizontal shaft beneath the tub by means of bevel-geers. On the extremity of this horizontal shaft is fixed the driving-pulley, (as shown in the figure.) This pulley is of

2277.



the form usually employed on small tilt or trip hammers; a belt passing round this pulley, and continually moving, communicates motion to the pulley whenever a binder brings the belt in close contact with its periphery. The binder is attached to an extremity of an oscillating frame, suspended from the top of the tub, as shown in the figure. The binder presses against the belt so as to communicate motion to the pulley. To stop the motion, the upper end of the oscillating binder-frame is pressed down by a handle; the binder relieves the belt, and a rope attached to the periphery of a small pulley on the binder-frame passing over a pulley fixed on the horizontal driving-shaft, and fastened at the other end to the bottom of the tub, acts as a friction-brake to retard the motion of the shaft, and consequently of the basket. To keep the binder-frame in extreme positions a movable weight is placed on the handle rod at the top of the frame, which slides from one end to the other of the rod, as the binder is raised or depressed.

The basket in this hydro-extractor is about three and a half feet in diameter; and in full action, should make about 800 revolutions per minute. The driving-belt is about eight inches wide; the driving-pulley eighteen inches diameter.

This machine is in operation at the Bay State Mills, in Lawrence, and at the carpet mill in Lowell; and machines similar in the main principle are employed in many of the mills in this country, and give complete satisfaction.

HYDROMETER. An instrument for determining the specific gravities of liquids, and thence the strength of spirituous liquors; these being inversely as their specific gravities. Various instruments of different forms have been proposed for ascertaining readily the specific gravities of fluids, but only two or three of them are deserving of description.

The hydrometer represented in Fig. 2278 consists of a hollow glass ball B, with a smaller ball C appended to it, and which, from its superior weight, serves to keep the instrument in a vertical position, to whatever depth it may be immersed in a liquid. From the large ball rises a cylindrical stem *a d*, on which are marked divisions into equal parts; and the depth to which the stem will sink in water, or any other liquid fixed on as a standard of specific gravity, being known, the depth to which it sinks in a liquid whose specific gravity is required, will indicate, by the scale, how much greater or less it is than that of the standard liquid.

Those most celebrated are the scales of Baumé, Cartier, Twaddell, and Guy Lussac. Most of these scales are arbitrary, and formed after the ideas of their projectors, but having no particular reference by which they may be understood.

The centesimal hydrometer, by Guy Lussac, is an exception, the extreme points being water and absolute alcohol; this space is divided into one hundred parts, thus showing in alcoholic mixtures the per centage of alcohol in the liquid. They are made of glass, brass, and silver, usually from six to ten inches long, of the form represented in the cut, the graduations being marked on the stem.

2278.

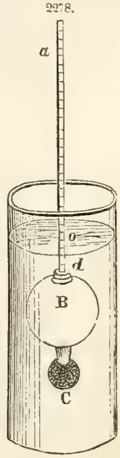


TABLE *showing the Comparative Scales of Guy Lussac and Baumé, with the Specific Gravities and Proof, at the Temperature of* 60°.

	Guy Lussac's Scale.	Baumé's Scale.	Specific Gravity.	Proof.

	35	16	958	29	
	30	15	964	35	
	25	14	970	48	

Explanation of Baumé's scale.—Manufacturers who employ Baumé's hydrometer, or have occasion to know the value of the degrees on his scale, may find the following formula useful:—

Let B = Baumé's degrees, and 100 = water. Then

$$\text{Specific gravity} = \frac{144}{144 - \text{B}}.$$

That is to say, 144 divided by the difference between 144 and the given degree of Baumé, is the specific gravity in question, stated in reference to water assumed = 100. Thus, suppose Baumé = 66°. Then

$$\text{Specific gravity} = \frac{144}{144 - 66} \text{ or } \frac{144}{78} = 1{\cdot}846 = \text{specific gravity}.$$

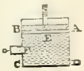
Scale of Specific Gravities indicated by Twaddell's Scale.

Twaddell.	Sp. Gr.	Twaddell.	Sp. Gr.	Twaddell.	Sp. Gr.	Twaddell.	Sp. Gr.
0	1000	50	1250	100	1500	150	1750
10	1050	60	1300	110	1550	160	1800
20	1100	70	1350	120	1600	170	1850
30	1150	80	1400	130	1650	180	1900
40	1200	90	1450	140	1700	190	1950

Hydrometer with weights.—There is a variety of kinds of hydrometers, with weights; the principal ones are Dica's and Sikes's. They are used for ascertaining the strength of spirituous liquors.

Another easy method of determining the densities of different liquids, frequently practised, is by means of a set of glass beads previously adjusted and numbered. Thrown into any liquid, the heavier balls sink and the lighter float at the surface; but one of them approaching the density of the liquid will be in a state of indifference as to buoyancy, or will float under the surface. The number on this ball indicates, in thousandth parts, the specific density of the liquid.

HYDROSTATIC PRESS. If there be any number of pistons of different magnitudes, any how applied to apertures in a cylindrical vessel filled with an incompressible and non-elastic fluid, the forces acting on the pistons to maintain an equilibrium, will be to one another as the areas of the respective apertures, or the squares of the diameters of the pistons.



Let A B C D represent a section passing along the axis of a cylindrical vessel filled with an incompressible and non-elastic fluid, and let E F be two pistons of different magnitudes, connected with the cylinder and closely fitted to their respective apertures or orifices; the piston F being applied to the aperture in the side of the vessel, and the piston E occupying an entire section of the cylinder or vessel, by which the fluid is contained.

Then, because by the nature of fluidity, the pressures on every part of the pistons E and F, are mutually transmitted to each other through the medium of the intervening fluid; it follows that these pressures will be in a state of equilibrium when they are equal among themselves.

Now, it is manifest, that the sum of the pressures propagated by the piston E, is proportional to the area of a transverse section of the cylinder; and in like manner the sum of the pressures propagated by the piston F is proportional to the area of the aperture which it occupies; consequently, an equilibrium must obtain between these pressures when the forces on the pistons are to one another, respectively, as the areas of the apertures or spaces which they occupy.

Hence it appears, that by taking the areas of the pistons E and F, in a proper ratio to one another, we can, by means of an incompressible fluid, produce an enormous compression, and that too by the application of a very small force.

Put $P =$ the force or pressure on the piston E.
$A =$ the area of the orifice which it occupies,
$p =$ the pressure on the piston F, and
$a =$ the area of the orifice or space to which it is fitted:

then, according to the principle announced in the foregoing proposition and demonstrated above, we shall obtain

$$a : A : : p : P.$$

But because, by the principles of mensuration, the areas of different circles are to one another as the squares of their diameters; if, therefore, we substitute d^2 and D^2 respectively for a and A in the above analogy, we shall have

$$d^2 : D^2 : : p : P;$$

and from this, by making the product of the mean terms equal to the product of the extremes, we get the general equation,

$$p\,D^2 = P\,d^2 \ldots\ldots\ldots\ldots (A)$$

This is the principle upon which depends the construction and use of that very powerful instrument, the *Hydrostatic Press*, first brought into notice about the year 1796, by Joseph Bramah, Esq., of London.

The improvement introduced by Mr. Bramah, consisted in the application of the common forcing-pump to the injection of water, or some other incompressible and non-elastic fluid, into a strong metallic cylinder, truly bored and furnished with a movable piston, made perfectly water-tight by means of leather collars or packing, neatly fitted into the cylinder.

The proportion which subsists between the diameter of this piston, and that of the plunger in the forcing-pump, constitutes the principal element by which the power of the instrument is calculated; for, by reason of the equal distribution of pressure in the fluid, in proportion as the area of the transverse section of the one exceeds the area of a similar section of the other, so must the pressure sustained by the one exceed that sustained by the other.

Therefore, if the piston F, in the preceding diagram, be assimilated to the plunger in the barrel of a forcing-pump, and the piston E to that in the cylinder of the hydrostatic press; then, the equation (A) involves every particular respecting the power and effects of the engine.

Example. If the diameter of the cylinder is 5 inches, and that of the forcing-pump one inch; what is the pressure on the piston in the cylinder, supposing the force applied on the plunger or smaller piston to be equivalent to 750 lbs.?

Here we have given $D = 5$ inches, $d = 1$ inch, and $p = 750$ lbs.; therefore, by substitution, equation (A) becomes

$$5^2 \times 750 = P \times 1^2;\ \text{that is, } P = \frac{PD^2}{d^2} = 18{,}750 \text{ lbs.}$$

Rule.—Multiply the square of the diameter of the cylinder by the pressure on the piston, of the forcing pump, and divide the product by the square of its diameter, and the quotient will express the intensity of the pressure on the piston of the cylinder.

$$p = \frac{P\,d^2}{D^2};$$ or, in words:—

Rule.—Multiply the given pressure on the piston of the cylinder by the square of the diameter of the forcing pump, and divide the product by the square of the diameter of the cylinder for the power required.

$$D = \sqrt{\frac{P\,d^2}{p}}.$$

Rule.—Multiply the pressure on the piston of the cylinder by the square of the diameter of the forcing pump, and divide the product by the force with which the plunger descends; then the square root of the quotient will be the diameter of the cylinder sought.

$$d = \sqrt{\frac{p\,D^2}{P}}.$$

Rule.—Multiply the force with which the plunger descends by the square of the diameter of the cylinder and divide the product by the entire pressure on the piston; then extract the square root of the quotient for the diameter of the forcing pump.

The Hydrostatic press is generally furnished with an *indicator* or *safety-valve* for measuring the intensity of pressure, which may be easily estimated by considering the diameter of the valve, and the pressure upon it as the plunger of the forcing pump, and using previous rules.

To determine the thickness of metal in the cylinder to withstand the required pressure.—The amount of force which tends to rupture the cylinder along the curved side, that is to divide the cylinder in halves lengthways, is equal to the pressure per square inch on each lineal unit of the diameter multiplied by the length of the cylinder.

Thus, let the piston of a hydraulic press be 10 inches in diameter, and the pressure 300 tons *net*; then the pressure per square inch of piston will be 300 tons divided by the number of square inches in the piston, or $\frac{600.000}{78.54} = 7.639$ lbs. The pressure per inch in length of the cylinder tending to split or tear it apart, is equal to the diameter multiplied by the pressure per square inch, or in this case, $10 \times 7639 =$ 76,390 lbs., of which, of course, each side sustains one half.

The cohesive strength of cast iron varies from 13,000 to 20,000 lbs. per square inch; of wrought iron, from 50 to 60,000 lbs.; 8,000 lbs. may be taken as the safe limit for cast iron, 20,000 for wrought iron; hence, to withstand a force equal $\frac{76390}{2}$ or 38,195 lbs. on each side; the thickness, if cast iron, should be about 5 inches; if wrought iron, 2 inches.

Presses made to withstand but little pressure, that is per square inch, are mostly made with cylinders of cast iron. Some of the cylinders of large presses are made of cast iron, bound with wrought iron hoops, as fig. 2289, but the best material to withstand great pressure, is wrought iron. Of this material R. Hoe & Co., of New York, make their presses, and of this are the jacks of R. Dudgeon constructed.

An English rule for the construction of cast iron cylinders, is to make the thickness of metal equal to the interior radius of the cylinder, and to determine the entire pressure in tons. When the diameter of the cylinder is given, the following simple rule is used:

Rule.—Multiply the square of the diameter in inches by the constant number, 2·9186, and the product will be the pressure in tons.

And again, when the pressure in tons is given, the diameter of the cylinder may be determined by reversing the process, or by the following rule:

Rule.—Divide the given pressure in tons by the constant number 2·9186, and extract the square root of the quotient for the diameter of the cylinder in inches.

Example.—The diameter of the cylinder in a hydrostatic press, is 10 inches; what is its power, or what pressure does it transmit?

Here, by the first rule above, we have, $P = 10^2 \times 2{\cdot}9186 = 291{\cdot}86$ tons.

Example.—What is the diameter, and what the thickness of metal, in a press of 300 tons power?

By the second rule above, we have, $D^2 = 300 \div 2{\cdot}9186 = 102{\cdot}81$ nearly;

therefore by extracting the square root, we obtain, $D = \sqrt{102{\cdot}81} = 10{\cdot}13$ inches;
consequently, the thickness of metal is, $t = 10{\cdot}13 \div 2 = 5{\cdot}065$ inches.

The hydrostatic press is one of the most convenient and simplest of all machines for transmitting great force; it is used for punching, pressing, lifting and pulling. It was used for raising the immense tubes of the Conway Tubular Bridge, and is in general use for the baling and pressing of materials and goods. At the United States Navy Yard, Washington, it is used as a proving machine for proving chain cables; as a jack it is made portable, and is applicable to all the purposes for which such machines are intended.

Figs. 2280, 2283 represent the front and side elevation of a small hydraulic press with a hand forcing pump: F is a strong metallic cylinder of cast-iron, or some other material of sufficient density to prevent the fluid from issuing through its pores, and of sufficient strength to preclude the possibility of rupture, by reason of the immense pressure which it is destined to withstand.

The cylinder F is bored and polished with the most scrupulous precision, and fitted with the movable piston D, which is rendered perfectly water-tight, by means of leather collars constructed for the purpose, and fixed in the cylinder by a simple but ingenious contrivance to be described hereafter.

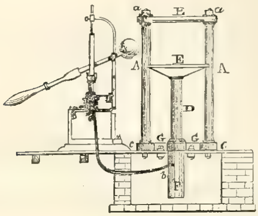
Into the side or base of the cylinder F, the end of a small tube *b b b* is inserted, and by this tube the

water is conveyed or forced into the cylinder; the other end of the tube is attached to the forcing-pump as represented in Fig. 2280; but this will be more particularly explained in another place.

A A are two very strong upright bars, generally made of wrought-iron, and of any form whatever, corresponding to the notches in the sides of the flat table E, which is fixed upon the end of the piston D and by workmen is usually denominated the "*follower*" or "*pressing-table.*"

B is the top of the frame into which the upright bars A A are fixed, and *c c* is the bottom thereof, both of which are made of cast, in preference to wrought-iron, being both cheaper and more easily moulded into the intended form.

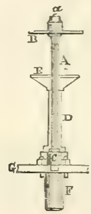
2280.



2281.

2282.

2283.



The bottom of the frame *c c* is furnished with four projections or lobes, with circular perforations, for the purpose of fastening it by iron bolts to the massive blocks of wood, whose transverse sections are indicated by the lighter shades at G G. The top B has two similar perforations, through which are passed the upper extremities of the vertical bars A A, and there made fast, by screwing down the *cup-nuts* represented at *a* and *a*.

Fig. 2281 represents the plan of the top, or, as it is more frequently termed, the head of the frame; the lower side or surface of which is made perfectly smooth, in order to correspond with, and apply to the upper surface of the pressing-table E, in Fig. 2280; this correspondence of surfaces becomes necessary on certain occasions such as the copying of prints, taking fac-similes of letters, and the like; in all such cases, it is manifest, that smooth and coincident surfaces are indispensable for the purpose of obtaining true impressions.

Fig. 2281 represents the upper side of the block, in which the middle part B (through whose rounded extremities *a* and *a*, the circular perforations are made for receiving the upright bars or rods A A, Fig. 2280, is considerably thicker than the parts on each side of it; this augmentation of thickness is necessary to resist the immense strain that comes upon it in that part; for although the pressure may be equally distributed throughout the entire surface, yet it is obvious that the mechanical resistance to fracture must principally arise from that part which is subjected to the reaction of the upright bars.

Fig. 2282 represents the plan of the base or bottom of the frame; it is generally made of uniform thickness, and of sufficient strength to withstand the pressure; for be it understood, that all the parts of the machine are subjected to the same quantity of strain, although it is exerted in different ways. The upright bars, cylinders, and connecting-tubes resist by tension, the pistons by compression, and the pressing-table, together with the top and bottom of the frame, resist transversely.

The circular perforations *c c* correspond to *a a* in the top of the frame, and receive the upright bars in the same manner; the perforations *d d d d* receive the screw-bolts which fix the frame to the beams of timber represented at G G, Fig. 2280; the large perforation F receives the cylinder, the upper extremity of which is furnished with a flanch, for the purpose of fitting the circular swell around the perforation, and preventing it from moving backwards during the operation of the instrument.

A side view of the engine, as thus completed, is represented in Fig. 2283, where, as is usual in all such descriptions, the same letters of the alphabet refer to the same parts of the structure.

F is the cylinder into which the fluid is injected; D the piston, on whose summit is the pressing-table E; A one of the upright rods or bars of malleable iron; B the head of the press, fixed to the upright bar A by means of the *cup-nut a*; *c* the bottom, in which the upright bar is similarly fixed; and G a beam of timber supporting the frame with all its appendages.

But the *hydrostatic press*, as here described and constructed, must not be considered as fit for immediate action; for it is manifestly impossible to bore the interior of the cylinder so truly, and to turn the piston with so much precision, as to prevent the escape of water between their surfaces, without increasing the friction to such a degree, that it would require a very great force to counterbalance it.

2284.

In order, therefore, to render the piston water-tight, and to prevent as much as possible the increase of friction, recourse must be had to other principles, which we now proceed to explain.

2285.

The piston D is surrounded by a collar of pump leather *o o*, represented in Fig. 2284, which collar being doubled up, so as in some measure to resemble a lesser cup placed within a greater, it is fitted into a cell made for its reception in the interior of the cylinder; and when there, the two parts are prevented from coming together by means of the copper ring *p p*, represented in Fig. 2285, being inserted between the folds, and retained in its place, by a lodgment made for that purpose on the interior of the cylinder.

2286.

The leather collar is kept down by means of a brass or bell-metal ring *m m*, Fig. 2286, which ring is received into a recess formed round the interior of the cylinder, and the circular aperture is fitted to admit the piston D to pass through it, without materially increasing the effects of friction, which ought to be avoided as much as possible.

The leather is thus confined in a cell, with the edge of the inner fold applied to the piston D, while the edge of the outer fold is in contact with the cylinder all around its interior circumference; in this situation, the pressure of the water acting between the folds of the leather, forces the edges into close contact with both the cylinder and piston, and renders the whole water-tight; for if the leather be properly constructed and rightly fitted into its place, it is almost impossible that any of the fluid can escape; for the greater the pressure, the closer will the leather be applied to both the piston and the cylinder.

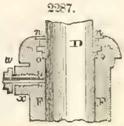
The metal ring *m m* is truly turned in a lathe, and the cavity in which it is placed is formed with the same geometrical accuracy; but in order to fix it in its cell, it is cut into five pieces by a very fine saw, as represented by the lines in Fig. 2286, which are drawn across the surface of the ring. The four segments which radiate to the centre are put in first, then the segment formed by the parallel kerfs, (the copper ring *p p* and the leather collar *o o* being previously introduced,) and lastly, the piston which carries the pressing-table.

That part of the cylinder above the ring *m m*, where the inner surface is not in contact with the piston, is filled with tow, or some other soft material of a similar nature; the material thus inserted has a twofold use: in the first place, when saturated with sweet oil, it diminishes the friction that necessarily arises, when the piston is forced through the ring *m m*; and in the second place, it prevents the admission of any extraneous substance, which might increase the friction or injure the surface of the piston, and otherwise lessen the effects of the machine.

The packing here alluded to, is confined by a thin metallic annulus, neatly fitted and fixed on the top of the cylinder, the circular orifice being of sufficient diameter to admit of a free and easy motion to the piston.

If a cylinder thus furnished with its several appendages be placed in the frame, and the whole firmly screwed together and connected with the forcing-pump, as represented in Fig. 2280, the press is completed and ready for immediate use; but in order to render the construction still more explicit and intelligible, and to show the method of connecting the press to the forcing-pump, let Fig. 2287 represent a section of the cylinder with all its furniture, and a small portion of the tube immediately adjoining, by which the connection is effected.

2287.



Then is F F the cylinder; D the piston; the unshaded parts *o o* the leather collar, in the folds of which is placed the copper ring *p p*, distinctly seen, but not marked in the figure; *m m* is the metal ring by which the leather collar is retained in its place; *n n* the thin plate of copper or other metal fitted to the top of the cylinder, between which and the plate *m m* is seen the soft packing of tow, which we have described above, as performing the double capacity of oiling the piston and preventing its derangement.

The combination at *w x* represents the method of connecting the injecting-tube to the cylinder: it may be readily understood by inspecting the figure; but in order to remove all causes of obscurity, it may be explained in the following manner.

The end of the pipe or tube, which is generally made of copper, has a projecting piece or socket-flanch soldered or screwed upon it, which fits into a perforation in the side or base of the cylinder, according to the fancy of the projector, but in this figure the perforation is in the side.

The tube thus furnished is forcibly pressed into its seat by a hollow screw *w*, called a union screw, which fits into another screw of equal thread made in the cavity of the cylinder; the joint is made water-tight, by means of a collar of leather, interposed between the end of the tube and the bottom of the cavity.

A similar mode of connection is employed in fastening the tube to the forcing-pump, the description of which, although it constitutes an important portion of the apparatus, does not properly belong to this place; the principles of its construction and mode of action must therefore be supposed as known, until we come to treat of the construction and operation of pumps in general.

Admitting, therefore, that the action of the forcing-pump is understood, it only now remains to explain the nature of its operation in connection with the *hydrostatic press*, the construction of which we have so copiously exemplified.

In order to understand the operation of the press, we must conceive the piston D, Fig. 2280, as being at its lowest possible position in the cylinder, and the body or substance to be pressed, placed upon the crown or pressing-table E; then it is manifest, that if water be forced along the tube *b b b* by means of the forcing-pump, it will enter the chamber of the cylinder F immediately beneath the piston D, and cause it to rise a distance proportioned to the quantity of fluid that has been injected, and with a force determinable by the ratio between the square of the diameter of the cylinder and that of the forcing-pump. The piston thus ascending, carries its crown, and consequently, the load along with it, and by repeating the operation, more water is injected, and the piston continues to ascend, till the body comes into contact with the head of the frame B, when the pressure begins; thus it is manifest, that by continuing the process, the pressure may be carried to any extent at pleasure; but we have already stated, in developing the theory, that there are limits, beyond which, with a given bore and a given thickness of metal, it would be unsafe to continue the strain.

When the press has performed its office, and it becomes necessary to relieve the action, the discharging-valve, placed in the furniture of the forcing-pump, must be opened, which will admit the water to escape out of the cylinder and return to the cistern, while the table and piston, by means of their own weight, return to their original position.

Theory of construction and description of the hydrostatic weighing machine.—If into the side of ar

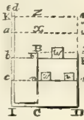
open cylindrical or other vessel a bent tube be inserted, and if on the surface of the fluid a movable cover exactly fitting the vessel be placed with a weight upon it, and the tube graduated:—

Then, any additional weight placed upon the cover, may be determined by knowing the height to which the fluid rises in the tube; and conversely:—If the additional weight be known, the height to which the fluid rises in the tube may be found.

Let A B C D represent a vertical section of a cylindrical vessel, or of any other vessel, whose sides are perpendicular to the horizon; and let K I C be the corresponding section of the equilibrating tube.

Let both the vessel and the communicating tube be open at the upper parts A B and $d e$, and conceive the vessel to be filled with fluid to the line E F or altitude D E; then, on the surface of the fluid at E F, let there be placed a movable cover exactly fitting the vessel, so that the whole may be water-tight.

2288.



Produce E F to b, then is the point b at the same level in the tube I K, as the surface of the fluid in the vessel whose level is E F: upon the cover E F let the weight w be placed, and suppose a to be the point in the tube, to which the fluid will rise by the action of the cover, together with the weight w which is placed upon it; in this case, the machine is in a state of equilibrium.

If some additional weight w' be placed upon the cover, then the original equilibrium will be destroyed, and can only be restored by the fluid ascending in the tube to a sufficient height to balance the additional weight.

Put $D = $ A B or D C, the diameter of the cylindrical vessel, of which A B C D is a section,

$d = d\,e$, the diameter of the communicating-tube K I C,

$h = b\,a$, the height of the original equilibrating column,

$w =$ the weight supported by the column $b\,a$,

$w' =$ the additional weight, whose quantity is required,

$h' = a$ K, the increased altitude of the supporting column,

$\delta =$ E m, the descent of the cover occasioned by the additional load w', and

$s =$ the specific gravity of the fluid.

Then it is manifest, that when the equilibrium originally obtains; that is, when the surface of the fluid in the tube is at a, and that in the vessel at E F, the pressure of the fluid in the tube exerted at b, is

$$p = \cdot 7854\ d^2 h\, s,$$

where the symbol p denotes the pressure at b; omitting the steps of the algebraic calculation, we obtain

$$w' = \cdot 7854\ h' s\,(D^2 + d^2).$$

If the fluid be water, whose specific gravity is represented by unity, the equation becomes somewhat simpler; for in that case, we have

$$w' = \cdot 7854\ h'\,(D^2 + d^2).$$

From this equation the magnitude of the additional weight, or the measure by which it is expressed, can very easily be ascertained; and the practical rule by which it is discovered is as follows:

Rule.—Multiply the sum of the squares of the diameters by ·7854 times the rise of the fluid in the tube, or the elevation above the first level, and the product will express the magnitude of the additional weight.

Example.—The diameter of a cylindrical vessel is 16 inches, and that of the communicating tube one inch; now, supposing the machine in the first instance to be in a state of equilibrium, and that by the addition of a certain weight on the movable cover, the water in the tube rises 6 inches above the original equilibrating level; how much weight has been added?

By proceeding, according to the rule, we have $D^2 + d^2 = 16^2 + 1^2 = 256 + 1 = 257$,

and by multiplication, we obtain $w' = \cdot 7854 \times 6 \times 257 = 1211{\cdot}0868$ avoirdupois lbs.

If the additional weight by which the water is made to rise in the tube be given, the distance above the first level to which it will rise, can easily be found; for let both sides of the equation $w' = \cdot 7854\, h'\,(D^2 + d^2)$ be divided by the quantity $\cdot 7854\,(D^2 + d^2)$, and we shall obtain

$$h' = \frac{w'}{\cdot 7854\,(D^2 + d^2)}.$$

And from this equation, we deduce the following rule:—

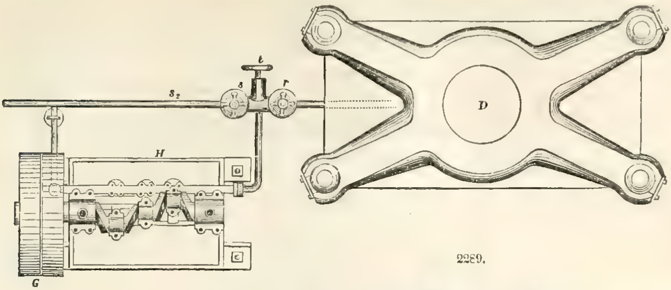
Rule.—Divide the additional weight by the sum of the areas of the movable cover and the cross section of the communicating tube, and the quotient will give the height to which the fluid will rise above the first level.

Example.—The diameter of the movable cover is 16 inches, and that of the communicating tube one inch; then, supposing that the machine in the first instance is brought to a state of equilibrium, and that a load of 1211 lbs. is applied on the cover, in addition to that which produces the equipoise; to what height above the first level will the water ascend in the communicating tube?

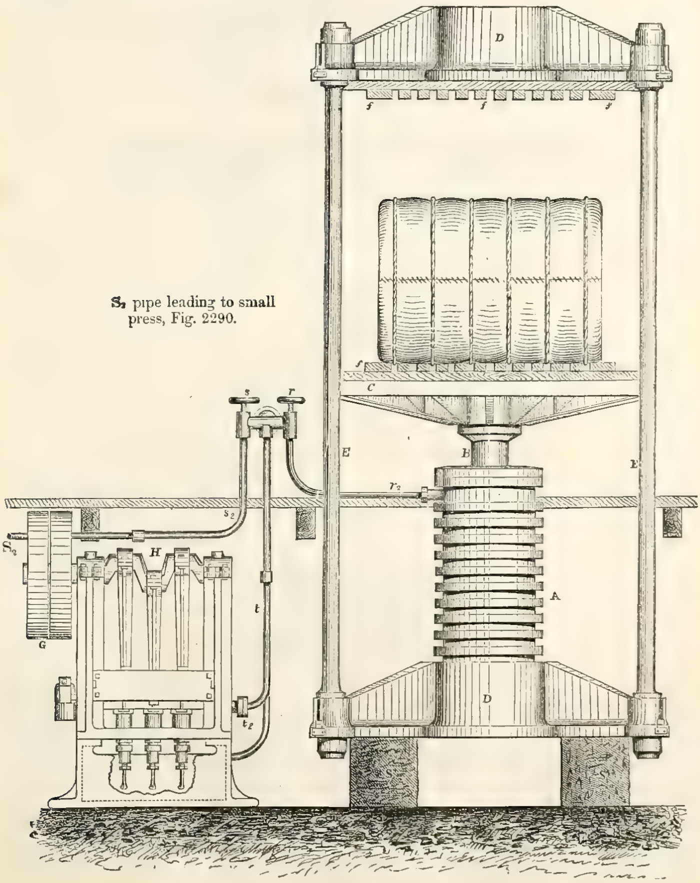
Proceeding, according to the rule, we obtain $\cdot 7854\,(D^2 + d^2) = \cdot 7854\,(16^2 + 1^2) = 201{\cdot}8478$ divisor;

consequently, by division it is $h' = \dfrac{1211}{201{\cdot}8478} = 6$ inches nearly.

And exactly after the manner of these two examples, may any other case be calculated; but in applying the principles to the determination of weights, mercury ought to be employed in preference to water, as it exerts an equal influence in less space, and besides, it is not subject to a change of density by putrefaction and the like.



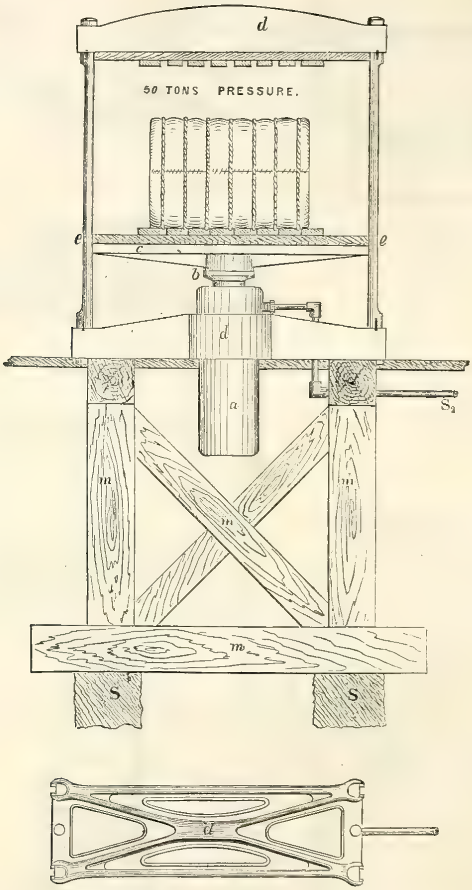
2289.



S_2 pipe leading to small press, Fig. 2290.

Figs. 2280 and 2290 show the elevation and plan of a press capable of giving a pressure equal to 200 tons weight; also of a press which is suitable for a pressure of 50 tons weight. By the arrangement shown, one set of pumps is sufficient to operate both presses.

2290.



The hand-wheels *s* and *r* operate valves which can be opened or shut as is wanted, so as to connect or shut off either press from the pumps. *w* is a hand-wheel moving a valve which allows either of the press cylinders to be drawn off, and returns the water into the tank under the pump through the pipe t^2. *t* is a pipe through which the water is pumped on its passage to the presses until it reaches the valves *s* and *r*, where it passes through the pipes r^2 or s^2 to either or both presses, as is wanted. The pumps have three pistons, which are operated by the three-throw crank H, and are driven by means of the pulleys G.

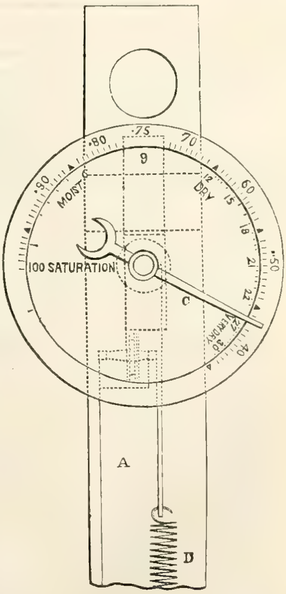
s s s s are foundation blocks, of stone, on which the presses are placed. *m m m m* is a wooden frame under the small press to raise it to a convenient height. A and *a*, are the chambers or cylinders of the presses. B and *b*, are the pistons. D D and *d d*, are the top and bottom pieces, and E E, *e e*, are the columns to the frames. C and *c*, are the platens or followers which are moved up by the pistons B and *b*. These presses are from the Lowell Machine Shop.

HYGROMETER, an instrument for measuring the degrees of moisture or dryness of the atmosphere Variations in the state of the atmosphere, with respect to moisture and dryness, are manifested by a great variety of phenomena, and, accordingly, numerous contrivances have been proposed for ascertaining the amounts of those variations by referring them to some conventional scale. All such contrivances are called *hygrometers;* but though the variety of form that may be given to them, or of substances that may be employed, is endless, they may all be referred to two classes; namely, 1st, those which act on the principle of *absorption;* and, 2d, those which act on the principle of *condensation.*

1. *Hygrometers on the principle of absorption.*—Many substances in each of the three kingdoms of nature absorb moisture from the atmosphere with greater or less avidity, and thereby suffer some change in their dimensions, or weight, or some of their physical properties. Animal fibre is softened and relaxed, and consequently elongated, by the absorption of moisture. Cords composed of twisted vegetable substances are swollen, and thereby shortened, when penetrated by humidity; and the alternate expansion and shrinking of most kinds of wood, especially when used in cabinet-work, and after the natural sap has been evaporated, is a phenomenon with which every one is familiar. Many mineral substances absorb moisture rapidly, and thereby obtain an increase of weight. Now it is evident that any of these changes, either of dimension or of weight, may be regarded as the measure of the quantity of moisture absorbed, from which the quantity of water existing in the atmosphere in the state of vapor is inferred; but many of them are so small in amount, or take place so slowly, that they afford no certain indication of the actual state of the atmosphere at any particular moment.

Saussure's hygrometer consists of a human hair, prepared by boiling it in a caustic ley. One extremity of the hair is fastened to a hook, or held by pincers; the other has a small weight attached to it, by which it is kept stretched. The hair is passed over a grooved wheel or pulley, the axis of which carries an index which moves over a graduated arch. Such is the essential part of the instrument, and it is easy to conceive how it acts. When the surrounding air becomes more humid, the hair absorbs an additional quantity of moisture, and is elongated; the counterpoise consequently descends, and turns the pulley, whereby the index is moved towards the one hand or the other. On the contrary, when the air becomes drier the hair loses a part of its humidity, and is shortened. The counterpoise is consequently drawn up, and the index moves in the opposite direction. The accuracy of the indications of this instrument depends on the assumed principle that the expansion and contraction of the hair are due to moisture alone, and are not affected by temperature, or other changes in the condition of the atmosphere. Experiment shows that the influence of temperature is not very great; but after all precautions have been taken in preparing the instrument, it is found to be exceedingly irregular in its movements, and subject to great uncertainties. Besides, the substance is soon deteriorated, and will scarcely maintain its properties unimpaired during a single year.

2291.



The hygrometer of De Luc consists of a very thin slip of whalebone, cut transversely or across the fibres, and stretched, by means of a spring, between two points. One end is fixed to a bar, while the other acts on the shorter arm of the index of a graduated scale. When the whalebone absorbs moisture it swells, and its length is increased; as it becomes dry it contracts; and the space over which the index moves by the one or the other of these effects, gives the measure of the expansion or contraction, and the corresponding change in the hygrometric state of the atmosphere. The action of this hygrometer appears to be more uncertain than that of Saussure.

The hygrometers which have been proposed on the principle of a change of weight arising from the absorption of moisture, are liable to still greater objections. Changes of weight may indeed be measured with greater accuracy by the common or torsion balance: but in the present case they are so small, that the particles of dust which are at all times floating in the atmosphere may produce a great alteration in the results.

Hygrometer, portable.—This hygrometer is of very simple construction, and is so arranged as to show the humidity of the atmosphere in decimal parts of the saturation, as well as to afford a means of ascertaining the dew-point. Fig. 2291 represents a front elevation of the instrument, with the details dotted. A is the back or main supporting piece, of metal or glass, to which is attached, at the lower extremity, a long thin strip of wood, the grain of which runs in a direction transverse to the length of the strip. The upper end of this strip is attached to the axis of the index C, which points out the degrees of saturation of the atmosphere. A helical spring D is fastened at its lower end to a bracket projecting from the front of the back piece A, its contrary extremity being fastened, by means of a connecting-cord, to the index axis C. The action of the spring upon the index is such as to tend constantly to hold it at its original position, while the expansion and contraction of the wood-slip, due to the greater or less amount of moisture in the atmo-

sphere, moves the index round accordingly, and thus indicates upon the graduated dial the ratio o moisture existing at the time being.

The dew-point is readily found by first ascertaining the exact temperature at the time of observation, and from this subtracting the number indicated on the dial by the hand C, the remainder being the temperature corresponding to the amount of moisture in the atmosphere, or, as it is technically termed, the dew-point.

2. *Hygrometers on the principle of condensation.*—The instruments of this class are of a more refined nature than those which we have been describing. In order to give an idea of the general principle on which they depend, let us conceive a glass jar, having its sides perfectly clean and transparent, to be filled with water, and placed on a table in a room where the temperature is, for example, 60°, the temperature of the water being the same as that of the room. Let us next suppose pieces of ice, or a freezing mixture, to be thrown into the water, whereby the water is gradually cooled down to 55, 50, 45, &c., degrees. As the process of cooling goes on, there is a certain instant at which the jar loses its transparency, or becomes dim; and on attentively examining the phenomenon, it is found to be caused by a very fine dew, or deposition of aqueous vapor, on the external surface of the vessel. The precise temperature of the water, and, consequently, of the vessel, at the instant when this deposition begins to be formed, is called the *dew-point*, and is capable of being noted with great precision. Now this temperature is evidently that to which, if the air were cooled down, under the same pressure, it would be completely saturated with moisture, and ready to deposit dew on any body in the least degree colder than itself. The difference, therefore, between the temperature of the air, and the temperature of the water in the vessel when the dew begins to be formed, will afford an indication of the dryness of the air, or of its remoteness from the state of complete saturation.

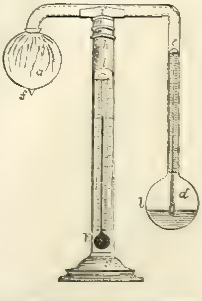
But the observation which has now been described is capable of affording far more interesting and precise results than a mere indication of the comparative dryness or moisture of the atmosphere. With the help of tables of the elastic force of aqueous vapor at different temperatures, it gives the means of determining the absolute weight of the aqueous vapor diffused through any given volume of air, the proportion of vapor existing in that volume to the quantity that would be required to saturate it, and of measuring the force and amount of evaporation.

The elastic force of aqueous vapor at the boiling point of water is evidently equal to the pressure of the atmosphere. This may be assumed as corresponding to a column of mercury 30 inches in height. Mr. Dalton, in the fifth volume of the *Manchester Memoirs*, has given the details of a most valuable and beautiful set of experiments, by which he ascertained the elastic force of vapor from water at every degree between its freezing and boiling points, in terms of the column of mercury which it is capable of supporting. As the same experiments have since been frequently repeated, and the different results present all the accordance which can be expected in so delicate an investigation, the tension of vapor at the different temperatures may be regarded as sufficiently well determined. Supposing, then, we have a table exhibiting the elasticity or tension corresponding to every degree of the thermometer, the weight of a given volume of vapor, for example, a cubic foot, may be determined as follows:—

Steam at 212°, and under a pressure of 30 inches of mercury, is 1700 times lighter than an equal bulk of water at its greatest density, or a temperature of about 40°, and a cubic foot of water at that temperature weighs 437,272 grains; the weight, therefore, of a cubic foot of steam at that temperature and pressure is, $437272 \div 1700 = 257{\cdot}218$ grains. Hence we may find the weight of an equal bulk of vapor of the same temperature under any other given pressure, suppose 0·56 of an inch; for the density being directly as the pressure, we have 30 in. : 0·56 in. : : 257·218 grs. : 4·801 grs., which is the weight required.

Having thus explained the principle of the condensation hygrometer, we will now describe one or two of the forms under which it has been most frequently constructed. Daniell's hygrometer is represented in Fig. 2292: *a* and *b* are two thin glass balls of 1¼ inch diameter, connected together by a tube having a bore about ⅛ of an inch. The tube is bent at right angles over the two balls, and the arm *b c* contains a small thermometer *d e*, whose bulb, which should be of a lengthened form, descends into the ball *b*. This ball having been about two-thirds filled with ether, is heated over a lamp till the fluid boils, and the vapor issues from the capillary tube *f* which terminates the ball *a*. The vapor having expelled the air from both balls, the capillary tube is hermetically closed by the flame of a lamp. The other ball *a* is now to be covered with a piece of muslin. The stand *g h* is of brass, and the transverse socket *i* is made to hold the glass tube in the manner of a spring, allowing it to turn and be taken out with little difficulty. A small thermometer *k l* is inserted into the pillar of the stand. The manner of using the instrument is this: After having driven out all the ether into the ball *b* by the heat of the hand, it is to be placed at an open window, or out of doors, with the ball *b* so situated that the surface of the liquid may be on a level with the eye of the observer. A little ether is then to be dropped on the covered ball. Evaporation immediately takes place, which, producing cold upon the ball *a*, causes a rapid and continuous condensation of the ethereal vapor in the interior of the instrument. The consequent evaporation from the included ether produces a depression of temperature in the ball *b*, the degree of which is measured by the thermometer *d e*. This action is almost instantaneous, and the thermometer begins to fall in two seconds after the ether has been dropped. A depression of 30 to 40 degrees is easily produced, and the ether is sometimes observed to boil, and the thermometer to be driven below zero of Fahrenheit's scale. The artificial cold thus produced causes a condensation of the atmospheric vapor upon the ball *b*, which first makes its appearance in a thin ring of dew coincident with the

2292.



surface of the ether. The degree at which this takes place must be carefully noted. In very damp or windy weather the ether should be very slowly dropped upon the ball, otherwise the descent of the thermometer will be so rapid as to render it extremely difficult to be certain of the degree. In dry weather, on the contrary, the ball requires to be well wetted more than once, to produce the requisite degree of cold. (Daniell's Meteorological Essays.)

The instrument which has now been described is extremely beautiful in principle; but it may be doubted whether, even when the greatest caution is observed, the temperature which it indicates is precisely that at which the deposition of dew takes place. The deposition first occurs in a narrow ring on a level with the surface of the ether in the ball *b*, thereby indicating that the ether is colder at the surface than a little under it. But if the temperature is not uniform throughout the ball, it is evident that only a small part of the bulb of the thermometer can be placed in the point where the greatest cold exists; consequently, the temperature indicated by the thermometer will be greater than is necessary for producing the deposition of moisture: in other words, the dew-point will be given too high.

HYPERBOLA. A plane figure, formed by cutting a section from a cone by a plane parallel to its axis, or to any plane within the cone which passes through the cone's vertex.

The curve of the hyperbola is such, that the difference between the distances of any point in it from two given points is always equal to a given right line.

If the vertexes of two cones meet each other so that their axes form one continuous straight line, and the plane of the hyperbola cut from one of the cones be continued, it will cut the other cone, and form what is called the *opposite hyperbola*, *equal* and *similar* to the former; and the distance between the vertexes of the two hyperbolas is called the *major axis*, or *transverse* diameter. If the distance between a certain point within the hyperbola, called the *focus*, and any point in the curve, be subtracted from the distance of said point in the curve from the focus of the opposite hyperbola, the remainder will always be equal to a *given quantity*, that is, to the *major axis;* and the distance of either focus from the centre of the major axis is called the *eccentricity*. The line passing through the centre perpendicular to the major axis, and having the distance of its extremities from those of this axis equal to the eccentricity, is called the *minor axis*, or *conjugate diameter*. An *ordinate* to the major axis, a *double ordinate*, and an *absciss*, mean the same as the corresponding lines in the parabola.

HYPERBOLIC LOGARITHMS. A system of logarithms, so called because the numbers express the areas between the asymptote and curve of the hyperbola, those areas being limited by ordinates parallel to the other asymptote, and the ordinates decreasing in geometrical progression. But as such areas may be made to denote any system of logarithms whatever, the denomination is not correct. The hyperbolic logarithm of any number is to the common logarithm of the same number in the ratio of 2·30258509 to 1, or as 1 to ·43429448.

ICE. Water in a solid, crystallized state, owing to the abstraction of its combined heat. Its specific gravity, according to Dr. Thomson, is ·92. The force of expansion exerted by water in the act of freezing has been found irresistible in all mechanical experiments to prevent it. Advantage of this wonderful phenomenon is taken to burst bomb-shells, and other massive vessels, by filling them with water, plugging them up, and then exposing them to the frost. The effects of this expansive force are often observable by the bursting of trees, and the rending of rocks, attended with a noise resembling the explosion of confined gunpowder. Water, after being long kept boiling, affords an ice more solid, and with fewer air-bubbles, than that which is formed from unboiled water; also pure water, kept for a long time in vacuo, and afterwards frozen there, freezes much sooner than common water exposed to the same degree of cold in the open atmosphere; and the ice formed of water thus divested of its air, is much more hard, solid, heavy, and transparent, than common ice. Ice, after it is formed, continues to expand by decrease of temperature; to which fact is probably attributable the occasional splitting and breaking up of the ice of ponds during the time of freezing, and sometimes, independent of other causes, the separation of icebergs from the great frozen continent at the poles. According to Dr. Black, ice requires 147 degrees of heat to reduce it to a fluid.

The *thickness* of ice required for supporting foot-passengers is about two inches; for horsemen and light carts, four inches; and for heavy carriages, not less than six inches: also, if eight inches thick, 24-pounder guns on sleighs may pass over it, or any load not causing a greater pressure than 1000 lbs. per square foot on the surface, covered by the runners or skids on which it moves; and if the ice is weak, they may have balks secured by lashings to the tires of the wheels, for them to slide upon, so as to spread the weight over a larger surface, or lines of planks should be laid down for them to pass over.

Weak ice may be made capable of bearing even heavy loads in a very short time during frost, by spreading upon it layers of straw or brushwood crossing each other, and sprinkling them with water, so as to form a solid road when frozen; and if any portion of the river remains unfrozen from the rapidity of the current, it may be made to freeze by mooring trees and brushwood so as to float in it.

When the ice is too thin for walking upon it, a man may often skate over it, and ice-boats, similar to those used in Canada, might also be used for this purpose. They consist of a slight frame supported on three skates or runners, one of which serves as a rudder; and, provided with masts and sails, they tack like a ship, with great rapidity, directly to windward, and attain a velocity of twenty miles an hour with a fair wind.

Floating ice is very liable to destroy bridges; and its effects in rubbing against the piers, when propelled by a strong current, are amazing, tearing off the smallest projecting portions, even if of iron. To resist this, *ice-breakers* in front of the piers are indispensable; they consist of a frame supported on two rows of piles meeting each other, and forming a small angle against the current: the upper surface should be planked over, and should slope upwards from the water's edge towards the top of the pier so that the floating ice may rise over it, and thus break itself up, so as to pass harmlessly between the piers, which, if of piles or trestles, should be carefully planked over, to prevent the ice catching in them.

To *cross rivers* full of floating ice, very strong boats or canoes, cut out of entire trees, are required tc resist the pressure; they may be dragged over the floes (even if in motion) which are too solid to admit of breaking canals through them.

Small barriers of ice, or the *keys* of barriers interrupting the navigation, or causing an inundation, may be destroyed by turning streams of water against certain points, so as to melt an opening, or by means of charges of powder in casks or bags, fixed underneath or lodged in holes bored in the ice, and fired simultaneously. A charge of six pounds, placed in the centre of ice two feet thick, will break it up into small pieces throughout a circle of ten feet radius.

Ice and snow, well rammed together, form temporary parapets capable of even more resistance against shot than those of earth.

ICE-BOATS. There are many descriptions of boats which come under this denomination; namely, those that are designed to sail upon the surface of the ice, and those that are employed to open the navigation of frozen rivers or canals, by breaking up the ice. The first mentioned kind of boats is much used in Holland, on the river Maeze and the lake Y. These ice-boats are propelled, it is said, with incredible swiftness, sometimes so quick as to render respiration difficult; they are found very useful in conveying goods and passengers over lakes and great rivers in that country. For this purpose a boat is fixed transversely over a thick plank, or three-inch deal, under which, at the extremities, are fixed irons, turned up forwards, resembling and operating as skates; upon this board the boat rests, with its keel at right angles to it; and the extremities of the boards serve as out-riggers to prevent the boat from upsetting, whence, therefore, ropes are fastened that lead to the head of the mast, in the nature of shrouds, and others passed through a block across the bowsprit. The rudder is made somewhat like a hatchet, with the edge placed downwards, which, being pressed down, cuts the ice, and serves all the purposes of a rudder in the water, by enabling the helmsman to steer, tack, &c.

The other kind of ice-boat alluded to, is a strong and heavy-laden canal boat, fitted up for the purpose of breaking the ice, by arming the fore-part of the keel and the bows with iron, which penetrate and break down the ice as the boat is drawn forcibly along by an adequate number of horses towing it on the path. This measure of opening the navigation of a canal is seldom adopted, except when the ice is only a few inches in thickness, or when a thaw has rendered thicker ice of little tenacity.

ICE-HOUSE. A repository for ice during the summer season. In America and other places ice is kept in deep cellars, from which the external air is excluded as much as possible, and provided with drains to keep them dry. When the surrounding soil is moist, a frame-work or case of carpentry is constructed, having a grating at bottom, and is so placed in the cellar as to be two or more feet distant from the floor, sides, and roof of the cellar. In this the ice is said to be as perfectly preserved as in a dry cellar. Some market-gardeners preserve ice in great heaps, by merely building it upon an elevated base in the open garden, and covering it over and around by a very thick stratum of straw or reeds. This plan of preserving ice is in accordance with Mr. Cobbett's recommendation in his *Cottage Economy*, wherein he observes that "an ice-house should not be underground, nor shaded by trees, but be exposed to the sun and air;" that its bed should be three feet above the level of the ground, and composed of something that will admit of the drippings flowing instantly off; and he adds, that "with some poles and straw, a Virginian will construct an ice-house for ten dollars, worth a dozen of those which cost the man of taste in England as many scores of pounds." The ice-houses built by the Virginians consist of an inner shed, surrounded by an outer one, and having a sufficient vacant space between the two to enable a person to walk round; the walls and roofs of both the sheds are made of thatch, laid on about a foot thick; and the ice is deposited in the inner shed on a bed of straw. In England and France, the common form of ice-houses is that of an inverted cone, or rather of a hen's egg, with the broad end uppermost. The situation of an ice-house should be dry, as moisture has a tendency to dissolve the ice; it should also be so elevated that water may freely run off. It should be exposed to the sun and air, not under the drip, or in the shade of trees, in order that the external deposit of moisture may be readily evaporated. The form of the building may be varied according to circumstances; but in the well or receptacle for the ice, it is desirable to have sufficient room for the deposit of two or three years' consumption, as a provision against mild winters. Where the situation is of a dry, chalky, gravelly, or sandy kind, the pit may be entirely below the surface of the ground; in which case, an ice-house on the following plan may be advantageously introduced.

Dig a pit of about twelve feet deep, and wide enough to permit the erection therein of a frame of rough wood posts. This frame is to be fourteen feet wide each way at the bottom, and sixteen feet each way at the top. The posts may be about nine inches in diameter, placed near enough to each other for thin laths to be nailed upon them, and the inside be dressed to an acute angle, so that as little wood as possible may touch the ice. On the inside let thin laths be nailed at about two feet apart. On the outside, at moderate distances, nail rough boards, and fill the place within with wheat or rye straw set on end. The inside of the roof to be made in the same way, and also the gables. Straw is to be sewed on the inside, and heath or straw on the outside of the door. The outside of the roof is to be thickly thatched with straw or heath; and heath, brushwood, or fir-tops, to be filled in between the outside boarding and the surrounding ground, and then neatly thatched or turfed over. The bottom of the house, for two feet deep, should be laid with large logs or stones, next with heath, fir-tops, or brushwood, and then with straw. The ice-house, thus completed, will look like a square beehive inverted, and is then ready to receive the ice or snow. But, unless the house be in a very shady place, it may be necessary to extend the roof, where the door is placed, five or six feet, making a second gable and door, finished in the same way as the first, and fill up the intervening space, except a passage, with heath or straw.

Mode of filling the house.—When the ice (or snow, if ice cannot be procured,) is put into the house, it must be well beaten down with a pavior's rammer, or mallet, and the surface *always kept concave*, as by this means any snow or ice that may melt will run to the middle, or interstices, and freeze. For the same reason, the ice ought always to be kept concave when it is taken out for use. Should the

frost be very intense when the ice-house is getting filled, it may be very beneficial at the close of each day's filling to throw in thirty or forty pails of water, which will fill the interstices and freeze. When the house is full, spread upon the concave surface a carpet, or sail split up in the middle, and upon the top thereof a foot thick of water When ice is required for the use of the family, or when it is necessary to put in fresh meat to lie on the face of the ice for preservation, or to take out for use, the straw and carpet, or sail, is to be opened in the middle. Should rats infest the place, an iron-wire frame or case may be required to put the meat or fish, &c., into when lying on the ice. A small open surface-drain ought to be dug round the house, to prevent any water running into it. Opening the door of the house does little harm. Damp or dense substances touching the ice are much more prejudicial than dry air.

ICE-SAWS. Large saws used for cutting through the ice, for relieving ships when frozen up. The vessels employed in the Greenland fisheries, and others that navigate the polar seas, are regularly furnished with these machines, as the lives of the crew not unfrequently depend on the expedition with which a passage can be cut, so as to disengage the vessel before the further accumulation of ice renders it an impossible undertaking. The saw, with a weight suspended to it, is introduced by means of a hole broken through the ice, and is suspended by a rope passed over a pulley fixed to a triangle. A party of a dozen or more men run out and back again with a rope, and thus move the saw up and down till it has cut its way so far as to hang perpendicularly from the pulley. The triangle is then moved a foot or two further, and the sawing recommences, the services of the whole crew being required in this laborious undertaking.

In Hood's machine, the saw is suspended by a slight sledge, and is worked by the power of only two or three men at the end of a lever; a bar, called a propeller, is fixed on the lever between the fulcrum and the saw, the other end resting on the surface of the ice, and so adjusted that each motion of the lever shall produce a cut of a given length, and at the same time, by means of the propeller, push the sledge on, so that the teeth of the saw shall always be in contact with the ice.

2293.

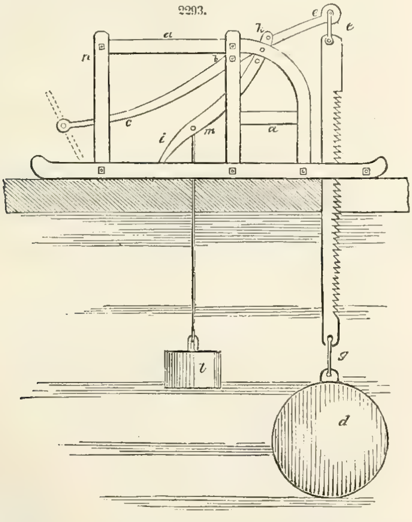


Fig. 2293 gives a side elevation of the machine. *a a a* is a sledge, of open frame-work, resting on the surface of the ice; *b* a transverse bar passing through the lever *c c*, and forming the fulcrum on which it moves; this lever has a cross-handle, as represented in perspective in dotted lines; *e* a clamp or brace consisting of two cheeks, one on each side of the lever, loosely pinned at top to the lever, and at bottom to the saw *f*; *g* a clamp similar to *e*, by which the weight *d* (which is of the shape of a double convex lens) is hung to the lower end of the saw; *i* the propeller, an iron bar, terminating below in two claws, and at top in a fork, and suspended on the lever by means of a transverse pin *k*; *l* a weight hung to the propeller at *m*; *n* a transverse bar, limiting the motion of the handle-end of the lever in an upward direction. It should be understood that there is a duplicate frame similar to that brought into view, on the other side of the machine, about 18 inches apart, and connected by transverse bars. To prevent the lever from swerving laterally, there are at the handle ends two upright bars, between which the lever moves. The saw, after having once entered the ice, will only require from two to four men to work it; and it should not be taken out of the ice till after the distance required to be cut through is accomplished. The saw can be guided by the lever in any direction, so as to cut the ice into

pieces most convenient for removal, either by pushing them under the adjacent floor of ice, or by dragging them out of the ship's track into clear water.

ICE-TRADE. The ice-trade of the United States was commenced by Frederic Tudor, of Boston, in 1805. The first enterprise resulted in a loss, but was, nevertheless, followed up until the embargo and war put an end to the foreign trade, at which period it had yielded no profit to its projector. After the close of the war, in 1815, Mr. Tudor recommenced his operations by shipments to Havana under a contract with the government of Cuba, which enabled him to pursue his undertaking without loss, and extend it, in 1817, to Charleston, S. C.; in the following year to Savannah, Ga.; and in 1820 to New Orleans. On the 18th May, 1833, the first shipment of ice was made to the East Indies, by Mr. Tudor, and since that period he has extended his operations to Madras and Bombay.

Previously to 1832 the trade had been chiefly confined to the operations of the original projector, although several enterprises had been undertaken by other persons and abandoned. The increase of shipments to this period had been small, the whole amounting, in 1832, to 4352 tons, which was taken entirely from Fresh Pond, in Cambridge, and shipped by Mr. Tudor, who was then alone in the trade. Up to this time the ice business was of a very complicated nature. Ship-owners objected to receive it on freight, fearing its effect on the durability of their vessels and the safety of voyages; ice-houses abroad and at home were required, and the proper mode of constructing them was to be ascertained. The best modes of preparing ships to receive cargoes were the subject of expensive and almost endless experiments. The machines to cut and prepare ice for shipping and storing, and to perform the operations of hoisting it into storehouses and lowering it into the holds of vessels, were all to be invented, involving much expense and vexation. Many of these difficulties have now been overcome, and since 1832 the trade has increased much, and appears destined to a still more rapid increase for some years. It has also been divided among many parties, and its methods have been further improved and a knowledge of them more widely diffused.

The ice has been chiefly taken from Fresh and Spy Ponds, and since 1841 mainly transported on the Charlestown Branch Railroad, which was constructed for that purpose. Quite recently, ice establishments have been made at most of the ponds near Boston, and it is probable that in a few years the product of all these waters may be required to supply the trade. In the year 1839 the great quantity of ice cut at Fresh Pond, and the consequent difficulties which had arisen among the proprietors as to where each should take ice, induced them to agree to distinct boundary lines, which were settled by three commissioners, on the principle of giving to each the same proportion of contiguous surface of the lake, as the length of his shore-line was to its whole border.

The shipments of ice from Boston coastwise, for the year ending December 31, 1847, amounted to 51,887 tons. The ice shipped to foreign ports during the same period amounted to 22,591 tons.

The freight paid during this year is supposed to have averaged as high as \$2.50 per ton, at which rate it would amount, on the 74,478 tons shipped abroad and coastwise, to	\$186,195
There is a great variation in the cost of securing ice and stowing it on board vessels, caused by winters favorable or otherwise for securing it, and by the greater or less expense of the fittings required for voyages of different duration, or by difference of season when the shipments are made. Taking all these contingencies into consideration, the cost of ice when stowed on board may be estimated to average \$2 per ton, which would give for the quantity shipped	148,956
There were in 1847 upwards of 29 cargoes of provisions, fruits, and vegetables shipped in ice to ports where otherwise such articles could not be sent, the invoiced cost of which, at Boston, would average about \$2,500 each	72,500
To these items may be added the profits of the trade to those engaged in it	100,000
Total returns	\$507,651

The methods and materials for preparing vessels for the transportation of ice have been various. Formerly their holds were ceiled up at the sides, bottom, and top, with boards nailed to joist-ribs secured to the side of the vessel, and with double bulkheads forward and aft. The spaces thus formed were filled with refuse tan, rice-hulls, meadow-hay, straw, wood-shavings, or like materials. These spaces were made of a thickness proportionate to the length of the voyage, and with reference to the season. The immediate surface of the ice was covered with the same materials, excepting tan. At the present time sawdust is used almost exclusively for voyages of considerable length. It is placed immediately between the ice and the side of the vessel. This material is obtained from the State of Maine, and before its use for this purpose was entirely wasted at the water-mills, and, falling into the streams, occasioned serious obstructions. During the year 1847, 4600 cords were brought to Boston, at an average value of \$2.50 per cord, delivered.

Almost the whole value of the returns of the ice-trade, including freight, are a gain to this country. The ice itself, the labor expended on it, the materials for its preservation, and the means of its transportation, would be worthless if the trade did not exist.

Ice being shipped and used at all seasons, large storehouses are required to preserve it. Exclusiv of ice-houses on the wharves at Charlestown and East Boston, in which ice is stored for short periods there had been erected in 1847, and previously—

At Fresh Pond, in Cambridge, ice-houses capable of containing	86,732	tons.
At Spy Pond, in West Cambridge	28,000	"
At Little Pond	2,400	"
At Wenham Pond	18,000	"
At Medford Pond	4,000	"
At Eel Pond, in Malden	2,000	"
At Horn Pond, in Woburn	4,000	"
At Sumner's Pond	1,200	"
Total	141,332	tons.

The ice-houses now in use are built above ground. In southern countries, where ice is most valuable, they are constructed at greater expense, usually of brick or stone, and the protection to the ice consists in air-spaces, or in dry, light vegetable substances inclosed between two walls. In this vicinity, on the borders of the lakes, where ice is least valuable, they are usually built of wood, in which case they are of two walls, formed by placing two ranges of joist upright, framed into plates at the top, and placed in the ground at the bottom, or framed into sills; these two ranges are ceiled with boards secured to that side of each range which is nearest the other, and the space between the two boardings filled with refuse tan, wet from the yards. This wet tan is frozen during the winter, and until it is thawed in the spring and summer, little waste occurs; afterwards the waste is more rapid; but, as a large portion of the ice is shipped or otherwise used before this takes place, the loss in quantity is small, and, occurring before the expenses of transportation have been paid, is of less pecuniary moment.

In one instance brick has been used in the construction of an ice-house, which covers 36,000 feet of land, and the vaults of this ice-house are 40 feet in depth, and its walls are four feet thick from outside to inside, inclosing two sets of air-spaces. Such a construction is more costly, but has the advantage of durability and safety from fire, to which ice-houses are much exposed from the frequent juxtaposition of railroad-engines, and the light, dry materials used about them to cover and otherwise preserve ice.

In the winter of 1847, about $650 were paid daily for labor of men, and $230 for that of horses, when the weather was most favorable for cutting ice. Such activity is, however, of short duration, as there are not generally more than 20 days in a season which are really favorable to the operation of securing ice. The price paid is usually $1 per day for horses and men.

At first the implements of husbandry only were used in securing ice; but as the trade became more important, other machines and different methods were adopted, and abandoned when better were brought forward, or when the increased magnitude of the business required greater facilities. More ice is now secured in one favorable day than would have supplied the whole trade in 1832. Ordinarily, before there has been cold enough to form ice of suitable thickness, snows fall on its surface. If this occurs when the ice is four or more inches in thickness, and the snow not heavy enough to sink the ice, it can be removed by using horses attached to the "snow-scraper;" and under such circumstances this is the method in common use. But if snow falls so heavy as to bring the water above the surface of the ice, it is removed, after it has congealed into snow-ice, with the "ice-plane."

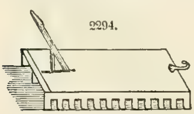
These preliminary expenses are often very great; frequently, after much expense has been incurred to remove a body of snow or snow-ice, the weather becomes warm, and spoils the ice on which so much has been expended. And, on the other hand, if it is not done, and the cold continues, there will be little or no increase of thickness to the ice, which is equally a disaster.

When the ice is made up for transportation, it is employed in ships as ballast, for which purpose it is carefully cut up into blocks to fit the hold, and covered with sawdust, straw, and charcoal dust, all non conductors of heat, under cover of which it is conveyed on the voyage. When the ice is regularly shipped as cargo, being cut into blocks, it is packed on board the vessel, in thin air-tight boxes, with straw and hay. In this manner it is conveyed without loss.

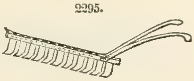
The machinery employed for cutting the ice is worked by men and horses in the following manner:—

From the time when the ice first forms, it is carefully kept free from snow until it is thick enough to be cut; that process commences when the ice is a foot thick. A surface of some two acres is then selected, which at that thickness will furnish about 2000 tons; and a straight line is then drawn through its centre, from side to side each way. A small hand-plough is pushed along one of these lines, until the groove is about three inches deep and a quarter of an inch in width, when the "marker," Fig. 2294, is introduced. This implement is drawn by two horses, and makes two new grooves, parallel with the first, 21 inches apart, the gage remaining in the original groove. The marker is then shifted to the outside groove, and makes two more. Having drawn these lines over the whole surface in one direction, the same process is repeated in a transverse direction, marking all the ice out into squares of 21 inches. In the mean time, the "plough," Fig. 2295, drawn by a single horse, is following in these grooves, cutting the ice to a depth of six inches.

2294.



2295.



2296.

One entire range of blocks is then cut out with the "ice-saw," Fig. 2296, and the remainder are split off towards the opening thus made with an iron bar. This bar, represented in Fig. 2297, is shaped like a spade, and is of a wedge-like form. When it is dropped into the groove, the block splits off; a very slight blow being sufficient to produce that effect, especially in very cold weather. The labor of "splitting" is slight or otherwise, according to the temperature of the atmosphere. "Platforms," or low tables of frame-work, are placed near the opening made in the ice, with iron slides extending into the water, and a man stands on each side of this slide armed with an "ice-hook." With this hook, Fig. 2298, the ice is caught, and by a sudden jerk thrown up the "slide" on to the "platform." In a cold day every thing is speedily covered with ice by the freezing of the water on the platforms, slides, &c., and the enormous blocks of ice, weighing, some of them, more than 200 pounds, are hurled along these slippery surfaces as if they were without weight. Beside this platform stands a "sled" of the same height, capable of containing about three tons, which, when loaded, is drawn upon the ice to the front of the storehouse, where a large stationary platform, of exactly the same height, is ready to receive its load, which, as soon as discharged, is hoisted, block by block, into the house, by horse-power. This process of hoisting is so judiciously managed, that both the taking up of the ice and the throwing it into the

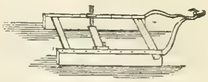
building are performed by the horse himself. The frame which receives the block of ice to be hoisted is sunk into a square opening cut in the stationary platform, the block of ice is pushed on to it, the horse starts, and the frame rises with the ice until it reaches the opening in the side of the storehouse ready for its reception, when, by an ingenious piece of mechanism, it discharges itself into the building, and the horse is led back to repeat the process.

Forty men and twelve horses will cut and stow away 400 tons a day. In favorable weather 100 men are sometimes employed at once. When a thaw or a fall of rain occurs, it entirely unfits the ice for market, by rendering it opaque and porous; and occasionally snow is immediately followed by rain, and that again by frost, forming *snow-ice*, which is valueless, and must be removed by the "plane."

2297.

2298.

2299.



The operation of planing is somewhat similar to that of cutting. A plane, Fig. 2299, gaged to run in the grooves made by the marker, and which shaves the ice to the depth of three inches, is drawn by a horse until the whole surface of the ice is planed. The chips thus produced are then scraped off, and if the clear ice is not reached, the process is repeated. If this makes the ice too thin for cutting, it is left *in statu quo*, and a few nights of hard frost will add *below* as much as has been taken off *above*.

In addition to filling their ice-houses at the lake and in the large towns, the company fill a large number of private ice-houses during the winter—all the ice for these purposes being transported by railway. It will be easily believed that the expense of providing tools, building houses, furnishing labor, and constructing and keeping up the railway, is very great, but the traffic is so extensive, and the management of the trade so good, that the ice can be furnished at a very trifling cost.

ICOSAHEDRON, or ICOSAEDRON, in geometry, one of the regular platonic bodies, comprehended under twenty equal triangular sides or faces. It is formed of twenty pyramids, whose bases are the twenty equal and equilateral triangles, the summits of which terminate in the centre of the body.

Let S represent the side; then will surface $= 5\,S^2 \sqrt{3} = 8{\cdot}66025403\,S^2$, and solidity $= \frac{5}{6} S^3 \frac{7 + 3\sqrt{5}}{2} = 2{\cdot}1816950\,S^3$.

ILLUMINATION. Without entering minutely into the subject, it is evident that the value of any means of illumination must depend upon two things—namely, upon the *quantity of light* evolved, and upon the *consumption of lighting material* which accompanies it. A candle, or a lamp, &c., will be the more valuable, the more light it gives from as little tallow or oil as possible. Light cannot be measured with reference to its quantity any more than heat; it cannot be estimated how much light a flame emits, but it can be scientifically ascertained how much more or less light it evolves, than another flame.

All determinations of this nature are, therefore, comparative. The most casual observation of two flames, for example, that of a candle and of gas, shows the one, although both are of equal size, to be infinitely brighter than the other.

The dissemination of light is entirely effected by radiation; the intensity may, therefore, be said to express the sum of the rays which are emitted to a certain surface, for example, to a square foot. It is evident, that the sum must be diminished by the distance from the source, as the rays separate more and more from each other. According to the laws of optics, the intensity is in relation to the square of the distance; when, therefore, a surface is illumined to the same extent by two flames, the rays of light from each will be proportional to the square of the distance at which each flame must be placed in order to produce an equal amount of light. It is upon this principle that the actual determination of the intensities and quantities of light depends; the measure for both is, therefore, the distance to which the flames to be compared must be brought, in order to produce an equal amount of light. (See PHOTOMETER, in article GAS.) Practically, however, it is not possible to determine, even approximatively, the degree of brilliancy; the degree of light is therefore not observed, but its negation, the *shadow*.

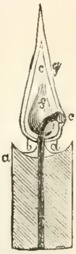
In such experiments a board is used, covered with unglazed white paper, before which, at a distance of from two to three inches, an iron rod is placed, which has been previously blackened by holding it in the candle. Opposite this board, but at the same height, the flames to be compared are so placed that both the shadows (for each throws a shadow) fall close to each other upon the board, and then the stronger flame is so far removed, or the weaker one approached, until both shadows appear equally deep, and lastly, their respective distances from the centres of the flames are measured. The squares of these distances give the relative intensities of light; if a flame, for example, has been three times as far removed as another, its intensity will be to that of the latter, as 3^2 to $1^2 = 9 : 1 = 1 : 9$, or 9 times greater. As such observations are simultaneous, and of like duration, they give likewise the relative quantities of light; for unequal lengths of time, this has only to be multiplied with the respective duration. When one of these flames, therefore, burns 3 hours, and the other only 2, then the quantities of light evolved will be in the proportion, $3 \times 9 : 2 \times 1$ or $27 : 2$.

One circumstance in particular requires notice: that when two perfectly similar shadows of this kind are observed from one side, the one appears brighter than the other, and the same is the case, the order only being reversed, when they are observed from the other side; so that the rule is, to observe them always from a position exactly opposite the board. Practice is here the best guide in forming rules.

The usual dimensions of a candle are not fixed arbitrarily or by chance, but are absolutely necessary to a well-regulated process of combustion. If the wick is too large in proportion to the surrounding mass of fat, as is the case in tapers, no reservoir is then formed, and all the advantages attending it are lost. In the opposite case, which applies to all common candles, the wick which is rather too small produces a flame, whilst the outermost layer of fat is beyond the sphere in which fusion is going on.

A thin ring-shaped wall, as is easily observed in the less fusible stearine candles, remains erect up to a certain height, and is very objectionable from the shadow which it throws, but more so from its being gradually undermined and falling into the reservoir, which it overfills and causes the candle to gutter. When it has once overflowed, the evil is doubled, for all the fat which, by overflowing, has formed ridges, is still further removed from the region of the flame. In night lights, made of stearine or wax, where intensity of light is a secondary consideration, this circumstance has been turned to account. These are made with a common-sized wick, but a disproportionate thickness of fat, so that a very deep and full reservoir is formed; an excess therefore of melted fat, which, as too much of the free part of the wick remains immersed, causes them to give a very small quantity of light. For the sake of safety, they are made so short that they will swim upright upon a basin of water. Several periods must be distinguished in the whole course of the process which is going on in a lighted candle. The heat generated by the flame, and for the greater part carried upwards by the current of air, acts however by radiation to such a degree downwards, that sufficient or rather too much fat is melted, for supplying food to the flame. The fat is supplied directly by the wick, the capillarity of which is constantly at work, sucking up the fluid matter, and carrying it to the sphere of combustion. The lower uncharred portion of the wick (up to *d*, Fig. 2300) acts the part of a sucking-pump; the decomposition takes place in the entire upper black portion: the fat, which arrives there, is immediately exposed to a high temperature, without being able to come into direct contact with the air; it is in the same position as if it were inclosed in an iron retort between red-hot coals, and it suffers, consequently, dry distillation. The gaseous and vaporous combustible products form the dark nucleus *f* of the flame, between which and the surrounding air, the sphere of successive combustion is situated. The air streaming from below upwards, to the gases in *f*, consumes in the first instance the hydrogen, and separates the carbon as incandescent soot; this occurs in the luminous part of the flame *i*. Lastly, on the outside, in the hardly perceptible bluish halo *g*, the carbon is consumed; this occurs chiefly at the base, which does not appear luminous, in consequence of the air exerting its full influence at that part.

2300.



Every portion of tallow, which burns and gives out light, prepares the following portion for undergoing the same process. The different states of the flame may be partially made visible by an interesting experiment that is easy of execution. If a bottle is filled with water, and supplied through the cork with a siphon in a downward direction, and a tube drawn out to a point in an upward direction, and this point be brought into the interior of the flame whilst the water is allowed to run slowly from the siphon, the bottle becomes filled with the combustible vapors in the form of a gray smoke. The vapors obtained from a stearine candle condense, for the most part, to a dry, solid, fatty acid; not so those from oil or tallow. On blowing with the mouth, these vapors may be expelled from the bottle, and they burn, when ignited, with a distinct flame, which is but slightly luminous, in consequence of the admixture of air. The experiment may be made without danger with a common pipe, and by suction with the mouth. The importance of using hard, solid tallow, to prevent guttering, is obvious, and all the materials should likewise be as pure as possible; for whatever is not decomposed in the same manner as tallow, or wax, will obstruct the capillary tubes of the wick.

It is not remarkable from the nature of candles and the mode in which they disseminate light, that their intensity and consequent power of illumination, even under the same circumstances, should be so very variable. In the beginning, when the wick is freshly snuffed, this variation is comparatively slight, and the intensity increases up to a certain point, when, from an excessive length of snuff, deposit of spongy matter, &c., it constantly diminishes, until the candle is again snuffed or the deposit burnt, and then the process is repeated. Peclet found (by comparison with Carcel's lamp) that the primary intensity of a candle = 100, (6 = 1 lb.,) became in 4 minutes 92, in 8 minutes 50, in 10 minutes 41, in 12 minutes 38, in 15 minutes 34, in 20 minutes 32, in 22 minutes 25, in 24 minutes 20, in 28 minutes 19, in 30 minutes 17, and in 40 minutes 14. Another candle, (5 to the lb.,) diminished from its original intensity, = 100, in 5 minutes to 76, in 10 to 55, in 15 to 44, in 20 to 39, in 25 to 32, in 30 to 30, in 35 to 24, and lastly, in 40 minutes to 15. Less than half an hour, therefore, is sufficient to reduce the light from a candle to $\frac{1}{7}$ of its original brilliancy. The same diminution was the result of Rumford's observations, namely, $\frac{1}{6}$ after 29 minutes. When, below, the intensity of candles is compared with Carcel's lamp, the mean intensity of 10 minutes' duration in tallow candles is to be understood, which is about the usual time suffered to elapse between each snuffing; in stearine, wax, and spermaceti candles, however, the highest intensity is taken, which occurs when the wick, without any deposition of snuff, has begun to emerge from the flame.

It has already been pointed out, that all determinations of the illuminating power are entirely relative, and hence arises the demand for a suitable point of comparison.

The flame of Carcel's clock-work lamp (see LAMPS) is of such very uniform brilliancy, remaining unimpaired for several hours after it has been ignited, that lamps, candles, and gas, are very generally compared with it. On comparing two exactly similar lamps of this kind in such a manner, that one was kept constantly burning, whilst the other was freshly ignited for each observation, it was found that the brilliancy which in the beginning was 100, increased in half an hour to 103; in one hour to 116, and in four hours to 117, which it then retained for four consecutive hours

(See Lamps, Light.)

IMPACT. The single instantaneous blow or stroke communicated from one body, in motion, to another, either in motion or at rest.

IMPENETRABILITY. In physics, one of the essential properties of matter, or body. It is a property inferred from invariable experience, and resting on this incontrovertible fact, that no two bodies can occupy the same portion of space in the same instant of time. Impenetrability, as respects solid bodies, requires no proof; it is obvious to the touch. With regard to liquids, the property may be proved by very simple experiments. Let a vessel be filled to the brim with water, and a solid incapable of solution in water be plunged into it; a portion of the water will overflow exactly equal in bulk to the body immersed. If a cork be rammed hard into the neck of a vial full of water, the vial will burst, while its neck remains entire. The disposition of air to resist penetration may be illustrated in the following way: Let a tall glass vessel be nearly filled with water, on the surface of which a lighted taper is set to float. If over this glass a smaller cylindrical vessel, likewise of glass, be inverted and pressed downwards, the contained air maintaining its place, the internal body of the water will descend, while the rest will rise up at the sides, and the taper will continue to burn for some seconds, encompassed by the whole mass of liquid.

IMPETUS. The product of the mass and velocity of a moving body, considered as instantaneous, in distinction from *momentum*, with reference to time, and *force*, with reference to capacity of continuing its motion. *Impetus*, in gunnery, is the altitude through which a heavy body must fall to acquire a velocity equal to that with which the ball is discharged from the piece.

INCIDENCE, in mechanics, is used to denote the direction in which a body, or ray of light, strikes another body, and is otherwise called inclination. In moving bodies their incidence is said to be perpendicular or oblique, according as their lines of motion make a straight line or an angle, at the point of contact.

Angle of incidence, generally denotes the angle formed by the line of incidence, and a perpendicular drawn from the point of contact to a plane or surface on which the body or ray impinges.

Thus if a body impinges on the plane at a point, and a perpendicular be drawn, then the angle made by this perpendicular and the incident ray is generally called the angle of incidence, and the complement of this the angle of inclination.

When light, or any elastic body, is reflected from a surface, the angle of incidence is equal to the

angle of reflection; and in the case of refraction, the sine of the angle of incidence has to the sine of the angle of refraction a constant ratio.

INCLINATION, denotes the mutual approach or tendency of two bodies, lines, or planes, towards each other, so that the lines of their direction make at the point of contact an angle of greater or less magnitude.

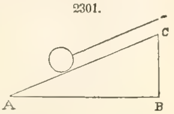
INCLINED PLANE. One of the mechanical powers: a plane which forms an angle with the horizon. The force which accelerates the motion of a heavy body on an inclined plane, is to the force of gravity, as the sine of the inclination of the plane to the radius, or as the height of the plane to its length. If $f =$ force accelerating the body on an inclined plane, of which the inclination is i, and if $g =$ force of gravity, $f = g$ sine i. Hence the motion of a body on an inclined plane, is a motion uniformly accelerated.

If two bodies begin to descend from rest, and from the same point, the one on an inclined plane and the other falling freely to the ground, their velocities at all equal heights above the surface will be equal. Hence the velocity acquired by a body in falling from rest through a given height is the same, whether it fall freely, or descend on a plane any how inclined. The space through which a body will descend on an inclined plane, is to the space through which it would fall freely in the same time, as the sine of the inclination of the plane to the radius.

When a power acts on a body, on an inclined plane, so as to keep that body at rest, then the weight, the power, and the pressure on the plane, will be as the length, the height, and the base of the plane, when the power acts parallel to the inclined surface; that is,

If the weight be measured by A C,
The power will be measured by B C,
And the pressure on the plane A B.

2301.



These properties give rise to the following rules:—

$$\text{power} = \frac{\text{weight} \times \text{height of plane}}{\text{length of plane}}$$

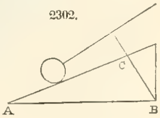
$$\text{weight} = \frac{\text{power} \times \text{length of plane}}{\text{height of plane}}$$

$$\text{pressure on the plane} = \frac{\text{weight} \times \text{base of plane}}{\text{length of plane}}$$

These rules express the conditions of equilibrium, and it is obvious, that if either the weight or the power be increased, (friction excepted,) motion of the body must ensue.

When the power does not act parallel to the plane, the conditions of equilibrium may be found thus: Draw a line perpendicular to the direction of the power's action; the weight, power, and pressure on the plane, will be as A C, C B, A B.

2302.



When the line of direction of the power is parallel to the plane, the power is least.

If two bodies, on two inclined planes, sustain each other by means of a string over a pulley, their weights will be inversely as the lengths of the planes.

The space which a body descends upon an inclined plane, when descending on the plane by the force of gravity, is to the space which it would fall freely in the same time, as the height is to the length of the plane; and the spaces being the same, the times will be inversely in that proportion.

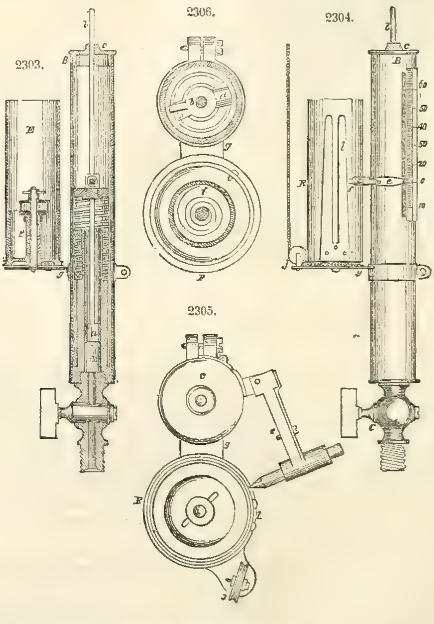
INDICATORS. The important and useful little instrument which we have represented in the following figures has very materially contributed to the perfection and efficiency of our modern steam-engines; not only by enabling the engineer to ascertain and register the exact values of the forces from which its power is derived, at the point where these forces come into effective operation, but also by pointing out the precise periods, in relation to the different parts of the stroke, at which these elements of power come into action, and thereby conducing to the most economical and perfect combination of them. By its use he is introduced, as it were, into the interior of his engine, and is made cognizant of its most occult and delicate movements.

The idea embodied in this ingenious and beautiful instrument was originated by the justly celebrated James Watt, who, at a very early period in the history of the steam-engine, employed a machine identical in the principle of its operation, though less compact in form than that now so extensively in use. His object was to ascertain with certainty the mean steam pressure, and, more particularly, the proportion which the vacuum in the cylinder bore, at different parts of the stroke, to that in the condenser, in order to determine the dimensions of cylinder required for any given power, as also the relative proportions proper to be given to the steam and exhaust ports, &c. Having attained these objects, and given to the world so many imperishable monuments of his genius, succeeding mechanicians seem to have despised the unpretending little instrument by whose assistance he had been led to such splendid results, and, during the space of nearly half a century, to have trusted implicitly, in the construction of their engines, either to the absolute accuracy of Watt's data, or of their own theoretical deductions, in many cases extremely fallacious. From this state of oblivion, the indicator has been, at a comparatively recent period, rescued by the late Mr. Macnaught, of Glasgow, who has greatly improved its construction, and put it into such a compact and portable form as to be easily applicable to steam-engines of every description. Its consequent general adoption has led to some notable improvements, and materially elevated the standard of *duty* in steam-engines; it has demonstrated the economy resulting from a liberal use of the expansive power of the steam, and the great advantage attendant upon a more rapid and complete exhaustion than could be attained by the arrangement of slide-valve previously employed.

Macnaught's Indicators.—The figure comprised under this head represents the form of the indicator as at present constructed by Mr. William Macnaught, being that employed to measure the power of high-pressure engines, and is also adapted to those in which steam of a tension not greatly exceeding that of the atmosphere is employed. The two instruments differ in no respect from each other in the principle of their action, and but little in the details of their construction; accordingly one description will suffice for both, in the course of which we shall notice the points in which each respectively differs from the other. The figures are to a scale of ½ of an inch to an inch.

General description.—From a glance at the drawings it will be at once perceived that the indicator is neither more nor less than a small atmospheric steam-engine, with the addition of a spiral spring and graduated scale to mark the degrees of pressure. The steam-cylinder A, Fig. 2303, is of gun-metal, very accurately bored out and fitted with a solid piston *a*, ground into the cylinder so as to be perfectly steam-tight. A slender steel rod *b b* is screwed into the piston, and is guided at its upper extremity by passing through the cover *c* of an external brass casing or cylinder B, screwed to the lower end of the steam-cylinder. At this point is also fixed a stop-cock C, destined to form a communication between the cylinder of the steam-engine and that of the indicator; in the high-pressure indicator this cock is formed with a screw at its lower end, for the purpose of attaching it to the socket-cock, which is permanently fixed to the cylinder cover, while, in the instrument as adapted to low-pressure engines, this attachment is considered to be sufficiently secure by the more convenient method of simply inserting the tapered end of the cock C into a corresponding socket accurately ground to fit it.

2306. 2304. 2303. 2305.



Towards the middle of the piston-rod *b b* a small stud *d* is fixed immovably by soldering, and to it is screwed a brass disk, having the end of a spiral spring D soldered into it. The opposite extremity of this spring is secured, in the case of the high-pressure indicator, to the steam-cylinder, and in that used for condensing engines, to the cover of the external casing. This difference in the arrangement of the springs is owing to the difference in the prevailing directions of the motion of the piston *a*, in either case; it being considered most expedient to make the springs act by distension, rather than by compression. In the stud is a small square socket, into which, through a slot or opening in the external casing B, is inserted a steel piece, part of which is formed into an index or pointer, adapted to work against an adjustable graduated scale, screwed to the outside of the casing B, Fig. 2304.

Figs. 2305 and 2306 represent plans of 2303 and 2304 respectively.

The principle on which the strength of the springs is regulated and the scales are graduated is as follows: The area of the piston, the resistance of the spring, and the divisions upon the scale, are so proportioned to each other that one pound of pressure in either direction upon the piston will cause the index to move through one division upon the scale. In the high-pressure indicator, although the size of

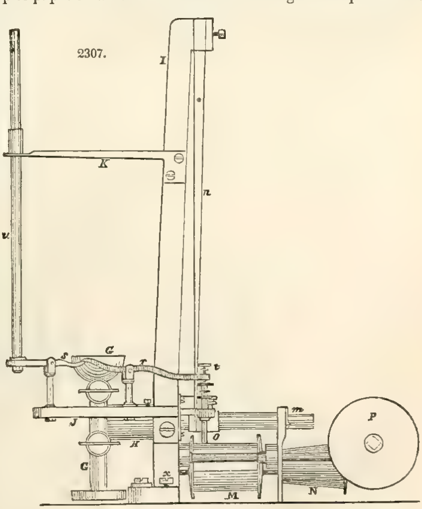
the piston is invariable, (being uniformly made equal to $\frac{1}{8}$ of a square inch in area,) the length of the divisions upon the scale is arbitrary, being determined by the amount of steam pressure to which the machine may at any time be subjected, and by the length of scale that can conveniently be applied. The instrument represented in the figures is adapted to indicate up to 60 pounds of pressure, and the scale is equally divided into 20ths of an inch, each of these divisions representing one pound of pressure upon the square inch of the piston. From these data the spring is to be very carefully constructed, so that 2 ounces (or $\frac{1}{8}$ of a pound) will move the index through one division of the scale.

In the low-pressure indicator the process is precisely the same in principle, though somewhat less involved. The tension of the steam being low, and the atmospheric pressure limited within 15 pounds to the square inch, the scale is divided into 10ths of an inch. The piston is made equal to $\frac{1}{4}$ of a square inch in area, and the elasticity of the spring is such that 4 ounces (or $\frac{1}{4}$ of a pound) acting upon the piston in either direction, will cause the index to move through one division of the scale, which, consequently, represents one pound of pressure upon the piston of the steam-engine to which this instrument is applied. The zero-point is that at which the index stands when the cock C is shut and the piston *a* remains undisturbed, and, therefore, when the instrument is in action, it denotes that point in the stroke at which the pressures above and below the piston are balanced.

From these explanations it will be obvious that, by attaching the instrument to the cylinder of a steam-engine, and observing the motion of the index upon the scale, the maximum steam pressure and vacuum may be at once ascertained. But this is not the only, nor even the most important function of the indicator. It was desirable to find out the exact periods and modes in which these two elements of power come into operation, and especially the *mean* effective values of each; the rapidity of the motion through so short a space precluding the possibility of taking these observations with any degree of accuracy. These important objects are fully attained by the help of a simple and beautiful contrivance, by which the instrument is made to register its own performances.

An arm or bracket *g* is firmly attached to the indicator by being clamped to the external casing B on which it may be set to any convenient elevation, and there secured by a screw. To this bracket is riveted an upright axis, on which, by a long socket, to insure steadiness of motion, is accurately fitted a cylindrical piece F, formed into a pulley at its lower end. The other extremity of the socket carries a small cylindrical box containing a spiral-spring similar to the main-spring of a watch, and attached at one end to the fixed axis, and at the other to the internal surface of the box in which it is inclosed. The bracket *g* carries also a small friction-pulley *j*, for the purpose of guiding a cord wrapped round and attached to the pulley F, to any convenient moving part of the engine; a small catch screwed into the latter, serving to circumscribe its motion to a single revolution. An external cylinder or drum E, which may be withdrawn from the instrument at pleasure, is fitted over the revolving cylindrical piece F, so as to partake of its motion, and upon it is fixed a slip of brass formed into a double spring *l l*, Fig. 2304, for the purpose of securing the slip of paper on which the instrument is to register its performance. This is effected by means of a pencil *f*, placed in a holder *e*, jointed to the piece of steel on which the index or pointer is formed, and fitted with a small spring, so as to press the point of the pencil gently against the paper cylinder, or admit of its being withdrawn from contact with it at pleasure. From these arrangements it will be seen that if the piston *a* be moved up and down, while the pencil is in contact with the cylinder E, a straight line will be traced upon it in the direction of its length; and if, on the other hand, the cylinder be made to turn upon its axis by pulling the cord, while the piston remains at rest, a straight line will be traced round it at right angles to the former. By the combination of these two motions when the instrument is in operation, a diagram is produced, which represents the performance of the engine at all parts of its stroke.

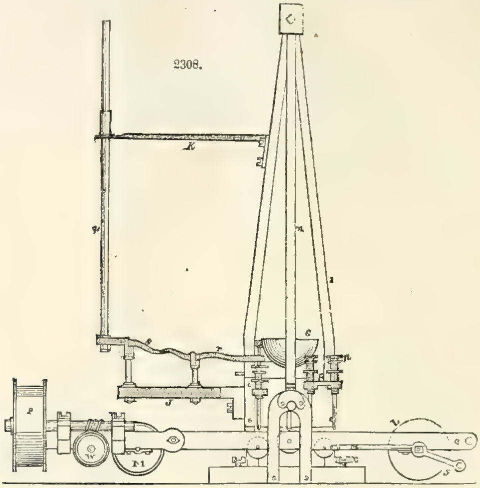
2307.



Action of the instrument.—The cock C is inserted into the corresponding socket prepared for its reception, and the cord which passes under the pulley *j* is attached to the radius-bar or other moving part of the engine, so as to cause the cylinder E to make one revolution on its axis, coincident with and representing the stroke of the engine; on the relaxation of the cord at the termination of the up stroke, it is taken up again by the action of the spring in the upright of the cylinder F, and the cylinder E resumes its original position. The slip of paper is then wrapped tightly round the cylinder, its ends being secured by the pressure of the two springs *l l*. These arrangements made, the pencil *f* is turned down into contact with the paper, and the engine allowed to make a stroke or two with the cock

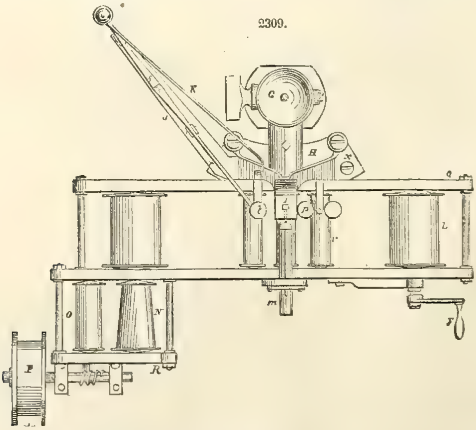
C shut, so as to form an *atmosphere line.* A communication is then opened with the interior of the cyl inder of the engine by turning the cock C, and a figure or diagram is traced upon the slip of paper, exactly representing the successive pressures of the steam above, and corresponding degrees of exhaustion below the atmosphere line, at every part of the stroke. To find the mean effective values of each of these pressures respectively, the figure is to be divided, in the direction of its length, into any number

2308.



of equal parts, the perpendicular distances of the outline of the diagram above and below the atmosphere line at each of these points, to be carefully measured upon the scale of the instrument, and the sum of these to be divided by the number of points taken. Hence the actual power of the engine is easily calculated.

2309.



Morin's Indicator.—That eminent French mechanician, M. Arthur Morin, conceiving, with reason, that considerable inaccuracy was likely to result from the difficulty of constructing the spiral springs in Macnaught's indicator, so as at all parts of the stroke to denote equal pressures by equal divisions; and, moreover, considering it desirable to ascertain with greater precision the mean pressures and conse-

quent actual power of engines by taking indications throughout several consecutive strokes, has invented a machine by which the former difficulty is obviated, and the latter object is attained. This instrument we have represented in the accompanying figures.

Fig 2307 is a side elevation, Fig. 2308 an end elevation, and Fig. 2309 a plan of the machine.

This indicator, like that we have already described, is adapted for being fitted to the cylinder cover of the engine; it carries a stop-cock pipe G, furnished with two keys; between these is situated a small horizontal cylinder H, in which a solid piston is accurately fitted to work steam-tight. Towards the middle of the piston-rod *m*, which is properly guided to a rectilinear course, is a square part in which is inserted the lower end of a long parabolic spring *n*, the other extremity of which is fixed to the summit of a standard I, forming part of the frame-work of the machine, the spring being so fitted as to admit of a certain amount of travel in the piston in both directions. The square boss of the piston-rod carries also a small pencil *o*, for the purpose of tracing the different degrees of tension of the steam on the opening of the lower cock G.

Two pencils *p p* are placed in holders fixed to the framing exactly opposite to the point at which the pencil *o* stands when the stop-cock G is shut, and being thus immovable, serve to mark a continuous atmosphere line. A third pencil *q*, which is susceptible of a slight degree of vertical motion in its socket, and is destined to mark the termination of each stroke, is brought into contact with the paper by placing the instrument so that the working-beam, cross-head, or any other rigid part of the engine may touch lightly at the end of the stroke, the top of an upright rod *u*, which is connected by a system of levers *r s t* with the top of the pencil *q*.

A continuous band or roll of paper may be subjected to the action of this machine for an indefinite period, so as to produce diagrams representing the action of the engine during several successive strokes. The manner in which this is accomplished is as follows: The roll of paper is first wound upon the cylinder L, by means of the handle *y*; it is then passed over the three small rollers *v v v* placed to oppose the pressure of the pencils, and is received upon the cylinder M situated at the opposite end of the framing Q Q. The axis of this latter cylinder is produced on one side so as to form also the axis of a conical pulley or fusee N, opposite to which is situated a cylindrical drum O, which receives a uniform motion from any rotating part of the engine to be operated on, by means of a worm-wheel *w* on its axis, geering with an endless screw on the axis of the strap-pulley P. The cylindrical roller O communicates motion to the conical roller N by a cord wrapped round both, and fastened at opposite extremities of each. The object of this arrangement is to compensate for the increased surface velocity due to the increased diameter of the cylinder M as the paper is wound on to it, by imparting to it a proportionally retarded motion.

This instrument, although highly ingenious in many of its details, and capable of giving very correct indications, is wanting in that portability and compactness which has very materially contributed to bring Macnaught's instruments into such general use. Moreover, although in any instrument of this nature the observations will be more or less accurate in proportion as the space through which the spring is made to act is more or less limited, yet a considerable advantage results from the length of range in the common indicators. The diagrams being made upon a large scale, the expert engineer is able, at a glance, and without reference to the scale, to ascertain by the mere contour of the figure whether his engine is performing all its functions properly.

The indicator of the steam-engine appears to fulfil two distinct and very important ends.

It enables us to discover whether there are any defects in those parts of the machinery by which the steam is admitted to the piston; for instance, it indicates whether the slides are properly set, or leaky; whether the stops on the intermediate shaft are properly placed; whether the steam-ports are large enough; and, consequently, whether a different arrangement of the working part of the machinery would be advisable. In fact, in the hands of a skilful engineer, the indicator is as the stethoscope of the physician, revealing the secret workings of the inner system, and detecting minute derangements in parts obscurely situated.

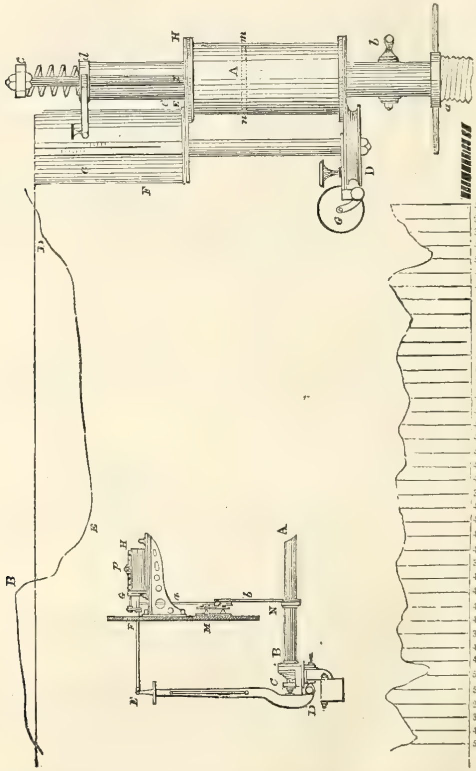
It discovers, at any instant of time, and under any given circumstances, when it may be desirable to apply it, what is the actual power of the engine.

We will first give a description of the instrument, and then proceed to its various uses.

Fig. 2310 is an external view of the indicator as constructed. The dotted lines are intended to show the internal parts. A is a hollow cylinder, whose upper end E H is open; the lower end being intended to fit into an orifice in some part of the engine (generally the top or bottom of the cylinder) by means of the screw *a*; *b* is a stop-cock, by which, when the instrument is attached, we can, at will, make or cut off a communication with the internal parts of the engine. Within the hollow cylinder A is a piston *m n* packed and fitting steam-tight. In practice this piston must not be packed *over-tight*, for fear of increasing the friction and preventing the free motion of the pencil; but the defect, if any, must be remedied by keeping melted tallow or oil on the upper surface.

Let us suppose, for perspicuity, the instrument to be in communication with the *top* of the steam cylinder. Then, when a vacuum is formed above the steam-piston, the atmospheric pressure will force down the piston of the indicator, and it will remain at its lowest position till fresh steam enters; but it would immediately, (unless prevented,) on receiving a new impulse, be blown out at the open top H E. To prevent this, and at the same time to enable us to measure the force of the steam, a spiral spring presses with its lower extremity against the surface of the piston, while its upper end rests against the fixed cross-piece *c*. By this arrangement the pressure of the steam will always vary as the place of the piston varies; for it is a mechanical fact, that the tension of a spring varies as the extension. Hence, the greater the pressure of the steam, the more the spring is compressed; and, on the contrary, as the steam loses its elastic force, the spring expands and the piston descends. So that, to get a clear idea of the instrument, conceive the piston to be acted on by opposing forces; on the lower surface by the pressure of the steam, (continually varying,) and on the upper surface by the pressure of the atmosphere, (constant,) and by the force of the spring varying so as to balance the steam-pressure Now, as

the steam-force is perpetually varying, it follows that the piston-tube de will be continually rising or falling. If a pencil be attached to the upper end of this tube de, in which the spring works, it will describe a vertical straight line on a piece of paper brought into contact with it. This, however, is not sufficient for our purpose. It would, after it was traced, tell us the maximum and minimum pressure during the stroke; but the pressure *at any particular portion of the stroke* would still be undetermined. We must, therefore, have some plan similar to that adopted in other cases where the vertical motion of a pencil under particular circumstances is to be *registered.* In all such instances, the paper on which the variation is to be laid down is drawn horizontally at a certain rate. If, for instance, we were desirous of recording how the pressure varies with the *time,* the paper must be drawn *uniformly,* by connecting it with clock-work, or some other apparatus for giving a *uniform* motion. But this, however, is not usually the desideratum in the steam-engine. Our object is here to have represented before our eyes the variation of the pressure for every portion of the stroke of the piston; and this is contrived as fol-



lows: the paper is wrapped round a cylindrical barrel C, which is brought back against a stop by a strong watch-spring contained in the box E F. A string passes round the pulley D, and is led away through a fair-leader G to some part of the engine having a similar motion to the piston cross-head, only much reduced, by which means the watch-spring and the string are always opposing each other. As the piston rises, the barrel will be pulled from left to right; and, on the contrary, as the piston descends the string having a tendency to slacken, the barrel will, by the force of the spring, be brought back from right to left. The pencil is attached to the upper end of the tube dg, and rising and falling with the indicator piston. It can be brought into contact with the paper on the barrel C or removed from it at will, by means of the joint at g. The rod z, and another one on the opposite side of the cylinder, serve as guides to the piston.

The paper is kept on the barrel by means of a strip of metal, which also serves another impor-

tant purpose. It will be seen that it is graduated, beginning from zero, and proceeding upwards and downwards. Now this zero is the level at which the pencil stands when the instrument is unconnected with the steam-engine, and therefore acted on by the atmospheric pressure above and below the piston. The pencil will be seen at this level in the figure. If the barrel be made to revolve under these circumstances, a horizontal line will be traced out. This is called the atmospheric or zero line. And, therefore, the pencil will also be at this level whenever the steam, taking the place of the atmosphere *below* the piston, exerts the same pressure; and, consequently, wherever the diagram cuts this horizontal line, the pressure of the steam is 15 pounds on the inch;* when on the level of the marks 1, 2, 3, &c., above this zero, the pressure is 16, 17, 18, &c.; and when on the level of the marks 1, 2, 3, &c., below this, the pressure is 14, 13, 12, &c.

The atmospheric line should not be drawn till after the diagram is taken; because, as the parts become warm by the steam, slight variations occur in its position, depending principally on the alteration in the force of the spring; and since this line serves as the origin from which the pressures are dated, it is necessary to have it laid down as correctly as possible.

The small hole in the side of the stop-cock *b* serves to let the air into the cylinder A when the steam is cut off by the stop-cock, and thus enables us to take the atmospheric line; it enables the stop-cock to perform the office of a four-way cock; for by turning it in one direction we allow the steam to enter, and exclude the external air, and by turning it in the opposite direction we admit the air and exclude the steam.

Having an indicator, a diagram is obtained by looking out for some part of the engine whose motion is proportioned to that of the steam-piston,† taking care that the space moved through at that part shall be somewhat less than the circumference of the traversing barrel; that is to say, whatever be the diameter of the traversing barrel, let the movement of the part you are looking for be not greater than *three* times this diameter. Fasten a string firmly to this point, and have a traversing loop in the loose end of the string; it must be of such a length that it may be connected with the string passing round the pulley of the indicator. Then close the stop-cock of the indicator, and fix it by the screw *a a* to some orifice previously prepared in the top or bottom of the cylinder.‡ Insert the pencil you intend to use in the small hole made for its reception, and clamp it there. The pencil should be hard, and have a fine point, to give as clear and distinct a line as possible. Have some pieces of clean writing-paper provided, long enough to be brought round the traversing barrel and overlap about an inch. Wrap a piece smoothly round the barrel, and fix it by means of the clasp containing the scale. Then tear away all the surplus paper, and examine what remains, to see if it be quite smooth; for if there be any ridges the curve will have an irregular appearance, and might lead us to suppose some of the geer for working the slides had become loose, or much worn. Next wind the indicator string round the pulley of the barrel D, and connect the hook at its extremity with the loop of the string attached to the engine. Adjust the string by means of the running loop, till you are satisfied of the motion of the barrel; allowing it to make nearly a whole revolution, but examining it most carefully to see whether it becomes slack, or overtaut. The stop-cock *b* may now be opened wide, and the indicator-piston will immediately start into motion; the piston must be well lubricated, to reduce the friction as much as possible, and at the same time to prevent leakage. Let the instrument work for a few seconds, to allow it to become thoroughly heated; and when it has arrived at the same temperature as the steam-cylinder, it is in a fit state to trace its diagram. When satisfied of the working of the machine, take hold of the pencil when it comes to the *bottom* of its stroke, and bring it gently into contact with the paper. This part of the operation requires some practice; for if the pencil be allowed to come forward too rapidly, the spring at *g*, by which it is pressed against the barrel, will break the point; and again, if held too long, the force of the steam, suddenly acting on the machine, will tear it out of the hand, or break the holder. When left to itself, it will trace out its curve on the paper. As soon as it has made a complete circuit, let the pencil be withdrawn from the paper, (being again careful to take hold of it when at the *bottom* of its stroke.) In order to have the line distinct, the pencil should not go over the same ground twice. Shut off the stop-cock and the piston will become stationary, both sides being acted on by the pressure of the atmosphere. Bring the pencil again in contact with the paper, and as the barrel traverses, the atmospheric or zero line will be drawn. The operation is now complete, so far as the curve is concerned. Withdraw the pencil once more, unhook the line, and take off the traversing barrel. Next take a fine-pointed hard pencil, and mark off upon the paper the scale of pounds, beginning with the atmospheric line, and proceeding upwards and downwards. After taking the paper from the barrel, it is completed by writing on it the date of the month, the name of the ship, that of the engine, (whether starboard or port,) top or bottom of cylinder, as the case may be, the number of revolutions, the pressure of steam by steam-gage, and of condensation by barometer-gage.

It is important to have a running loop, or other means of shortening or lengthening the string attached to the indicator. Too much attention cannot be paid to this circumstance. If too much strain be brought upon the string it will stretch, and if the string be too long it will become slack; and in either case the barrel will be stationary for a small interval while the steam-piston is moving, and the curve will not be a true indication of the motion.

It is well known that the pressure of the steam and the state of the vacuum on the diagram do not correspond with the boiler-pressure and condenser-vacuum. The truth is, the result will always be less. The difference will depend on the size of the ports, and the work the engine has to do; the distance

* More strictly, 14·75 pounds, or a quantity differing from this slightly, according to the state of the weather.

† That is to say, when you are wishing to find how the *pressure* varies with the *stroke* of the engine.

‡ If the top of the cylinder be chosen, the orifice for the grease-cup will generally answer the purpose. In some cases a pipe leads from the top to the bottom of the steam-cylinder, and the indicator is attached to this pipe. It is provided with stop-cocks, so that when once fixed the arrangement is very convenient for taking two diagrams almost simultaneously from the upper and lower part of the cylinder. The only objection to it seems to consist in the tendency of the steam to condense in the pipe. For this reason it is advisable to have the indicator as close to the cylinder as possible.

the steam has to travel, the impediments it meets with in its passage from the boiler to the cylinder, and from the cylinder to the condenser. It is evident that the diagram taken from the top of the cylinder shows only the pressure and vacuum on the upper surface of the piston, and therefore cannot indicate what is going on below the piston. If our object be merely to calculate the horse-power of the engine, and it be in tolerably good working condition, it is not of much consequence whether the diagram be taken from above or below; but if the actual state of the engine be required, it is necessary to examine into what is passing both above and below the piston, because the errors in one part may have no connection with the errors in another. This will be the case if the slide is too long or too short, so that the upper part may be properly covered, and the lower one disarranged; or the upper slide may be steam-tight, and the lower one leaky; and if the indicator be applied to top and bottom, it will detect all these inaccuracies, and prevent our attempting to improve the working of one end to the detriment of the other. It ought to be remarked here, that in unbalanced engines the diagram from below the piston is generally superior to the other; because, since the steam has more work to accomplish, the piston does not run away from the steam so readily, and, in consequence, the steam-pressure is better maintained; and there is generally a little more lead to the slide, to allow a freer ingress to the steam. And, therefore, if great accuracy be required, the mean of the top and bottom diagrams should be taken for the horse-power.*

The string carrying the running loop must not be attached to any part of the engine indiscriminately. Generally speaking, we wish to obtain the pressure of the steam for different portions of the stroke of the piston; therefore, the string must be fastened to some part of the engine having a stroke proportioned to that of the piston, only much reduced. The part selected must be as near the indicator as other circumstances will permit; for the greater the distance the longer the string, and consequently the greater is the chance of error from its stretching. Caution must be used also to prevent the string from slipping on the rod to which it is attached. One of the best contrivances for giving a free and proper motion to the string is to fasten a wooden pulley to the radius-shaft,† to the groove of which the fixed end of the string can be connected. It will be necessary, in most cases, to make use of fair-leaders for the purpose of conveying the motion from the part chosen to the indicator; and due regard must be paid to this, to ascertain whether the motion of the engine will be fairly represented by the indicator.

We must bear in mind that all *vertical ascending* motions are caused by an *increasing* pressure of the steam, and that the *descent* of the pencil is the consequence of the elasticity becoming diminished: and again, that as the traversing barrel revolves from right to left, the piston is descending; while, on the contrary, as the pencil moves from right to left, the piston is ascending;‡ hence we shall arrive at the following general conclusions:—

1. If the motion of the pencil be vertically upwards, the steam-pressure is *increasing*, but the piston is *not* moving.

2. If the motion be downwards, the steam-pressure is *decreasing*, but the piston *not* moving.

3. If the line traced be horizontal to the right, the steam-pressure *does not vary*, but the piston is *descending*.‡

4. If the line be to the left, the steam-pressure *does not vary*, but the piston is *ascending*.

5. If the line run obliquely to the right upwards, the steam-pressure is *increasing*, and the piston is *descending*.‡

6. If the line run obliquely to the right downwards, the pressure is *decreasing*, and the piston *descending*.‡

7. If the line run obliquely to the left downwards, the pressure is *decreasing*, and the piston *ascending*.‡

8. If the line run obliquely to the left upwards, the pressure is *increasing*, and the piston *ascending*.‡

Let us refer to the accompanying diagram, Fig. 2312, taken from above the piston of an American steamer, and explain it.

First, we will put numbers round the diagram, in conformity with the principles laid down in the last paragraph.§ Then, supposing the pencil to commence at A, and trace out the curve in the direction of the arrows, we see that the steam preserves its first and highest pressure for a considerable portion of the stroke, viz. from A to C; from C to B the downward stroke continues, but the steam rapidly loses its pressure, although at a variable rate, decreasing rapidly at D. At B the motion of the piston ceases, but the steam continues to fall, till at length the pencil moves back nearly horizontally for some space, showing the pressure to continue invariable, although the piston is rising. At F, however, 8 shows the steam-pressure to increase rapidly and suddenly, the piston still ascending, till, as this oblique line merges into the vertical one at G, we perceive that the piston has arrived at the upper end of its stroke, and the fresh influx of steam drives the pencil up to A. From this point the pencil will retrace the same curve. G D is the atmospheric or zero line.

When the pencil is at G (or, it may be, rather before arriving at G) the slide is in the position represented at Fig. 2311, and is rising, so that the steam is about to enter the cylinder. Now this will

* We ought further to remark, that there is a difference between the motion of the slide in the up and down stroke. When the centre of the eccentric has reached that part of its orbit furthest removed from the slide, the motion of the slide is slowest; and when at that part nearest to the slide, the slide's motion, though slow, is comparatively quick. But at such times the piston is moving very quick, and, consequently, in the former case the steam-line is further extended than in the latter. This will therefore help to account for our getting a better diagram from the top of the cylinder of a beam-engine, and from the bottom of a direct-engine; and the difference becomes more marked in engines having a short connecting-rod. This is fortunate, for it assists in balancing the engine.

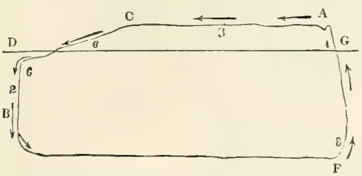
† In most direct-engines a pin can be fixed on the main centre of the air-pump beam. In Seaward's direct-engine the string may be attached to the *centre-line* of the radius-bar.

‡ This will be the case in one engine, but not necessarily so in another engine; and moreover, if the string be led in another direction the reverse will happen; but this the practical man can correct for himself according to circumstances, and substitute *ascending* for *descending*, and *vice versa*.

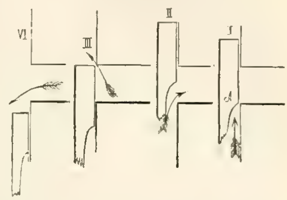
§ These diagrams should be reversed; that is to say, the right side should be in place of the left.

take place, as the diagram shows, very slightly before the upward stroke of the piston is accomplished and since the piston and slide are both on the ascent, the lower edge A will have ascended a trifling space when the piston is at its highest. This slight space, though trifling in amount, is important in its results on the working of the engine. It is denominated the *lead* of the slide. As the piston descends the valve rises, and the admitting orifice becomes larger, so that although the piston is gaining speed in its downward course, yet in well-contrived engines the first pressure is continued, as we find in the diagram, through a considerable portion of the stroke.

2312.



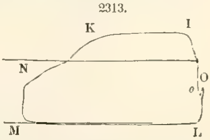
2311.



The slide, however, has already begun its downward motion, and when the pencil arrives at C it has returned into the position it had in Fig. I. It is clear that as it continues to descend no more steam can be admitted; whatever the cylinder contains will remain pent up; and as the piston continues to move downwards the steam relaxes its force, and we trace a corresponding depression in the diagram from C to D. But a still greater change is to be expected before the piston arrives at its lowest place. Ere that happens the slide will have come into the position shown by Fig. III.; for it is found to be disadvantageous to allow the steam to be kept in the cylinder till the end of the stroke, because the entering steam at the reverse stroke would meet with so much opposition, till the vacuum on the opposite side had become tolerably good, that the equability of the motion would be much affected. This being granted, we see that the port will be open for eduction before the end of the stroke, consequently a rapid fall in the curve takes place at D. Moreover, the slide continues to fall, not only after the piston has come to the bottom, but evidently during the greater portion of the up stroke. Although after a very short interval, from the great rate at which the steam rushes into a vacuum, the state of the vacuum is nearly unaltered, and but little different from that in the condenser; hence, after turning the right-hand corner, the pencil runs nearly horizontally. At F, however, the slide has returned to the position represented in Fig. III., and is *rising;* the piston is also rising, and near the top; consequently the steam that has not yet made its escape is pent up, and, becoming more and more compressed, the pencil rises rapidly, till, the fresh steam entering, it starts up suddenly to A and retraces the curve.

The accompanying diagram, Fig. 2313, though being taken from the same engine as that represented in Fig. 2312, differs in many respects.

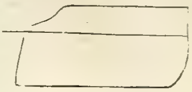
2313.



We observe, in the first place, that the steam-line I K is shorter than in Fig. 2312, while the exhaust-line L M is longer than in the latter; we infer, therefore, that the steam had a shorter time to come into the cylinder, and a longer time to make its escape. We observe, likewise, that the engine had made a considerable portion of its downward stroke before fresh steam was admitted. Now, these phenomena can be explained by supposing, from some cause, the slide to be removed bodily below the place it had when the former diagram was traced. For let us refer to the series of representations of the slide before noticed: Thus the point I shows us the steam comes in later in this diagram than in the former, and the valve is rising; consequently its lower edge will be at some point lower than it would be in ordinary circumstances. Again, the point K of the diagram indicates to us that the steam is cut off again sooner, but the slide is descending, and therefore, also, the lower edge is lower than it ought to be. Again, N being too far from the end of the stroke, we see that the exhaust takes place too early; in other words, the upper edge of the slide is too low. And lastly, the point L (where the cushioning commences) being carried too far to the left, shows us that too great an interval elapses before the upper edge of the slide reaches the upper edge of the port. And, consequently, every part of the reasoning proves to us the fact that the slide is lower than should have been the case. Now, in pursuing our inquiries, we shall find this is caused by one of two defects, viz., either the slide-rod is too long, or the eccentric-rod is not of the proper length. But in seeking for the remedy, we must look to the slide-rod alone, because its length can be more easily adjusted than the eccentric-rod, by means of the nuts and screw by which it is fastened to the cross-head. The derangement of the engine, when the diagram represented in Fig. 2313 was taken, was obtained by lengthening the slide-rod $\frac{3}{8}$ths of an inch. The projection at the point O remains to be noticed, although it would never appear except in exaggerated cases, such as the one before us. It will be seen that the cushioning takes place from L to O, and consequently the pencil rises because the steam is compressed; but the fresh steam does not yet enter, and therefore as the piston descends, this steam, till now compressed, loses its elastic force and the pencil drops, till at *o* a fresh supply enters and the pencil starts up from *o* to I, taking a motion compounded of the motion of the piston and the pressure of the steam, for it is to be noticed that the line *o* I bends sensibly to the left; this arises from the increasing velocity of the piston, and is not observable in the standard diagram, Fig. 2312, except near the top, because the piston is all but stationary during the short time the steam is entering.

The opposite effects would have taken place if the slide-rod had been shortened; that is to say, the upper portion of the diagram would have been spread out, and the lower part contracted. If the whole slide be of the proper length, it is clear that when we get a faulty diagram taken from above the piston, the one taken from below it will be similar to Fig. 2314, and *vice versa*. Hence, therefore, we see one advantage of taking both a top and bottom diagram. But if the one diagram be similar to one of those just exhibited, and the other be satisfactory, the fault lies with the slide itself, and cannot be remedied but by the engine-makers. The only plan for the engineer is to divide the fault as equally as he can between the upper and lower parts, by lengthening or shortening the rod, according to circumstances. Moreover, we conceive an engineer should not be satisfied that he has done all, when he has obtained a good diagram from one end of the cylinder; because, if the fault lay with the slide, he would be improving one to the injury of the other.

2314.



All the motions of the slide, whether up or down, would take place sooner than ordinary, if the stop on the eccentric were too far advanced; that is to say, the cushioning, the introduction of fresh steam, the cutting off, and the exhaust, would all commence sooner. The curve, therefore, instead of being like the standard diagram, will be similar to Fig. 2315, assuming somewhat of a lozenge-shape, the upper right and lower left corners being acute-angled, and the other two obtuse. Again, a little reflection will enable us to discover that similar defects will be exhibited in the lower diagram under these circumstances, and not opposite defects, as was the case when the slide or eccentric rod was at fault.

2315.

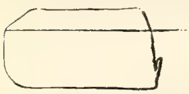
This curve was obtained by inserting a piece of metal, half an inch thick, between the stop on the eccentric and that on the shaft.

It can be readily ascertained, by inspecting the diagram, if the stop on the shaft were not sufficiently advanced; for in such a case all the motions of the slide will be later than they would be in a well-constructed engine; consequently, all the upper part of the curve will be drawn towards the right, and all the lower part to the left. And, as in the former case, the same distortion will be observable if a diagram be taken from the lower part of the cylinder. Moreover, if the defect be great, we shall meet with the hump in the lower right-hand corner, similar to that before noticed.

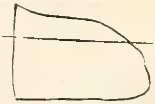
Fig. 2316 was taken after removing back the stop on the shaft 7-16ths of an inch.

When the ports of the cylinder or the steam-pipe are too small, the steam will not be able to enter or escape so freely as it ought; the pressure at first entrance will not be maintained for any length of time, and the vacuum will not be formed rapidly enough, the steam and vacuum lines will therefore lose their horizontality, as is easily discovered in the diagram here given, which was taken from one of our largest engines, afterwards altered by shortening the gab-lever.

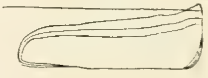
2316.



2317.



2318.



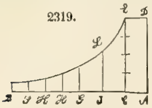
When the steam is throttled the upper line of the diagram will rapidly decline, as in Fig. 2317, for the same reason that it would if the steam-pipe or the port were too small, and it will not be so high altogether as in ordinary cases. The vacuum-line, however, will be better than it would otherwise be; for since the quantity of steam admitted is not so great, the speed of the piston will be reduced. But the exhaust-port is of the same size whether the steam be throttled or not; and therefore there is more time for the expended steam to rush through this orifice into the condenser, and consequently the vacuum-pressure in the condenser and in the cylinder will be more nearly equal, and better in both than when the full power is set on.

Fig. 2318 represents three diagrams taken from the engine before referred to, the steam being throttled to various degrees.

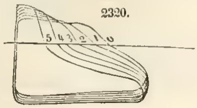
Fig. 2319 will represent a diagram when the expansive geer alone is used. For let A B represent the whole length of the cylinder, and when the piston has traversed the space A C, let the ingress of the steam be suddenly stopped. Then, from this epoch, the steam-pressure will decrease, and the pencil begin to descend. Now if the temperature of the steam be unaltered, the pressure will vary inversely as the space it occupies. Divide, therefore, the space C B into intervals C J G, &c., each equal to A C; and therefore when the piston is at J, the space A J being *twice* A C, the pressure of the steam at J is *half* that at C, at G it will be one-third, at H one-fourth, &c.; and if lines be drawn through C J G, &c., parallel to A D, and of the length we have just indicated, making C E = A D, J L = half A D, &c., and through the upper extremities of these lines a free curve be traced, it will give us an idea of what we ought to expect. But since the slide-valve also acts, we shall have the modification this would produce too, for the slide-valve is placed between the expansion-valve and the cylinder, in most engines; it follows, therefore, that the effective volume of the steam, intercepted by the expansion-valve, is the whole of the space between it and the piston, and the slide-valve interposes an additional barrier when it begins to cut off the steam. The case, therefore, is somewhat similar to what it would be if there were two expansion-valves, one nearer to the cylinder than the other, and the outer one acting first.

Fig. 2320 represents a series of diagrams taken from the same engine. Here 0 gives the full steam without using the expansion-geer, 1 that produced by the first grade of expansion, 2 that produced by the second grade, and so on. We must here remark, that in the interval that elapsed between taking the diagram in Fig. 2317 and the series here represented, the engine had been improved by shortening the gab-lever, and thus enlarging the aperture for steam and eduction. The effect will be observable by comparing the diagram S with that in Fig. 2317.

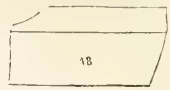
2319.



2320.



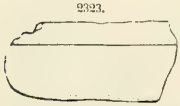
2321.



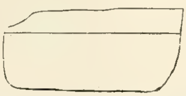
We must always rest satisfied that an engine is in good working condition when the general features of the diagram are satisfactory; for in the hands of an inexperienced person, the indicator may trace an unfaithful representation of the condition of the engine. When the piston is near one end of its stroke, if an undue strain be brought on the string it will stretch, and the indicator-barrel remaining stationary while the steam is entering, the pencil will have a vertical ascending motion, such as is represented in Fig. 2322. On the other hand, if the barrel come back against its stop before the opposite stroke is accomplished, the pencil will fall vertically, as in Fig. 2321. These two figures ought to have been precisely similar, the only cause of difference being the accident of the string.

The series of steps in the right upper portion of the diagram represented in Fig. 2323 arises from the piston of the indicator being packed over-tight, on which account it descends by a series of jerks as the steam-pressure relaxes.

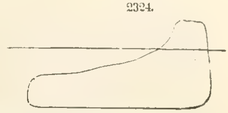
2323.



2322.



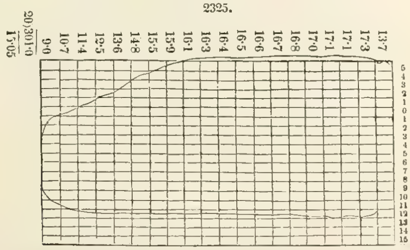
2324.



The steam-line in Fig. 2324 does not descend so rapidly as in the imaginary curve spoken of in the last page, because the expansion-valve of the engine it was taken from was leaky, and therefore did not entirely cut off the steam.

The most accurate way of ascertaining the power of an engine is by means of the indicator, because the diagram gives the pressure on the piston, and hence, knowing the number of revolutions and the length of stroke, the laboring force can be ascertained. The mean pressure on the piston is obtained as follows: Divide the diagram by a series of equidistant vertical lines, as in Fig. 2325, (the closer the better,) and, taking the horizontal line marked 0 as the origin, draw a series of other lines parallel to it at distances equal to the intervals corresponding to the scale of pounds on the indicator. This being

2325.



accomplished, if our object be only to form an estimate of the gross power, observe in the middle of each vertical space the number of pounds included between the steam and vacuum lines to tenths, which will be best done by taking the distance with a pair of compasses, and setting it off on the scale of pounds. Write these in their proper columns, as in the figure, along the diagram, and add them together. Then divide the gross result by the number of columns, and we obtain the gross average pressure on the one side of the piston during the up and down stroke. From this it is usual to deduct from 1 pound to 1·5 pounds, according to the size of the engine, for friction, for small engines have more friction in proportion than a larger; then the result is taken as the effective pressure per square inch, acting *uniformly* during one whole revolution. Take now the diameter of the cylinder in inches, and square it; then multiply the product by ·7854, the result is the number of square inches in the surface of the piston. Multiply this again by the pressure per square inch, as got from the indicator, for the whole pressure in pounds on the surface of the piston. And if this be multiplied by the length of a double stroke, and finally by the number of revolutions, we shall obtain the work done by the engine.

It is usual to divide this quantity by 33,000, (supposing this to be the number of pounds a horse would be able to raise one foot a minute, and the quotient is then called the horse-power of the engine. If there be two engines, as is usually the case in steamers, this quantity must be doubled.

Example.—In the preceding diagram, let the number of revolutions be 38, and therefore the number of single strokes 76.

Then, since the diameter of steam-cylinder = 20 inches,

$$
\begin{array}{lr}
\therefore \text{Diam.}^2 = & 400 \\
 & \cdot 7854 \\
\hline
 & 314\cdot 2000 \text{ sq. inches.} \\
\text{But pressure of steam} & = 15\cdot 05 \text{ lbs.} \\
\text{Deduction for friction} & = 1\cdot 50 \\
\hline
\therefore \text{Effective pressure per inch} & = 13\cdot 55 \\
 & 314\cdot 2 \\
\hline
 & 2710 \\
 & 5420 \\
 & 1355 \\
 & 4065 \\
\hline
\text{Pressure in lbs. on piston} & = 4257\cdot 410 \\
 & 76 \\
\hline
 & 2554446 \\
 & 2980187 \\
\hline
 & 323563\cdot 16 \\
 & 2 \\

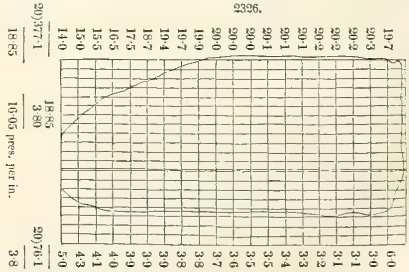
$$

If it be necessary to find, *separately*, the value to be given to the steam and vacuum pressures, we must get the actual pressure, and not the difference of pressure between the steam and vacuum lines. And therefore we might measure the height of the spaces above the atmospheric line, and the depth of the vacuum below it. But, in regard to the steam-line, a difficulty has to be surmounted, which would not be easily got over by practical men unaccustomed to analytical investigations. It is this; that part of the steam-line is usually above the atmospheric line, and part below it; and the results of the one must be subtracted from the results of the other. This is more particularly to be noticed in cases where the engine is working expansively, and a great portion of the steam line is in consequence below the atmospheric line. The following suggestion will, however, get over the difficulty: consider the atmospheric line, as in Fig. 2325, to be 15 lbs. (which is its actual pressure,) and reckoning downwards, call

2326.



the lines below it 14, 13, &c., till we come to 3, 2, 1, 0: the line marked 0 we will assume as that line from which the pressures are measured, and both the steam and vacuum line will be above this new zero line; and the actual pressures of each will, by these means, be ascertained, and not the relative pressure, as compared with that of the atmosphere. In the preceding diagram, this second method of computation has been performed; the numbers on the right-hand side beginning from the absolute zero, and the figures along the top and bottom of the curve giving the steam and vacuum pressures respectively. The mean of the steam-pressure is 18·85 lbs., and of the vacuum 3·8 lbs. The difference is 15·05, as we obtained before.

To determine the work done in one single stroke of the piston, we must suppose the piston to be descending; then the steam-pressure acts above the piston, and the vacuum-pressure below the piston; that is to say, the steam-pressure must be got from the top diagram, and the vacuum-pressure from the bottom diagram; and we must, therefore, make use of the method proposed in the answer to the last question. Thus, to obtain the mean pressure during the down stroke, take the steam-pressure from the top diagram, and the vacuum-pressure from the bottom diagram, and subtract the latter from the former. Again, to obtain the pressure during the up stroke, take the *vacuum*-pressure obtained from the *top* diagram, from the *steam*-pressure got from the *bottom* diagram.

To ascertain by the indicator the quantity of steam an engine uses, we have only to fix on any con

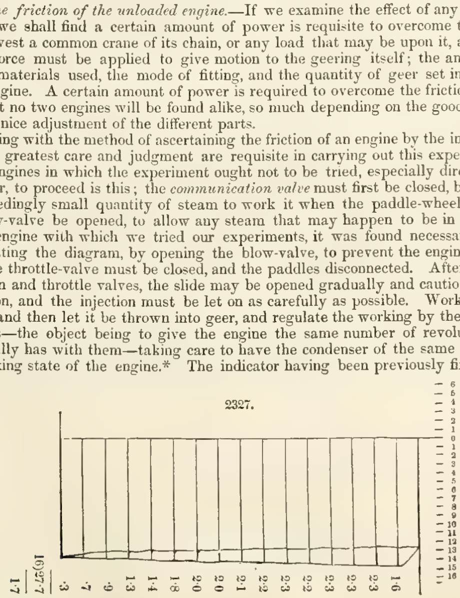
venient part of the steam-line between that point where the steam is cut off and the opening is made to the condenser; that is to say, between the points C and D in Fig. 2312. Observe, by counting the vertical spaces, what proportion the portion of the stroke, as far as this point, bears to the whole length of the stroke. Notice also the pressure of the steam at this point. Then we shall have a certain fraction of the cylinder filled at each stroke with steam of a given pressure. If now the cubic contents of the cylinder be determined, and the number of times the cylinder is filled per minute, we shall have the quantity of steam of known pressure supplied to the engine per minute. Thus, suppose that in the engine before alluded to $\frac{9}{10}$ of the cylinder were filled with steam of 15 lbs. pressure; then, since the number of cubic inches in the cylinder twice filled is 15079·6, the number of revolutions being 34 at the time of experiment, the whole number of inches in a minute $= 51252·64, \therefore \frac{9}{10} \times 512526·4 = 461273·76$, and the number of cubic inches of atmospheric steam in an hour $= 461273·76 \times 60 = 27676425·60$. But each inch of water is supposed to form 1711 cubic inches of steam at the atmospheric pressure, and therefore the number of cubic inches of water evaporated $= \frac{27676425·6}{1711} = 16,175$; and the number of gallons (English) of water evaporated $= \frac{16175}{277·274} = 58$ nearly.

Now, if the theory be correct, this should be the quantity of water evaporated from the boiler, due allowance being made for condensation, &c., in the steam-pipe and passages. But this is far from being the case, for the number of gallons actually evaporated by the boiler was ascertained to be 108 gallons in the hour. We can do nothing more at present than to state the discrepancy, and offer the following hypothesis to account for it. From the violence of the ebullition, the steam is in all likelihood not so dry as that on which careful experiments are made, as is frequently made manifest in boilers that "prime;" so that, even in good boilers, it is very possible for the steam to contain much more watery vapor than it would if it were not so rapidly consumed. If so, an inch of water would not under these circumstances form 1711 cubic inches of steam under the atmospheric pressure, and might perhaps form only one-half that quantity, which would be requisite to give the proper number of gallons of evaporated water. It remains to be seen by future experiments whether this be the fact; and if true, it will throw doubt on the tables of relative volumes of steam and water contained in most works on the steam-engine.

To determine the friction of the unloaded engine.—If we examine the effect of any machine at work, however simple, we shall find a certain amount of power is requisite to overcome the friction of the engine itself. Divest a common crane of its chain, or any load that may be upon it, and it will still be found that some force must be applied to give motion to the geering itself; the amount of force depending on the materials used, the mode of fitting, and the quantity of geer set in motion. So it is with the steam-engine. A certain amount of power is required to overcome the friction of all its parts; and in this respect no two engines will be found alike, so much depending on the goodness of the workmanship, and the nice adjustment of the different parts.

Before proceeding with the method of ascertaining the friction of an engine by the indicator, we would observe, that the greatest care and judgment are requisite in carrying out this experiment; there are many classes of engines in which the experiment ought not to be tried, especially direct-acting engines. The way, however, to proceed is this; the *communication valve* must first be closed, because the engine requires an exceedingly small quantity of steam to work it when the paddle-wheels are disengaged. Then let the blow-valve be opened, to allow any steam that may happen to be in the steam-pipe to escape. In the engine with which we tried our experiments, it was found necessary to destroy the vacuum, befor getting the diagram, by opening the blow-valve, to prevent the engine flying off at too great speed. The throttle-valve must be closed, and the paddles disconnected. After slightly opening the communication and throttle valves, the slide may be opened gradually and cautiously, to admit the steam to the piston, and the injection must be let on as carefully as possible. Work the engine a few strokes by hand, and then let it be thrown into geer, and regulate the working by the throttle and communication valves—the object being to give the engine the same number of revolutions without the paddles as it usually has with them—taking care to have the condenser of the same temperature as in the ordinary working state of the engine.* The indicator having been previously fixed and adjusted,

2327.



* We would strongly advise the insertion of the bulb of a thermometer in the condenser of every engine in addition to the barometer-gage. The bulb must be entirely within the condenser, and the scale (at least that part of it which is above 50° or 60°) outside, in the engine-room. The thermometer chosen for the purpose must be graduated higher than the temperature of the steam in the boiler, otherwise it will burst when the engine is blown through. It must be placed in some part acted on freely by the steam, but free from the splash of the injection water. When the engine is free from air it will then serve as a most delicate test of the vacuum. The temperature preserved should be about 100°.

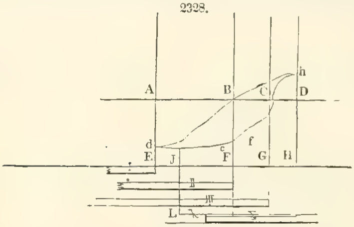
let a diagram be taken: it will be widely different from that when the load is on. Both the steam-line and vacuum-line will be much below the atmospheric line. The diagram may then be taken off, and divided as in the former case. Let the result of this diagram be worked off in the same manner as the common diagram, and the amount is the work the steam has performed, or in other words, the friction of the unloaded engine. This has been accomplished in the diagram, Fig. 2327.

This is what is commonly subtracted from the gross result obtained under ordinary circumstances, and denominated friction; but it is manifest that it is much less than the actual friction of the engine when turning the wheels, for the friction of every machine increases with its load; and moreover, the injection water, &c., raised by the air-pump increases likewise, and all this goes under the head of friction. The friction of large engines is less in proportion than that of smaller ones; in large engines it is usual to allow 1 lb. on the square inch of the piston for friction, and in small engines from 1·5 to 2 lbs.; and in most cases it would be better, except as a matter of experiment, to trust to this than to attempt the difficulty of ascertaining it.

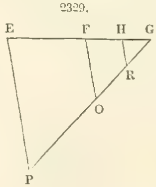
A *slide* diagram is that in which the indicator-string is connected with the cross-head of the slide, and not with that of the piston; so that the horizontal motion of the pencil backwards and forwards corresponds to ascents and descents of the slide, and *vice versa.* And this process will give us many particulars of the slide, without the trouble of taking the engine to pieces for measurement. If the indicator be applied to the upper end of the cylinder, it will give us information of the upper slide-face; and if to the lower end, of the lower slide-face. As was before stated, the string must be connected with some part having the motion of the slide; but generally it will be necessary to reduce the motion, because the stroke of the slide is more than the indicator-barrel will allow; in small engines it may be attached to the cross-head direct. As was before remarked, so long as the pencil is moving from left to right, the slide is rising; and when moving from right to left, it is falling; and any rise or fall of the steam-pressure is due to the change of pressure in the steam, as in the common or piston diagram. Then the difference in the two cases would be this: that in the common case we have changes of pressure corresponding to motions of the *steam-piston;* and in the *slide diagram* we have changes of pressure corresponding to the motions of the *slide;* and the important thing to notice is, that every sudden change of pressure refers to some prominent epoch in the slide's motion; and consequently we are enabled to trace successively on the paper, the various positions of the slide from its lowest point as it cushions the steam, allows fresh ingress, &c., and finally arrives at its highest point.

The following is a slide diagram, obtained by connecting the string to the slide cross-head of our model engine. The whole length of the figure is the same as the travel of the slide. If not, a plan must be adopted to be afterwards explained. When the pencil is at *d*, the slide is at the lowest point, and the vacuum is very good, as the slide rises till the pencil comes to *c*; but since we know *à priori*,

2328.



2329.



that the vacuum remains good in the engine till the cushioning commences, therefore when the slide has risen from *d* to *c*, the cushioning commences; the cushioning continues as the slide rises till the pencil arrives at *f*, when fresh steam enters, and after this epoch the slide still rises till the pencil has reached the point *h*. As the upper line is not so marked in its character as the lower one, we shall not say any thing of the downward stroke. Through the points *d c f*, &c., draw the vertical lines A *d*, B *c*, C *f*, D *h*, cutting the atmospheric line in A B C D, and the horizontal line E H in E F G H. Suppose E H to be the nozzle of the steam-port, on which the face of the steam-slide moves, (the cylinder being for convenience of illustration supposed to be lying *horizontally;*) then, since when the pencil comes to *c*, the cushioning commences, F must be the upper edge of the port. Take F J equal to the depth of the port, (which we will suppose known.) Again, since when the pencil is at *d* the slide is at the lowest, therefore we must suppose it to have started from E; and consequently, at starting, the upper edge of the slide was below the lower edge of the port, the space J E. When the *upper* edge of the slide arrives at G, fresh steam enters; in other words, the lower edge of the port is at J, and therefore the depth of the slide-face is J G. Moreover, since the slide still rises through the space H G, H G will be the greatest amount of opening for steam. The successive positions here spoken of are laid down in the figures under the line E H. F J is the depth of the port. In I the slide is at its lowest; in I I the cushioning is commencing; in I I I the steam is about to enter; in N the slide is at its highest.

When the travel of the slide is greater or less than the breadth of the diagram, let G E (Fig. 2329) be the breadth of the diagram, as in the last paragraph; from G draw G P, making any finite angle with G E, and equal to the travel of the slide. Join P E, and through F and H draw F O, H R, parallel to E P, and then proceed with the line H P, as in the last paragraph with the line H E, considering O to be the upper edge of the steam-port, &c.

It should be observed here, that the piston diagram does not necessarily return into itself, and forms

closed figure, as in the preceding diagrams. This only happens because the indicator-barrel contains the spring which, as has been stated, draws back the barrel directly the string relaxes. But we can by a different arrangement produce a figure, of some value, in which the curve proceeds continuously in one direction, and which, therefore, we shall call the "continuous diagram." Let the spring fitted to the traversing cylinder, for bringing it back, be taken out, and also the stop that prevents the cylinder from going too far; because our object is to let the barrel revolve freely. The clasp, by which the paper is usually secured, must also be taken off, and the paper must be secured by turning it over the top of the cylinder, and be folded in such a manner that the pressure of the pencil will help to keep it down. Let now some part of the engine be selected where a double pulley may be fitted to revolve, one groove of the pulley having about the same diameter as the pulley attached to the barrel, and the other to the diameter of the paddle-shaft. A string must be passed round this latter pulley and the shaft, and they will revolve in the same time. Another string must be passed round the pulley of the barrel and the smaller of the two pulleys; and then the indicator-barrel will revolve nearly in the same time as the engine shaft. And if we suppose the shaft to be revolving uniformly, which it will be nearly, especially where there are two engines, the barrel will have a uniform motion in one direction. If the pencil be put to the paper, as in ordinary cases, when the indicator-piston is at the lowest, it will commence tracing its curve. It should be allowed to remain for one entire revolution, and longer if convenient, provided one line do not interfere with the other in going twice over the paper.

The chief practical utility of these diagrams is, that they serve to show *the rate* at which the steam-pressure increases or decreases. It will be observed by the continuous diagram, Fig. 2310, that the steam-pressure does not increase instantaneously, as many suppose, and as the common diagram would lead us to believe. The vacuum commences at D and continues to E, the cushioning from E to A; the fresh steam enters at A, and causes the pencil to rise till it reaches its highest at B.

If we examine this diagram in page 56 by any of the previous tests, we shall find it rounded off at the corner, a circumstance not easily accounted for. For in all former cases we can only correct a defect in this corner at the expense of the lower corner. As the indicator persisted in giving this outline, and all attempts according to the foregoing principles (by altering the set of the slides, &c.) failed, it was at length proposed to examine the steam-piston itself; and accordingly, steam was let in at the lower port, and the cock of the grease-cup opened, when it was discovered that the piston was not steam-tight in the cylinder; and therefore, although when the engine was working the first impulse of the steam sufficed to drive the pencil up, yet as soon as the piston had got into motion, the escape of steam by leakage did not allow the pencil to rise so rapidly as it otherwise would have done.

It is evident that no part of the diagram can be below the atmospheric line, when an engine is worked without condensation; for the pressure can never be less than that of the atmosphere. And since the steam has not a free escape into the air, but is obliged to force open the foot-valve and delivery-valve, and make its way through the air-pump bucket, the resistance it meets with will cause the pressure to be greater than that of the atmosphere. Engines, whose steam-pressure is not considerably greater than that of the atmosphere, cannot be worked on the high-pressure principle. The next diagram was taken from an engine whose boiler-pressure is 7 lbs. In high-pressure engines, the diagram will be similar; because the steam having to escape by the blast-pipe, is pent up, and causes the lower part of the diagram to be above the atmospheric line. In general, the steam and vacuum lines must be worked out separately by the plan proposed in page 57; for it will be observed, that the lines intersect each other in the diagram. The indicator for high-pressure engines should be made expressly for the purpose: the scale of pounds should have a higher range, but need not go below the atmospheric line.

2330.

This curve presents a singular appearance, from the steam and exhaust line intersecting. Since the cushioning begins at the usual place, that is to say, at the same part of the stroke as when used as a low-pressure engine, the steam pent up on the exhaust side, and commencing with a pressure greater than that of the atmosphere, soon surpasses that of the boiler, so that when the port begins to open, the pressure suddenly falls. Again, when the entering steam is cut off, the pressure gradually falls, and before the end of the stroke it is less than that of the eduction; and when opened again to exhaust, steam enters from the condenser, and the loop of the left-hand corner is formed.

The *Dynamometer*, an instrument somewhat similar to the indicator, has been introduced into screw-vessels, for the purpose of enabling the engineer to record the exact amount of pressure given off by screw-shaft, and, consequently, the force the engine, by means of this instrument, is exerting to propel the ship. It is merely a lever, or a combination of levers; the shaft pressing near the fulcrum, and the farther end of the lever, or combination, being attached to a Salter's spring-balance. In the diagram, Fig. 2310, A B is the screw-shaft pressing as it revolves against a movable pin which is contained in the plomer-block at C, and can slide freely backwards and forwards; D E is the lever, having the fulcrum at D; the pin at C presses against a knife-edge on the lever, as is seen in the figure. The rod E F is connected with the spring of a Salter's balance, which cannot be seen in the figure, but is concealed from sight by the cylindrical barrel I K; F is also attached to the rod G H. This rod, as we perceive, has several grooves in it, so that the small fork carrying the pencil p may be brought in contact with more than one part of the barrel in succession, if desirable.

The barrel is made to revolve by means of a strap $a\,b$, connecting it with the screw-shaft; and it will be seen by the figure, that there are pulleys of different sizes connected with the bulk-head at M, and the shaft at N, by which the motion of the cylinder can be regulated, and be made quicker or slower at pleasure. The curve will evidently be somewhat similar to the *continuous indicator diagram*, consisting of a series of undulations according to the force of the steam and its action on the propeller. A

zero-line must be got, as in the case of the indicator. When the dynamometer is applied to large engines, the levers can be relieved of the pressure of the shaft; and this being accomplished, the index of the spring-balance will stand at 0, when the zero-line may be traced. The balance will also give the scale of pounds. After the diagram is traced, draw a series of equidistant lines at right angles to the zero-line, as in Fig. 2310, in the article on the indicator, which represents a dynamometer diagram taken on board a man-of-war steam-vessel, the dimensions being reduced one-half. The distance between the curve and zero-line must be measured and compared with the scale of pounds on the balance. Let this be registered on the diagram in its proper space. The sum of all these is then to be taken, and divided by the number of spaces taken into account. Thus we shall obtain the mean force of the lever on the spring of the balance; let this be multiplied again by the *leverage* of the dynamometer, and the result will be the pressure of the screw-shaft on the dynamometer, and, therefore, on the vessel.* To obtain the leverage, if the lever be compound, multiply together all the long arms, (measuring from the fulcrum,) and divide the product by all the short arms multiplied together, (measuring also from the fulcrum.)

The horse-power of an engine is to be found by the dynamometer in the following manner:

Having found the number of *pounds* pressure exerted by the screw-shaft, multiply it by the speed of the ship in knots, and the product by 6080, (the number of feet in a knot;) then divide the result by 60, (the number of minutes in an hour,) and by 33,000, and the quotient will be the horse-power.

Or the work may be shortened, thus:

Multiply the number of pounds pressure by the speed of the ship, as before, and this product by ·00307, and the product gives the horse-power.

This, it will be observed, is the *effective* horse-power after making allowance for friction and loss by useless resistance.

The diagram before referred to will elucidate the process of working out the result. This was taken simultaneously with two others; and the mean of the three pressures was 41·309 lbs. Multiplying by the power of the system of levers, the result was 8086·4 pounds, (the pressure exerted by the screw-shaft.)

The speed of the ship was 9·893 knots.

Hence $8086·4 \times 9·893 = 79998·7$.

And $79998· \times ·00307 = 245$ nearly, the horse-power required.

The horse-power by indicator at the same time was 465·6, showing a loss of 220·6 by friction, resistance, &c.

INDIGO. A blue substance much used as a dye-stuff. The best indigo is obtained from an Asiatic and American plant, the *Indigofera.* The plant is bruised and fermented in vats of water, during which it deposits indigo in the form of a blue powder, which is collected and dried, so as to form the cubic cakes in which it usually occurs in commerce. Indigo is quite insoluble in water; when heated it yields a purple vapor, which condenses in the form of deep blue or purple acicular crystals. When indigo is exposed to the action of certain deoxidizing agents, it becomes soluble in alkaline solutions, losing its blue color and forming a green solution, from which it is precipitated by the acids *white;* but it instantly becomes blue by exposure to air. This *white indigo* has been termed *indigogene,* and indigo appears to be its oxide. It is best obtained by mixing 3 parts of finely powdered and pure indigo with 4 of green vitriol, 5 of slaked quicklime, and 100 of water, repeatedly shaking the mixture. In about twenty-four hours the supernatant liquor, which is transparent, and of a green color, is to be decanted off, and poured into dilute muriatic acid, when the deoxidized indigo is thrown down; but, in order to prevent its absorbing oxygen and becoming blue, it must be most carefully excluded from the contact of air, which may be effected by siphoning it off into the acid, collecting it in vessels filled with hydrogen, and washing it with water deprived of air and holding in solution a little sulphate of ammonia. In this white state indigogene absorbs between 11 and 12 per cent. of oxygen to become blue indigo. It would appear from Dumas' experiments that indigogene is a compound of

	Atoms.		Equivalents.
Carbon	45	=	270
Hydrogen	15	=	15
Nitrogen	3	=	42
Oxygen	4	=	32
	1		359

and that indigo consists of 1 atom of indigogene = 359, and 2 of oxygen = 16. The chemical equivalent of indigo, therefore, is 375.

When indigo is dissolved in concentrated sulphuric acid, it forms a deep blue liquid, known to the dyers by the name of *Saxon blue.* The great mart for indigo is Bengal, and the other provinces subject to the presidency of that name, from the 20th to the 30th deg. of N. lat.; but it is also cultivated, though not nearly to the same extent, in the province of Tinnevelly, under the Madras government in Java; in Luconia, the chief of the Philippine Islands; and in Guatimala and the Caracas, in Central America. The following remarks, from the *Commercial Dictionary,* will exhibit the history of this now indispensable commodity, and the difficulties with which it had to contend before it obtained a permanent footing in the commerce of Europe. "It appears pretty certain that the culture of the indigo plant, and the preparation of the drug, have been practised in India from a very remote epoch. It has been questioned, indeed, whether the *indicum* mentioned by Pliny was indigo; but, as it would seem,

* A doubt has been expressed by some as to whether this is really the force exerted by the shaft on the vessel, on account of the shaft acting on a lever that yields to its force; but independently of the fact that none of the thrust can be lost, it is clear that the thrust at C is equal to the thrust at D and that at E, and these are the two forces acting on the vessel.

without any good reason. Pliny states that it was brought from India; that when diluted it produced an admirable mixture of blue and purple colors, (*in diluendo misturam purpuræ cæruleique mirabilem reddit;*) and he gives tests by which the genuine drug might be discriminated with sufficient precision. It is true that Pliny is egregiously mistaken as to the mode in which the drug was produced; but there are many examples in modern as well as ancient times to prove that the possession of an article brought from a distance implies no accurate knowledge of its nature, or of the processes followed in its manufacture. Beckmann (*Hist. of Inventions*, vol. iv., art. 'Indigo') and Dr. Bancroft (*Permanent Colors*, vol. i., p. 241–252) have each investigated this subject with great learning and sagacity, and agree in the conclusion that the *indicum* of Pliny was real indigo, and not, as has been supposed, a drug prepared from the *isatis* or woad. At all events, there can be no question that indigo was imported into modern Europe, by way of Alexandria, previously to the discovery of the route to India by the Cape of Good Hope. When first introduced, it was customary to mix a little of it with woad to heighten and improve the color of the latter; but, by degrees, the quantity of indigo was increased; and woad was, at last, entirely superseded. It is worth while, however, to remark, that indigo did not make its way into general use without encountering much opposition."

In common painting indigo is seldom or never used without a small mixture of white. A preparation from the leaves of the *anillo* is sometimes fraudulently substituted for indigo, but may be at once detected by throwing a piece into the fire, *as genuine indigo will not burn.*

INERTIA. (See FORCE.)

INVOLUTE CURVE, is that which is traced out by the end of a thread (while being unwound) that is coiled round another curve. This species of curve is frequently used in the formation of the teeth of wheels. (See GEERING.)

IRON, (Sanscr. *ais;* Mod. Hindost. *lohah;* Mod. Pers. *auhun;* Chald. *perzela;* Heb. *barzel;* Gr. *sidēron;* Swed. *jern;* Dan. *jern;* Icel. *jarn;* Franco-theot. *isar, isarn;* Mæso-Goth. *ais;* Germ. *eisen;* Ang. Sax. *isen, isern, iren;* Low Germ. *isen;* Fries. *ixsen;* Dutch, *yzer;* Erse, *jarann;* Welch, *haiarn;* Lat. *ferrum;* Ital. *ferro;* Sp. *hierro;* Fr. *fer*, &c.,) one of the longest known, the most generally used, and most extensively applicable of all the metals. Although found *native*, as it is called, it nowhere exists perfectly pure in nature. In the arts, it occurs under four conditions; 1. as pure iron: 2. crude, or cast iron; 3. malleable, or wrought, or bar iron; and 4. steel. Its precipitate, or release from a chemical solution or combination, is always pulverulent, and does not present the most important practical characteristics of the metal. Deposited in the electrotype-way, it is more coherent, but still friable. It is difficult to be produced by this method in large plates: pieces of an inch square are rare. Seen by reflected light, its surfaces in this condition are more brown than gray, owing to its immediate oxidation. A fresh fracture is, however, clear gray. Its texture is crystalline, or, more properly, an assemblage of crystals loosely cohering, which appear cubic. In this state it is not at all malleable. When fresh it is highly magnetic; but this property rapidly diminishes on exposure to the air or moisture. Its density is not known, and can with difficulty be accurately ascertained. When broken into spiculæ and approached to a wire no longer at a red-heat, or even to the lateral flame of a spirit-lamp, it decrepitates slightly and becomes converted into powder of the peroxide. Its other properties in this condition have not been thoroughly examined; nor are they likely to present much interest except for merely speculative, and, perhaps, for medicinal purposes.

In the condition of *steel*, on the other hand, all the peculiarities and habitudes of this metal are important enough to require a special detail and discussion in a separate article. (See STEEL.) Under this one will be considered what is proper to it in its two conditions of *crude* and *malleable* iron. The means for artistically producing these two different states, *i. e.* the manufacture of cast or bar iron, being different, must of course be detailed separately. In other regards they will be spoken of together, but distinctly wherever necessary; and it will be understood, that when not otherwise expressed, the term *iron* means *malleable* iron.

Physical properties. The *color* of crude iron varies according to the state of combination and proportion of its chief foreign ingredient, carbon, from dark gray to silvery white; passing through divers intermediate stages of gray, mottled, bright, and white. It is upon these indications, coupled with those of texture, (which will be spoken of directly,) that the metal is classified in commerce. Dark gray iron, crystalline, with small facets, is supposed to denote a fitness for foundry purposes, *i. e.* for being cast into various forms; and the denomination of such a whole class is *foundry-iron*, or *founders' pig.* As its color brightens and grows more and more silvery, with a bladed texture, it is considered better suited for conversion into malleable iron; and the whole class obtains the name ordinarily of *forge pig.* These distinctions, further than as applied to *classes*, are extremely loose and uncertain; and we are yet without positive knowledge as to either what causes or is a permanent practical consequence of *color* in crude iron. In malleable iron the distinctions in this respect are much less marked. A full gray hue, with something of a bluish tint, is generally supposed to attach to the best specimens. Of course, all these remarks apply only to the phenomena of a fresh fracture; and the color and lustre which may be given to surfaces of iron in either condition by finishing and polishing are, it will be readily conceived, entirely artificial, and dependent in no small degree upon the processes that may have been resorted to.

In the same manner, it may be presumed, another property, which is chiefly superficial, is dependent upon the artistical processes employed in developing it, and this is the *adhesion* of iron, *i. e.* the force with which it attaches itself to a liquid surface. This property has not been experimentally examined to any extent, though a research upon it would probably be fruitful for all questions touching the friction of machinery, and, perhaps, would also shed light upon the internal structure of the metal. The indefatigable Guyton-Morveau, only, has made observation upon it in the case of iron and several other metals, by polishing with an equal amount of labor the face of a disk, one inch French in diameter, (1·0658 in. English,) of the metals respectively, allowing each to repose an equal time upon the surface of mercury in a dish, and then seeing what weight was sufficient to overcome the adhesion. He found

the weight necessary in several cases (abstraction being made of that of the disks themselves respectively) to be as under:

Gold	required 446 gr. Fr.	= 365·72 gr. Eng.			Zinc	required 204 gr. Fr.	= 167·28 gr. Eng.	
Silver	" 429 "	= 351·78	"		Copper	" 140 "	= 114·80	"
Tin	" 418 "	= 342·76	"		Antimony	" 126 "	= 103·32	"
Lead	" 372 "	= 305·04	"		IRON	" 115 "	= 94·30	"
Bismuth	" 317 "	= 259·94	"		Cobalt	" 8 "	= 6·56	"

Although the *adhesion* of a surface in contact with the liquid in these experiments would be in part a function of the aptitude of the metal itself to amalgamate with quicksilver, yet these results are nowise accordant with such aptitude, as far as it can be inferred from other observations. And it seems to be equally independent of the density and cohesion of the solid. It is probably dependent in much greater degree upon the absolute perfection and smoothness of surface which, in bodies worked upon with the same force and for the same time, manifests itself according to another property, that of *hardness.* In ordinary speech, and sometimes even in exacter phrase, this term *hardness* is used to express the resistance of a substance to change of form of any kind. Such resistance depends mainly upon cohesion and elasticity, and covers, in part, the characteristics of malleability and stiffness. But *hardness*, in its technical sense, is resistance to removal or abrasion of substance, as in cutting, boring, filing, and the like. Any material which will *scratch* a given substance is therefore *harder* than that substance. Kirwan was the first to classify substances in this respect after a decimal scale, beginning with talc and ending with diamond. The eight intermediate tests are uniform and easily accessible minerals. Measured by such a scale, native iron (which may be considered as nearly the type of the malleable iron of commerce, though it contains a notable proportion both of lead and copper, generally,) is ranked in hardness at 4·5; that is to say, it scratches fluor-spar as much as it is itself scratched by phosphate of lime. Crude iron is harder, and most specimens of gray foundry pig are just scratched by felspar; it may, therefore, hold an average rank on Kirwan's scale of 5·8. But *white* forge pig will generally cut glass, and may therefore be ranked at 7 in hardness by the same scale. It will readily be understood that in applying these tests, something depends upon the shape and sharpness of the fragment used; a dull surface will merely rub without scratching; and in the case of white iron and glass, unless the lamellar crystals of the former be used with their edges, the latter will not be cut. It is the same with the diamond, the hardest known substance; only its spherical edges cut glass. In drawing a practical inference from such observations, regard must be had, too, to the ordinary *texture* of the substances, *i. e.* their mode of aggregation and cohesion. Thus white iron, hardened steel, quartz and granite, &c., have all the same theoretical index of *hardness;* but steel, for instance, is much more coherent than quartz, which is a brittle substance, and still more so granite; it is, therefore, used readily for working both. So sandstone, which is principally grains of silica held together with a siliceous cement, and therefore has an index of 7, is yet ordinarily worked with the same tools that are used for marble, whose index is but 3·5. But the causes and modes of these apparent inconsistencies readily manifest and reconcile themselves upon a little reflection.

So far as metals are concerned, the following table may be taken to give what is known in this particular; the foregoing cautions being equally applicable.

Table of Metals in the probable Order of their Hardness.

Mercury,	IRON,
Sodium,	Cobalt,
Potassium,	Nickel,
Lead,	Crude Iron, (gray,)
Zinc,	Steel, (soft,)
Tin,	" (hardened,)
Antimony,	Manganese,
Gold,	Titanium,
Silver,	Crude Iron, (white,)
Cadmium,	Chromium,
Bismuth,	Rhodium,
Tellurium,	Iridium, Osmium,
Copper, copper and zinc, (brass,)	
Platinum, copper and tin, (gun-metal,)	
Palladium,	Hardest steel, varying from white iron to the top of the list.
IRON,	

How much *hardness* is dependent on *texture*, has been already mentioned; and it is owing to the varying circumstances of this last property that iron in different conditions is found to shift about so much in the list just given. In practice, another property, that of affection by heat, or *specific heat*, (which will presently be mentioned,) has also an influence; and a substance, hard at first, becomes sensibly warm by attrition, and finally yields to the action of a material less hard than itself at low temperatures, but endowed with a greater capacity for heat. It is thus in one aspect that crude iron under a red heat may be cut and sawn almost like wood; and in the other, that a wheel of soft malleable iron, rapidly revolving, may be made to cut the hardest steel. Workmen have the opportunity of appreciating these affections in manipulations with the cold chisel.

The *texture* of crude iron is in most treatises said to be granular. It is in fact crystallized; as we learn from the chemical experiments of Daniell, and the microscopic observations of Schafhaütl and Alexander. According to the last-named, the crystals of gray iron "belong to the octahedral system, [in which the axes of crystallization are equal and at right angles,] and present themselves under the primary forms of several of its classes." "The maximum limit of these, when cubic, is not above $-\frac{1}{5000}$

of an inch in linear dimension, and about $\frac{1}{2000000000}$ of a grain in weight." Crystals in white iron are smaller, and "most frequently occur in six-sided prisms, sometimes connected in fascicles by their sides, at others by their ends, in a sort of stellated or radiated arrangement. The white color of the mass seems to be mainly arising from these arrangements of particles." Malleable iron is supposed to have a filamentous structure; but metallurgists are not agreed how far this arises from (as it is certainly in some degree dependent on) the processes employed in the manufacture. The amount of forging which the bars have undergone, the degree of heat to which they have been subject, as well as the ultimate size to which they may have been reduced, all affect the texture of specimens, whose other characteristics, originally and subsequently, are apparently the same. Nevertheless, this property and that of color are the chief commercial tests of the quality of iron. It is generally supposed that a *fracture* more pointed than irregular, and a tendency to become filamentous upon being forged into bars of an inch square or under, are indications of the two main characteristics of good iron, viz. strength and stiffness. But there is as yet no criterion by which, on simple inspection, the quality of the metal can be determined, and both the manufacturer and the consumer are compelled to rely (in the absence of actual experiment) upon the constancy of Nature in furnishing materials, and the uniformity of Art in subjecting them to the same processes. The same ores treated in the same way ought to produce the same metal; and so they generally do.

Closely connected with texture is the property of *density*. The variations in this respect between the results of different observers are to be attributed partly to the difference of methods, partly to the inaccuracy of the weights employed, (a much more influential cause of error than is generally imagined,) and partly to the variations of the individual specimens. Their limits are, however, sufficiently close to allow of taking as a probable average (the *density* or *specific gravity* of distilled water being called 1) the specific gravity of

Crude iron, foundry or gray iron, 7·
" forge pig or white " 7·5
Malleable iron,........................ 7·6

In estimating absolute weight, it is sufficient for practical purposes to consider a cubic foot of distilled water as equal to 1000 ounces avoirdupois; so that a cubic foot of iron in its different conditions will weigh one thousand times the indices of specific gravity given above, respectively, in avoirdupois ounces, sixteen of which go to the pound. For rough approximations, iron in general may be taken as weighing one-fourth of a pound to the cubic inch. So far as crude iron is concerned, the specific gravity has been recently considered in reports upon ordnance to the American government to be an index of another physical property, (of the greatest interest where cannon and guns are concerned,) viz., the tenacity or cohesive force of the metal. Of course, such indications are not regarded as absolute, but merely relative; and they have been supposed hitherto to apply only to the best sort of gray foundry iron.

Upon this property of *tenacity* or cohesion of iron in its different conditions, experiments have been very numerous and varied, with results as accordant as could be expected. They may be found detailed more or less fully in several special treatises; such as of Barlow, Duleau, Karsten, Navier, and Tredgold. The results of those whose apparatus may be considered as the most reliable, seem to show that cohesion depends not only upon the chemical composition of the metal, but also upon the way in which it has been treated; the amount of heat, for instance, to which it has been subject, the extent of forging it has received, and also the dimensions which have been given to it, and the form in which it has been left. Were the theory of the resistance of materials perfect, the behavior of the metal under one position or set of circumstances would determine for any or all; but in the absence of such theory, it is necessary here to give the observed results in the chief positions and circumstances in which the resistance of iron is practically called into play. These are four, viz.: 1. Resistance to a force tending to pull asunder in the direction of length; this is usually termed *absolute cohesion:* 2. Resistance to a force tending to crush in the same direction; this is termed *relative cohesion:* 3. Resistance to a force applied at any angle with the longitudinal axis of the mass, or a *transverse* force; this is termed *respective* cohesion: 4. Resistance to a twisting force, or to *torsion.* As to resistance to impact or *resilience*, that will be spoken of under the property of elasticity.

1. The *absolute* cohesion of malleable iron may be taken for square bars of different sizes as under; the resistance per square inch being proportioned to the *breaking* weight of the respective sizes.

In bars $\frac{1}{4}$ inch square; resistance per square inch = 90,000 lbs.
" $\frac{1}{2}$ " " " = 70,000 "
" 1 inch and over " " = 56,000 "

When the bars are round with the same area, they will show a somewhat higher resistance than the above; and when forged flat they appear more resistant than when round. Iron wire, from the mode of manufacture, is generally supposed to exert a greater proportionate resistance than hammered iron; but its average may be taken as included in the number given above. In fact, the increase of resistance inversely as the area seems to progress with wire to a certain point, when it changes sign, and the proportionate strength diminishes with the area. Thus, in Telford's experiments,

a wire $\frac{1}{5}$ inch in diameter gave a resistance per square inch of 94,080 lbs.
and " $\frac{1}{21}$ " " " " 80,192 "

Dufour's experiments, however, do not justify this inference. Annealed iron is hardly half as strong as the same wire unannealed. All these numbers being *extreme* loads, it will be readily understood that the metal ought never to be strained to such a limit. Up to a certain point, a bar or wire will stretch, and when the strain is taken off, return to its former dimensions; but beyond, although it will continue to stretch, it returns no more, the alteration and injury are permanent. As a general rule, it is injudicious to load iron with more than *one-third* of its breaking weight. The tables of Tredgold, which are extensively used and found safe in practice, allow the strength of malleable iron in this sense at

17,800 lbs. per square inch, which it can bear without permanent alteration. This may be taken for ordinary use at 18,000 lbs. per square inch.

Crude iron is but rarely employed as a tie; so that a knowledge of its absolute cohesion is comparatively of little practical consequence, and there have been proportionably few direct experiments. The mean of Tredgold's gives 44,620 lbs. per square inch as the breaking weight. The results of Muschenbrock, Brown, and Rennie, the former very much in excess and the latter in defect, do not appear reliable. In practice, we may take 15,000 lbs. per square inch as the strain that gray crude iron will bear in the direction of its length without permanent alteration. It is, therefore, about one-sixth weaker than malleable iron. White crude iron has not been experimented upon in this sense; but it is known, from observations on transverse strains, to be much weaker than gray iron. Iron of the second fusion (*i. e.* melted and cast from a cupola) is, in general, stronger than when run from the high-furnace. The method of casting (*i. e.* in vertical or horizontal moulds) does not, as far as observed, affect its absolute cohesion.

The following table gives the mean absolute cohesion of divers metals cast in pounds per square inch, viz.:

		Ratio.			Ratio
Cast-steel, tilted	135,000 lbs.	3·	Tin, cast	4,700 lbs.	0·104
Crude iron, gray	45,000 "	1·	Zinc, cast	2,800 "	0·062
Gun-metal, (copper and tin,)	34,000 "	0·756	Lead, cast	1,800 "	0·040
Brass, cast	20,000 "	0·444	Antimony cast,	1,000 "	0·022
Gold, cast	20,000 "	0·444			

And the following the mean proportionate cohesion of some of them when drawn into wire; iron wire being 1, or unity.

Copper	0·587	Gold	0·273
Platinum	0·500	Zinc	0·200
Silver	0·342	Tin	0·064
Gold	0·273	Lead	0·051
Iron	1·000		

2. In *relative cohesion*, or resistance to crushing, the two conditions of the metal appear to change places; crude iron being the strongest. The mean of many experiments of Karsten gives the resistance in this sense of crude iron, gray, at 168,750 lbs. per square inch.
" white, " 210,540 " "

The specimens were of the first fusion, cast from a cupola, and poured from a reverberatory furnace; the cupola castings were very uniformly the weakest, and those from the air-furnace the strongest of the sets. Those moulded *vertically* were also at a mean $2\frac{2}{3}$ per cent. stronger than those moulded *horizontally*. Wrought-iron has not been extensively observed in this respect. The mean of the experiments of Rondelet gives 70,000 lbs. per square inch (very nearly) as the weight under which bars from $\frac{1}{4}$ to 1 inch square began to give way. Its texture appears to prevent it from being *crushed*, even with the weight that would crush crude iron; for if the height of the specimen be triple its thickness, it will bend and double up sooner than be crushed. The practical effect in either case upon the equilibrium of constructions is pretty nearly the same. We are warranted, then, in considering the useful *relative cohesion* of wrought-iron at one-half that of gray crude iron. The following table exhibits this property as supposed to be ascertained for some other metals, viz.:

Crude iron, white, resistance per cubic inch,		210,000 lbs.	ratio	1·0000
" gray,	" "	170,000 "	"	0·8095
Copper, cast,	" "	117,000 "	"	0·5571
Malleable iron,	" "	85,000 "	"	0·4048
Copper, wrought,	" "	55,000 "	"	0·2620
Tin, cast,	" "	9,000 "	"	0·0429
Lead, cast,	" "	8,000 "	"	0·0381

The last four were not crumbled under the pressure, but flattened; their resistance was therefore entirely overcome; although their texture did not allow the same phenomena as belong to the crystallized structure of the others.

3. Experiments on *respective* cohesion of iron, *i. e.* its resistance to transverse strains, have been very numerous. Theoretically, their results should be functions of the *absolute* cohesion of the substance; but, partly from defect of theory, and partly from inherent difficulties and errors in observation, this is not exactly the case. As this is the sort of resistance most extensively required in practice, its determination is of the greatest interest. In addition to the variations arising from the qualities of the metal itself, it depends so much upon the dimensions and position of the mass exposed to strain, upon the angle of direction of the force or weight, and upon the degree of deflection that the equilibrium of construction will allow, that the statement of results can hardly be more condensed than the statistics of the experiments themselves. To give tables for practical use is liable to the same objection of taking up undue space, and also to the inconvenience of being limited in their application. All that will be done here, then, is to furnish general rules which may safely be calculated upon in all cases for apportioning the weight to the dimensions of the beam which is to bear it, viz.:

$$w = 100000\,\frac{b\,d^3}{l^2};\ \text{for gray crude iron.}$$

$$w = 62500\,\frac{b\,d^3}{l^2};\ \text{for white "}$$

$$w = 135000\,\frac{b\,d^3}{l^2};\ \text{for wrought-iron.}$$

Practical Rule.—Divide the product of the breadth of the beam and the cube of the depth by the square of the length, all in inches; and multiply the quotient by 100,000 for the weight in pounds when *gray iron* is used. With white iron multiply by 62,500; and with malleable iron, by 135,000 for the load in pounds. These coefficients correspond to a maximum deflection in the middle of the beam (which is assumed to be solid) of $\frac{1}{80}$ of an inch per foot in length; which it is not judicious to exceed although it is very often surpassed. The use of *white* iron should be as much as possible avoided in resisting strains of this kind. It is not only very little more than half as strong, but it is also less uniform and more uncertain.

These formulæ and rules apply to instances where the beam is supported at both ends, and strained by a force acting in the middle of the length, as in the case of mill-shafts, &c. Where the load is uniformly distributed over the length of such a supported beam, the effect is the same as if *five-eighths* of this load were applied in the middle of the length, and the weight borne in this case will be $1\frac{6}{10}$ times that ascertained by the rule just given.

When the beam is *square*, the formulæ and rules equally apply as when it is merely rectangular. If it be *cylindrical*, supported at both ends and loaded in the middle, divide the weight obtained by the rule for a square beam whose side equals the given diameter by $1\frac{7}{10}$ for the load that will produce the same deflection. If the load is to be uniformly distributed over the length of a *cylindrical* beam, it is near enough in practice to consider that its strength and stiffness will be the same as in a square beam with sides equal to the diameter of the cylinder, and loaded with the same weight in the middle of its length.

In all these cases, the weight of the beam itself must be taken into the account as part of the load, either uniformly distributed or centered in the proportion of 5 : 8, as the case may require. To diminish as far as possible the useless load in such instances, it is not unusual to make the beam or shaft a hollow cylinder. The rule for determining the dimensions becomes complicated; for strength and stiffness do not follow the same ratio of diameters. In general, it may be remembered that when the thickness of the metal is one-fifth of the diameter, (which, if the load is considerable, is not more than a safe proportion,) the strength of the hollow cylinder is nearly two-thirds, and the stiffness one-half nearly of what they would be respectively in a square beam of the same depth, while there is a saving of one-half the quantity of metal.

4. The capacity to resist *torsion* is of great importance in the substance of which the revolving parts of machinery are made; for it is not unfrequently by a submission to torsion that both power and durability are secured. Navier has explored the theory of this resistance; but the experimental constants which are required to make the theory of practical application are unfortunately deficient. The results of the observations made hitherto are remarkably discordant. The following table gives the proportionate resistance in this respect of various metals.

Cast-steel,	19·56	Crude iron, (cast horizontal,)	9·94
Shear "	17·06	Hard gun-metal,	5·00
Blister "	16·69	Fine brass,	4·69
Crude iron, (cast vertical,)	10·63	Copper, (cast,)	4·31
Wrought-iron, (coal,)	10·13	Tin,	1·44
" (charcoal,)	9·50	Lead,	1·00

It appears from this, that iron in all its conditions exercises this resistance pre-eminently; and that crude iron does not differ in this respect materially from wrought-iron. It has been generally assumed in metallurgic treatises hitherto, that resistance to torsion is in proportion to absolute cohesion. The experiments, so far, do not sustain this, as between malleable and crude iron.

In a preceding paragraph, a distinction has been made between *strength* and *stiffness*. Although both are in part functions of the absolute cohesion, yet the latter is a measure more particularly of another physical property—that of *elasticity*. It is in virtue of its cohesive strength that a substance resists *any* change of form or position; it is in proportion to its elasticity that such changes, when occurring, are not *permanent*. Thus, up to a certain point, a bar or wire which has been lengthened by a strain will, when the strain is removed, return to its original length; or a beam that has been deflected by a load will, upon being relieved from the load, reassume its horizontal position. When this point is passed, and the extension or deflection remain permanent after the cause producing them has ceased to act, we say ordinarily that the piece, whatever it may be, has *taken a set*, and, technically, that its elasticity is overcome or destroyed. Gray crude iron will allow an extension, within the limits of its elasticity to recover, of $\frac{1}{1200}$ of its original length when the strain is acting in that direction: it is not safe to allow for a greater deflection in masses which have to bear a permanent load, (such as joists, girders, &c.,) than $\frac{1}{80}$ of an inch for each foot in length, or say $\frac{1}{1000}$ of the length, in round numbers. White iron is not reliable either for extension or deflection. Malleable iron will bear an extension without injury of $\frac{1}{1500}$ of its length, only its deflection ought not to be allowed to surpass $\frac{1}{1000}$ of its length. These deflections are of course measured where they are the greatest, viz. in the middle of the length.

There is another manifestation of elasticity in resistance to *impact*, or, as it is technically termed, in *resilience*; in virtue of which a substance yields in form or position to the momentum of a sudden impulse or blow, and then returns to its original state. This resistance is of great importance in machinery, to aid in determining what velocity the moving masses should be allowed to have; for the impact and shock are the same whether the substance in question strikes against a body at rest, or, itself at rest is struck by a body in motion. In theory, *resilience* is a function of absolute cohesion, and of density as well as of elasticity; and hence certain woods possess this property in a higher degree than many metals, and nearly as high as iron itself. Whalebone exhibits it in a pre-eminent degree.

Table showing the proportionate Resilience or Resistance to Impact of divers Substances.

Iron, (crude or wrought,)	1·000	Iron, (crude or wrought,)	1·000
Gun-metal, (copper 8 + tin 1,) cast,	0·819	Brass, (cast,)	0·400
Yellow Pine, (American,)	0·740	Beech,	0·326
Oak, (English,)	0·724	Larch,	0·315
Mahogany,	0·630	Lead, (cast,)	0·246
Elm, (English,)	0·620	Zinc, "	0·190
Ash,	0·600	Tin, "	0·142
White Fir,	0·567	Whalebone,	3·000

The following comparative summary may be taken of the chief practical resistances of iron and some other substances employed in constructions and in machinery.

	Strength.	Extensibility.	Stiffness.
Crude iron, (gray,)	1·00	1·00	1·00
Brass,	0·44	0·90	0·49
Gun-metal, (copper and tin,)	0·65	1·25	0·54
Iron, (malleable,)	1·12	0·86	1·35
Lead,	0·10	2·50	0·04
Marble, (white,)		1·00	0·14
Oak,	0·25	2·80	0·09
Tin,	0·18	0·75	0·25
Zinc,	0·37	0·50	0·76

The remaining properties of iron connected with its texture do not, as yet, admit of being numerically valued or proportioned. Such is the case, for instance, with *malleability*, or the capacity of being extended in one or more directions by hammering. White crude iron does not display this property at all; gray iron possesses it generally in a slight, and sometimes in a considerable degree. Wrought-iron in this respect is inferior to gold, silver, copper, tin, cadmium, platinum, lead, and zinc; the order of the names here representing the order of malleability in actual extent of surface which can be given to a unitary mass of the same volume, by the most suitable treatment. All other metals are inferior to iron in this aspect; though, if the question were as to the extent of surface which could be gained by a continuous hammering, its relations would be altered. It tends to become very brittle by forging; and, besides requiring the application of great force in the aggregate, has to be frequently softened by heat during the process. The *harder* the iron is in its original state as wrought-iron, the more often such softening has to be resorted to; whence it may be inferred that, *ceteris paribus*, the softer the iron the more malleable it should be. And the same inference attaches in the property of *ductility*, or capacity for being drawn into wire. This is in so far different from malleability, that heat is a necessary part of the process if it is carried to any great degree; and the order of ductility of the several metals varies from that of their malleability accordingly. Gold, silver, and platinum are the only metals more ductile than iron.

Magnetism, or the property of permanent polarity, was formerly supposed to belong to iron only. Later researches show that this is to be shared, though not equally, with nickel, cobalt, and chromium. Occasional magnetism may be excited in most substances; as is shown by their influencing the oscillations of a freely suspended magnetic needle. But this influence is much weaker in all other substances than the four named. *Silver*, which stands the highest of all the other metals, is nine times feebler in this respect than iron; gold fifteen times, and marble nearly twenty times, more weak. Iron acquires magnetism by contact or suitable friction with a magnet; by being suitably rubbed or struck in a proper position; by exposure to refracted light of the sun; and even by being left to stand in a nearly vertical position. The processes for this purpose will be described under the proper article. (See MAGNETISM.) It is enough to say here, that owing to the ease with which it is accidentally developed, it is extremely difficult to find in the shop of a philosophical instrument-maker, for instance, a tool or scrap of iron which is not in some degree magnetic. In all its conditions and states it is susceptible of this property, but develops it differently in each. Thus, gray crude iron becomes sooner and more intensely magnetic than white iron; but yields in both these regards to wrought-iron and to steel. Soft ductile iron is more easily and more strongly magnetizable than steel, but does not retain its magnetism as well. A similar relation is observable between untempered and tempered steel. The magnetism of iron may be weakened or lost by methods similar to those which originally impressed it. The filings of a magnet are less magnetic than the solid mass. A heavy, sudden blow or shock, against a hard body, will sometimes destroy magnetism. Heat always diminishes it; although there are some peculiarities which have been observed in this regard that are difficult of explanation. It undergoes deterioration whenever similar poles of two equally strong magnets are kept in prolonged contact; and finally, is always abated by alloying with other substances, and may be destroyed entirely by increasing the proportion of alloy. Arsenic is, in this regard, the most active of the metals; though an alloy of two-thirds arsenic does not entirely prevent the mass from being attracted by the needle. Mushet, however, affirms that twenty-two per cent. of manganese effectually destroys magnetism in an alloy of iron.

Malleable iron is an excellent conductor of *electricity;* and although in this respect inferior to copper and zinc among the easily oxidized metals, and to gold, silver, and platinum among the others, it is yet, for economy, universally employed for lightning-rods. In the Voltaic pile it follows zinc in the order of electro-positive metals.

Its *electro-magnetic* properties are very remarkable, in the facility with which it is converted into a magnet of great energy during the passage through it of an electric current. It is to this that the electro-magnetic telegraph owes, in part, its adaptation and success.

Hitherto the properties of iron have been considered as manifesting themselves at ordinary temperatures. It remains to speak of the modifications and peculiarities which arise from its affection by heat. Of all the metals, this has the greatest *specific heat; i. e.* the greatest capacity for heat, or faculty of resisting change of temperature. It bears a greater quantity of caloric for a longer time, and with less alteration of its own sensible temperature. The index of its specific heat has been observed by Dulong and Petit as follows:

32° F. to 212° F.	0·1098
392° F.	0·1150
572° F.	0·1218
662° F.	0·1255

Supposing the capacity for heat to augment in the same ratio, we would have at the supposed epoch of *red-heat* an index = 0·1402, and near the probable point of fusion = 0·3282; that of water in equal weight being 1·000. The specific heat varies according to the condition of the metal, and appears to be in some proportion to the quantity of carbon associated in each. Thus the specific heat of steel, as observed by Regnault, is represented by the index = 0·11848, and that of white crude iron = 0·12983. Gray crude iron, as far as may be inferred from observations of refined iron, would have a lower index than white iron, but there are not observations to settle this.

The *expansion* of iron by heat presents it in a similarly advantageous character. It expands less than any of the metals except platinum, palladium, and antimony. The observations hitherto have been made principally upon its expansion in one direction; *i. e.* its linear expansion, or *extension.* It is supposed to be accurate enough for practice to consider this extension as equal in all directions, and as, therefore, the one-third of the cubic expansion. All the experiments upon the extension of crude iron have been with metal of the second fusion, which is almost always gray. It may be presumed from practical phenomena on the large scale, that white iron expands less than gray. The mean of the results of Roy, Lavoisier, and Daniell with cast-iron, gives an extension in length of 0·0010974249 between 32° F. and 212° F.; the original length being 1· at 32° F. This corresponds to an extension (sufficiently accurate for practical use) of $\frac{6}{1000000}$ of the original length at 32° for each degree of Fahrenheit. The extension of wrought-iron has been more frequently and more variantly observed. The results lie between 0·000600 of Bonguer and 0·001446 of Hallström, as the extension on a length originally 1· at 32° F. Theoretical considerations, as well as an average of the most reliable observations determine this extension at 0·0011356 for 180° between the melting of ice and the boiling of water; corresponding to $\frac{63}{10000000}$ of the original unity for 1° F. The extension of steel appears to be uniformly higher than this, and to vary according to the temper of the metal in that condition. (See STEEL.) Between the limits given, the rate of expansion may be taken as constant for each degree, although in strictness such is not the fact; beyond 212° F. it would not be proper to rely upon such an assumed constancy: but at these higher temperatures a knowledge of the dilatation is chiefly interesting in theoretical science. Rinman supposed, from some observations, that between ordinary summer-heat (say 76° F.) and what is called *red-heat,* crude iron extended $\frac{1}{80}$ and wrought-iron $\frac{1}{140}$ of its original length: but these estimates can hardly be relied upon. The following table presents the most probable values in this particular, as well as certain other phenomena:

Table showing the actual Extension of Wrought-Iron at various Temperatures.

Degree of Fahrenheit.	Length.	
32°	1·	
212	1·0011356	
392	1·0025757	
572	1·0043253	Surface becomes straw-colored, deep yellow, crimson, violet, purple, deep blue, bright blue.
752	1·0063894	
932	1·0087730	Surface becomes dull, and then bright red.
1112	1·0114811	
1652	1·0216024	
2192	1·0348242	Bright red, yellow, welding heat, white heat.
2732	1·0512815	
2912	cohesion destroyed.	Fusion perfect.

In the property of *conducting* heat, iron occupies a low rank. The following statement is warranted by the observations of Dergnetz:

Substances.	Conducting Power.	Substances.	Conducting Power.
Gold	2·6728	IRON	1·
Platinum	2·6223	Tin	0·8121
Silver	2·6009	Lead	0·4801
Copper	2·4010	Marble	0·0625
Zinc	0·9722	Porcelain	0·0326
IRON	1·	Brick-clay	0·0302

These observations refer to malleable iron. Crude iron, whose specific heat is greater than its dilatability is less than the same properties of wrought-iron, is, it may be inferred, a worse conductor. Upon its power of *absorption, radiation,* and *reflection* of heat, in either condition, there have been no reliable observations.

Besides the influence upon dilatation, an effect seems to be produced upon the *cohesive force* of iron by temperatures either higher or lower than ordinary. In regard to low temperatures, it may be assumed, in general, that they promote fragility. It is uniformly observed that iron is much more brittle in winter than in summer; and this holds good equally for all conditions of the metal. Cold weather is, therefore, unfavorable for any practical test of quality, (such as for cannon, chain-cables, &c.;)

especially one dependent in any way upon impact. On the other hand, with temperatures higher than ordinary, but yet below the point of boiling water, Tredgold supposes the absolute cohesion to be diminished $\frac{1}{5000}$ by an elevation of 1° F. in temperature. Under temperatures which transcend the boiling point of water, the table given above has already indicated the most remarkable phenomenon—the *iridescence* or succession of colors during the augmenting application of heat. To what this effect is owing is not known; partially, perhaps, to the color produced by the contact of thin plates, and partially to an oxidation of surface. This last cause is assured by the permanence of the color after the heat has ceased to be applied. The *straw* color is developed fully at 400° F., the fusing point of tin; the deep *yellow* occurs at 420° F.; *crimson* follows at 450° F., where bismuth fuses; from that *violet*, *purple*, and *deep blue* succeed, till 540° F., the melting point of lead; this blue brightens, passes into sea-green, and at last disappears at 700° F., the fusing point of zinc. Beyond this, the epochs of temperature have no distinctive test. But if the heat is continued, there occurs a secondary, and, finally, just before red heat, a tertiary succession of the same color and in the same order, only less vivid and less lasting. If the metal be withdrawn at the close of this tertiary series, its surface will be found covered with a thin pellicle of oxide, whose constitution has not yet been examined. The practical utility of these color-tests is principally found with *steel*, where they serve as guides to determine the probable temper imparted. The deep-blue color is also used in the arts as an ornamental and anti-oxidable tint. Iron, in its different conditions, is not similarly affected in this respect. In general, steel is colored at a lower temperature than what has been given as applicable to the case of malleable iron, and gray iron at a higher one. White iron has not been as yet experimented on. But as there is reason to conclude that the colors occur in the direct ratio of the hardness of the metal, white crude iron may be expected to surpass steel. Of the same bar, the harder and softer portions are emphatically designated in this process. The coloring thus depending on hardness, its brilliancy is determined by the state of polish of the surface. And as the hardness of the metal thus influences the phenomena of colors, so it is in its turn reacted on by the heat which produces them. It is on this account that iron which has become hard in being wrought and hammered, is exposed to heat in order to soften it, as has been noticed before. The degree of heat requisite is in proportion to the hardness existing and to the softness required: in practice, however, it is generally a full-red heat. Iron, in all its conditions, appears to be permanently softened by being thus heated, whatever may have been its character or treatment before. The hardness and brittleness which may be cured by this resort, must be distinguished from the same characteristics arising from a peculiar chemical composition. Thus, there is a sort of iron which becomes brittle by the application of heat. Metal of this class is well known under the name *red-short*, or *hot-short*, and is met with in all conditions. Again, there is a kind of iron precisely opposite: brittle at ordinary temperatures, it becomes tenacious when hot; though, like the other, it undergoes no permanent change, and the modified characteristic belongs only to the modified temperature.

Sudden cooling appears to augment the effect of low temperature, and to impart greater or less hardness to the metal, according to its previous quality. In the case of steel, this is of the utmost interest; for on it depends the whole business of *tempering*. In other conditions the effect is less marked, but sufficiently sensible whenever the conducting power of the cooling material is not out of proportion to the mass of metal acted upon. The conducting power of the air is never sufficient, ordinarily, to produce any of the phenomena of sudden cooling: exposed to that, the cooling is always slow, and, according to its temperature, follows, more or less, the softening effects which have been already spoken of, and which are technically known as *annealing*. But this will be spoken of more particularly under the metallurgic treatment of iron.

The effect of sudden cooling is more manifest in temperatures higher than red heat, and especially upon the metal in fusion. The observation of this is more readily made upon crude than wrought-iron; and the most remarkable effect is the conversion of gray iron into white, which takes place more or less completely in proportion (other things being equal) to the mass operated upon. On the other hand, white iron can be converted into gray by an opposite method of treatment; and this not only on the small scale, but also in large. Indeed, as was said before, iron of the second fusion, allowed to cool slowly, is almost uniformly gray. But gray iron, cast in moulds of any sort which conduct heat with sufficient rapidity, (such as cast-iron moulds,) uniformly *chills*, as it is termed; i. e., becomes converted, to a greater or less depth from the surface, into white iron. Practical advantage is taken of this in the manufacture of wheels for railroad cars, which are always purposely chilled to increase their durability.

It is at temperatures above red heat that the most important and practically useful modifications of this metal take place in all its conditions. Not to refer any further to steel, the *welding* of malleable iron and the *fusion* of crude iron, by which either of these are made applicable to the arts and wants of mankind, occur at about the same epoch of temperature, somewhat further removed from red heat than this last is from ordinary states. The table before given has already indicated the temperature of the probable fusion of malleable iron, which is a little above that of crude iron. The uncertain indications of Wedgwood's pyrometer for a long time induced an erroneous estimate of the amount of heat required for the fusion of metals generally, and especially that of iron. Daniell has shown, by experiment with a much more reliable apparatus than that of Wedgwood, that cast-iron (so called) cannot require a higher temperature for fusion than would be expressed by 2786° F.; while Alexander has demonstrated, from the known relations and properties of cohesive force and specific heat, that bar-iron (whose utter infusibility was long maintained) must become fluid at about 2774° Fahr. We are yet deficient in a pyrometer whose indications would be uniform when applied in temperatures as high as this, a desideratum whose supply would contribute materially to the filling up of the theory of the manufacture of iron. It is probable that an air-thermometer, whose tube, where it entered the furnace, is of platinum, would afford the most unexceptionable and reliable results.

The capacity for being *welded*, i. e. performing an intimate and perfect union of two surfaces, occurs at the epoch of incipient fusion. This property is possessed by iron alone of all the metals, except platinum and palladium. White crude iron, under ordinary treatment, does not show this characteristic

at all. Gray iron is weldable, but in such narrow limits of temperature that the operation has to be effected with great quickness in order to succeed. With bar-iron and steel, in sufficient masses, welding is of every-day application. If the masses be very small, they cool too quickly to be welded in the ordinary way. Crude iron in fusion occupies a less space than when solid; in this respect its anomaly (which is to be traced to crystallization) is shared with antimony, bismuth, sulphur, and zinc, among the metals, all of which shrink in melting. The same may be observed of water, which is more dense when fluid than when crystallized in the shape of ice. If a mass of crude iron be made hot and laid upon a bath of melted metal, it floats; but if it be cold, it tends to sink. Perhaps this may be owing to the repulsive effect of heat. White iron, in this respect, shrinks less than gray. On an average, good gray foundry iron shrinks rather more than the $\frac{1}{96000}$ of its volume when cold. The general allowance of the founders in making their patterns is $\frac{1}{8}$ of an inch to the foot lineal.

Exposed to heat at any temperature from red heat upwards, with access of air, iron, in all its conditions, is readily covered with a coating of oxide. Bar-iron is thus oxidated more easily than crude iron; and of this latter, gray iron forms, at the same temperature, a more friable oxide than white. The following contrast may be taken to exhibit the most important characteristics of the two conditions of crude iron when exposed to high temperatures, viz.:—

Gray Iron

Is less easily oxidated; preserves its character longer, but loses it (cohesion, &c.) more completely at last; suffers these changes more when protected from the air; heated below the fusing-point, with access of air, demands more heat and more air to assume a certain malleability; requires a higher temperature for fusion; when fused is more liquid; expands more in cooling; fused rapidly and cooled quickly, tends to become *white;* fused rapidly and cooled slowly, retains its character or becomes more soft.

White Iron

Is more easily oxidated; loses its character sooner, and becomes granular, grayish, and steel-like in malleability and temper; suffers these changes more when protected from the air; heated below the fusing-point, with access of air, becomes quite malleable, and may be tempered to take an edge; fuses at a lower temperature; when fused is less liquid and more pasty; expands less in cooling; fused rapidly and cooled quickly, becomes extremely brittle; fused rapidly and cooled slowly, becomes *gray.*

The precautions necessary in view of these peculiarities, as well as the general processes, will be described under the head of FOUNDING; and what has been said may be considered as covering the chief physical properties of the metal.

Chemical affinities and reactions.—These have been observed for the most part with the iron of commerce, which is never entirely pure, but contains carbon, silicon, phosphorus, sulphur, arsenic, chromium, titanium, magnesium, aluminum, and manganese, in very minute proportions. Nitrogen is sometimes met with; but oxygen, which was formerly considered a constituent, has not been recognized in the later researches of the most accurate chemists. The chemical symbol of iron is **Fe**, and its atomic weight 339·205, oxygen being taken as 100. In the system where hydrogen = 1· the atomic weight of iron is 28·, as an average round number.

With *oxygen,* iron combines in two proportions, whose resulting compounds appear capable of fresh combinations, so that in point of fact *four* compounds are known to exist. The first is the state of protoxide, which does not exist naturally nor artificially, except as a hydrate. The second in the proportion of oxygen is the *forge-cinder,* formed on the surface of the metal by heat, with access of air, and thrown off under the hammer or squeezer. The third is the *black* or *magnetic oxide,* (the *oxidum ferroso-ferricum* of Berzelius,) which exists also naturally; and the fourth is the *peroxide, red oxide,* or *sesqui-oxide,* the first and last of which epithets are used according to different theories of its constitution. This also exists as a mineral, under the name of *red hematite,* and is massive, fibrous, or crystallized, according to circumstances. Its hydrate is known to mineralogists as *brown hematite.*

The following table contains all that need be given about these oxides:—

Name.	Composition. Iron.	Oxygen.	Iron.	Oxygen.	Atoms. Iron.	Oxyg.	Proportionate Index of Oxygen
Protoxide	0·7723 +	0·2277	100 +	29·48	3 +	6	24
Forge-cinder..........	0·7516 +	0·2474	100 +	32·90	3 +	7	27
Magnetic oxide	0·7178 +	0·2821	100 +	39·30	3 +	8	32
Peroxide...............	0·6934 +	0·3066	100 +	44·22	3 +	9	36

The three first are attracted by the magnet, the last is not. The colors which have been before spoken of as accompanying different degrees of the application of heat, are also doubtless due to the formation of oxides, whose constitution, however, is not known. The affinity of iron for oxygen appears to be in proportion to its own purity, and also, though in a less degree, to the state of its surface. So, in respect to that peroxidation which is very familiar as *rust,* and which tends to occur more or less upon this metal when exposed to the action of the air, (and especially damp air,) white iron is less affected than gray, and any crude or cast-iron less than the malleable metal. This difference of the different conditions holds good in the case of moisture alone, and in general with most chemical agencies.

Pure *water,* disengaged of air, does not act upon iron at all at ordinary temperatures. Above 120° Fahr., the water is slowly decomposed, and yields its oxygen; at 212° Fahr., the decomposition is quite sensible; and at a red heat it is very rapid, hydrogen is given off, and magnetic oxide formed. At intermediate degrees, the action is nearly in proportion to the temperature. In practical cases, where the oxidation of the metal is an inconvenience, (as in steam-boilers, &c.,) it may be remedied to a considerable extent by the introduction of other metals having a greater affinity for oxygen. Pieces of zinc, for instance, will serve the purpose very well, to keep the boiler clean and unimpaired. Impure water acts in proportion to the activity of the salts it may happen to hold in solution, and differently upon different conditions of the metal. Thus, *sea-water,* which merely gives a coat of oxide to bar-iron

(anchors, chain-cables, &c.) to a depth proportionate, but in a diminishing ratio, to the time of immersion, converts cast-iron (cannon, cannon-balls, &c.) into a substance resembling *plumbago*, or *graphite* i. e. into carbon, associated with metallic and oxygenated iron. Such conversion appears to be less with white than gray iron.

Air and moisture together appear to exercise a more powerful agency in producing oxidation than either separately, and as this is precisely the joint influence to which this metal is in most practical cases exposed, there is the more interest in providing a preservative. This is found not only, as was said just now, in the polish of the surface, but also in the means by which such polish is produced, in special coatings of substances which resist humidity, and also in the protecting action of incipient oxidation itself. Thus, in the first instance, a polish acquired under the use of oils (and still more as those oils may be themselves unalterable) is more lasting than one obtained with water. One of the best preservatives of the second kind, is a solution of caoutchouc in oil of turpentine, which is applied upon the polished surface, and is then removed, or rather brought down to extreme thinness, by a brush dipped in the same oil, heated. Among the third sort has been already mentioned the *bluing*, which is effected by a temperature of about 550° F.; and *bronzing*, as it is called, is of similar result. This is done by washing the surface, which should be smooth, with acids, and mostly hydrochloric acid, exposing it for a suitable time to the air, until it becomes thoroughly covered with a uniform coat of oxide, and then removing that rust with olive-oil as a menstruum, until the surface ceases to soil white linen. This is the common resort for gun-barrels. Electric gilding, (see GILDING,) although beginning to be extensively used in the bright parts of machinery, which are not subject to friction, does not come properly in the category of the preservatives we have been considering.

The combination of *carbon* with iron gives rise, in fact, to the different conditions of this metal. In white iron and steel it is chemically combined with the mass; in gray iron it is partly combined in polycarburets dispersed about the mass, and partly free, as graphite, (called, by the workmen, *kish*;) in malleable iron it does not exist at all, or only in insignificant proportions. Karsten considers 5·3 per cent. as the limit of saturation, which would give for the atomic constitution of the percarburet, *one* atom of carbon to four atoms of iron. In gray iron the whole quantity of carbon does not, at a maximum, exceed 4 per cent., of which 1 per cent. may be taken as *combined*, and 3 per cent. to be mechanically associated as graphite. Although the occurrence of carbon is the principal modifier of the condition of this metal, it is probable that the differences, so far as crude iron is concerned, are owing to other associations also. Thus, as *nitrogen* has been found only in *white* iron, it is likely that some of its characteristics depend upon the formation of compounds of nitrogen and carbon, and, ultimately, of cyanurets of iron. It is very much to be desired that this suggestion could be studied in the synthetic way. The practical precautions which have to be taken in consequence of the affinity of iron for carbon, will be referred to hereafter, under the head of *Foundry*, and also under the article STEEL.

Sulphur combines with iron in several definite proportions, both artificially and in nature. Until the proportion reaches 2 atoms of sulphur for 1 atom of iron, (or 53 per cent. sulphur nearly,) the compound is attracted by the magnet. This proportion may be considered as that of the natural *magnetic pyrites*. Four atoms of sulphur to one of iron constitutes the common iron pyrites. Sulphur promotes the fusibility of iron extremely, so much so that a plate or bar of iron, kept only at a red heat, may be pierced to a considerable depth (say an inch, or more) by a stick of sulphur. Unfortunately, the quality of the metal becomes so far impaired as not to allow avail of this peculiarity in the arts. Sulphur combined with iron causes brittleness at all temperatures, and especially what has been before spoken of as *red-shortness*. Experiment has shown that $\frac{1}{3000}$ of sulphur is enough to produce the first characteristic, and $\frac{1}{10000}$ the second. It is hence that many ores cannot be advantageously (and some not at all) applied in the reduction of this metal. Where the proportion of sulphur is minute, it may be partly volatilized by previous roasting, and partly taken up by excess of lime in the flux. By this last application, the sulphur in the coke of some of the English furnaces is gotten rid of. The remarkable action of sulphur upon iron-filings, when made with water into a paste, (which, after a while, develops intense heat, and finally bursts forth in spontaneous flame,) belongs more properly to the formation of sulphuric acid, but may be mentioned, once for all, here. The influence of compounds of sulphur and carbon together has not yet been satisfactorily studied.

As sulphur gives the property of *red-shortness*, so *phosphorus* seems to impart that of *cold-shortness*, or brittleness at low temperatures, but not to an equally prejudicial extent. There is hardly any iron in which a trace of this substance cannot be found. With bar-iron occurring in proportions as high as $\frac{1}{4}$ per cent., it only hardens the metal without diminishing tenacity; at $\frac{3}{4}$ per cent. the tenacity is seriously diminished; and over 1 per cent. makes the iron of very bad quality and very limited use. Phosphorus lessens the capacity for heat of the metal, and increases the facility with which bar-iron can be welded. Crude iron it makes more fusible and retains longer melted, so that in minute proportions it is rather an advantage for castings. Phosphorus appears capable of uniting with iron in all proportions, but at a high temperature there is but one definite compound, consisting of 2 atoms of iron and 1 of phosphorus, or iron 0·776 + phosph. 0·224. The natural kingdom does not afford any phosphuret of iron, but phosphates are widely extended and numerous. Phosphorus is supposed to behave with carburets of iron in a similar manner with sulphur, but, like this last, has not in this respect been studied.

The effect of *acids*, of whatever kind, upon iron, appears to depend upon the presence and decomposition of water; and hence, in an anhydrous or concentrated state, their action is uniformly more feeble than when dilute. The presence of carbon, too, and its state of combination, also affect, and in their proportion weaken, the influence of the acid. Thus steel is distinguishable from iron by the ease with which it is attacked and stained by nitric acid, and white iron is more affected in this manner than steel. Hard iron, in all conditions, is less easily attacked than soft; and upon this, as well as the state of combined carbon, rests the art of *damascening*, or watering the surface of iron and steel.

Acetic acid acts readily upon iron and upon its peroxide, but slowly upon the protoxide. The acetate of iron thus produced is used extensively in calico-printing, under the name of *iron liquor*.

Carbonic acid, without the presence of water, does not act at all on iron or its oxides, artificially, though *carbonates of iron* form a very extensive and important class of minerals. The different sorts of coloring-matter known as *Prussian-blue*, are carbo-azotic compounds, or hydrocyanates of iron, whose practical use is better understood than their theoretical composition. (See PRUSSIAN BLUE.)

Gallic acid, which is a compound of oxygen, hydrogen, and carbon, acts very feebly upon iron and its protoxide, or, perhaps it may be said, not at all; but upon the peroxide it acts energetically, striking a deep, black, and permanent color, and constitutes, in fact, the basis of all ordinary black inks.

Hydrochloric acid acts with great readiness upon iron and its oxides. For all applications in the arts where the object is to produce or remove oxidation, it is undoubtedly the best, though not the most economical agent. Upon crude iron it is best to be employed concentrated.

Nitric acid, highly concentrated, has but a feeble action upon iron; at its average concentration it acts with great energy. On account of its peculiar behavior towards carburets of iron, it generally enters as an ingredient in etching-liquors. Thus, for making damascene designs upon cutlery, Rinman recommends a wash composed, by weight, of 4 nitric acid + 2 sal-ammoniac (hydrochlorate of amm.) + 1 sulphate of copper + 72 water. Where the etching is required to be deep, as, for instance, in mosaic damascening, where gold is to be inlaid, the nitric acid is inconvenient, in depositing a salt difficult to be cleaned out.

Phosphoric acid attacks iron with great avidity, but not its oxides at ordinary temperatures. The artificial phosphates thus produced are without interest to the arts as yet; the natural ones form an extended mineral class.

Dilute *sulphuric acid*, as well as *sulphurous acid*, act upon iron at ordinary temperatures, and with energy as the temperature, and to a certain extent the dilution, increase, forming, ultimately, sulphates of iron. They also combine with the oxides of iron in various proportions. The crystallized sulphate of the protoxide is known in commerce as *green vitriol*, or *copperas*. When this is heated in close vessels it parts with its water of crystallization, and upon continuance of the heat, after divers changes and disengagements, becomes converted into pure peroxide of iron, which is the *colcothar* of commerce, or the *crocus martis* of the old druggists, and the plate-powder or *rouge* of the silversmiths and polishers of steel and speculum-metal.

Solutions of the *alkalies* or *alkaline earths* do not appear to act upon iron or its oxides. On the contrary, their presence seems rather to retard the decomposition of water. At a red heat iron will take up about 10 per cent. of *ammoniacal gas*, becoming white and extremely brittle, but less liable to alteration from air or moisture. At the same temperature, *potassa* and *soda* are deoxidized by malleable iron; if crude iron be fused with these alkalies, it parts progressively with all its carbon, and becomes bar-iron. It has been generally supposed that the metallic bases of the alkalies do not combine with iron, or rather, are sublimed at the temperature required for such alloy. But more recent observations disaffirm this supposition. *Potassium* and *sodium*, for instance, can be combined synthetically with iron, and *magnesium* and *calcium* are often found, though in minute proportions, in the crude iron of commerce. How far they influence the character and quality of this metal is yet obscure. Karsten observes that $\frac{1}{2000}$ of *potassium* causes the alloy to be hard, and to be welded with difficulty, while $\frac{1}{1000}$ of *calcium* is enough to impair materially the qualities of iron. Magnesium appears to be got rid of entirely in the processes of refining and puddling. Barium no otherwise affects the metal than by embarrassing the operations of the high-furnace, when present with the minerals there as sulphate of baryta.

The *earths*, so called, (of which need only be mentioned *silica* and *alumina*,) exercise, at ordinary temperatures, or even at any temperature below fusion, no appreciable chemical action upon iron. Associated with carbon, at this last temperature, they are reduced to their metallic bases, (either by the iron or by the carbon,) which enter into combination with the iron, and modify it more or less. *Silicium* is found more abundantly in gray iron than in white; its maximum, as yet observed, may be stated at 4½ per cent., including that which is found free in the condition of silica in the cavities of crude iron. Its average hardly exceeds 1 per cent. There is no reason to suppose that this proportion affects the quality of the metal; on the contrary, it may be assumed not to interfere with, if it does not promote the fusibility and fitness for castings. The opinion among practical iron-workers (which is not, however, partaken of by chemists generally) is, that a certain small proportion of silicium augments tenacity. The operation of refining generally drives off 9-10ths of the silicium contained in the crude metal; but a proportion is often restored in subsequent processes, of which it would be well for manufacturers to take account, in view of a particular quality that may be desired. Thus Boussingault found bar-iron, melted in a Hessian crucible, to have taken up more than ½ per cent. of silicium. Synthetic experiments in the small way warrant the belief that a smaller proportion than this hardens iron and makes it less tenacious. Karsten presumes the action in this last respect of silicium to be more injurious than that of phosphorus. Whether, as has been supposed, the conversion into *steel* is due to silicious as well as to carbonized combinations, is not yet understood. No higher than a trace of *aluminum* has been observed either in crude or in malleable iron. Such traces are more distinctly marked in gray than in white iron, and most distinct in cold-short iron. There can be no doubt that this base injures the tenacity of the metal. Stodart and Faraday's experiments upon the manufacture of *wootz*, or Indian steel, (in which ¾ per cent. of aluminum has been found, and which is considered to owe its peculiar properties to the association,) will be spoken of under the article STEEL.

Iron forms an alloy with most of the other metals in varying proportions, dependent chiefly upon temperature. With *antimony* it has a great affinity, and associated with ¼ per cent. of this last, it becomes very brittle, either cold or hot. When united in the proportion of single atoms, (when the antimony is 70 per cent. of the mass,) the elements are inseparable by the highest degree of heat.

Arsenic in the proportion of $1\frac{6}{10}$ per cent. has been observed to destroy entirely the tenacity of iron On account of the extreme volatility of this metal, it is difficult to effect directly so high a combination There is no doubt that a very much smaller proportion acts injuriously.

Bismuth does not readily form an intimate union with iron. At the temperature of fusion of this last a great part of the former is volatilized, and its effect seems more felt in the treatment than in the quality produced; $\frac{3}{10000}$ of bismuth do not affect the strength or malleability of the metal.

Chrome unites with iron in all proportions, making alloys very hard, brittle, crystalline; more brilliant than iron, less fusible, much less magnetic, and much less oxidable. And these characters are more marked as the proportion of chrome increases. An alloy containing 60 per cent. of chrome is very fragile, whiter than platinum, and so hard that it scratches glass as deeply as a diamond. On the other hand, from 1 to 2 per cent. of chrome hardens cast-steel, and gives it the property of damascening beautifully, without diminishing its malleability.

Cobalt unites with iron in all proportions and without altering its properties, at least until the quantity of the former becomes considerable.

Copper can hardly be said to make a true alloy with iron, though when fused together a small proportion of the former will be taken up and retained upon subsequent fusion. Of *crude* iron it increases the tenacity when in the proportion of 1 or 2 per cent., and it might, therefore, be advantageously and economically employed for certain castings. As much as ¼ per cent. in bar-iron injures its capacity for being welded; a larger proportion makes a metal brittle at a red heat.

Gold may be alloyed in all proportions with iron, for which it has a remarkable affinity, and to which it imparts no new quality until its own quantity becomes considerable. When the gold is from 20 to 25 per cent. of the mass, the alloy is silvery and very hard, so much so that cutting tools may be made of it. On the other hand, when the iron is from 15 to 20 per cent. (to be classed more properly as an alloy of gold) it makes what the jewellers know as *gray gold*, of late much used for little trinkets, and admired for the beautiful polish that can be given it. Gold is also used as a *solder* for delicate steel-work.

Lead does not form an alloy with iron directly, with crude iron not at all, and with bar-iron, treated with litharge, in proportion not exceeding 2 per cent. This (and even a smaller proportion) renders the mass more brittle and more fusible. The ores of lead, which are sometimes found associated with those of iron, and have to be treated together in the high-furnace, are reduced, but the metallic lead lies in the hearth without uniting with the iron. It is sometimes found there when a furnace is blown out, not only in this state, but also as red-oxide or *minium*, and as a crystallized silicate.

Manganese, on the contrary, has a remarkable affinity for iron, and of all the metals is found most frequently in association with it. In small proportions the manganese renders the alloy harder, without impairing its tenacity; the limit in this respect is not ascertained, but it may be safely assumed at 1¾ per cent. The addition of manganese diminishes the fusibility of iron, but increases its oxidability. Alloys of these metals almost always exhale an odor of hydrogen upon being breathed on, and this greed of manganese for oxygen is one of the means by which the crude iron from manganesian iron-ores may be refined, so as to part with nearly or quite all of its alloy. The tendency of such manganesian ores to yield a metal easily convertible into *steel* has caused them to acquire the name of *steel-ores* with some persons. But this tendency, as well as the uniform liability of such ores (unless treated suitably) to give a white iron in the high-furnace, does not appear to arise directly from the manganese, but indirectly only, from the influence which this last has upon the behavior of carbon.

Molybdenum, like tungsten, unites with iron in moderate proportions, without altering its qualities, further than augmenting its hardness. An alloy of 1-5th molybdenum in iron is fusible, extremely hard, with small resistance to impact, but tenacious in other respects.

Nickel behaves with iron very much like cobalt, especially in the white color it gives, and in the facility and variety of its combinations. An alloy of 1 atom of nickel to 12 atoms of iron, (which corresponds to about 8⅓ per cent. of the former,) is one often met with in nature, under the name of *meteoric iron*. This is less oxidable and less ductile than iron unalloyed, but in other respects the metal is of good quality. Not to speak of the sword of Alexander, which is said to have been made of an alloy like this, nor of the sabres of Jehanguire, fabricated of a similar metal some 2000 years later, the sword presented to Bolivar in 1821 was forged of the meteoric iron of Santa Rosa, near Santa Fé de Bogota, whose atomic constitution is almost precisely what has been given above.

Palladium renders iron brittle when in even moderate proportions; when the proportion is small, it induces no further alteration than increased hardness. The same affinities and effects belong to alloys with *rhodium*, *iridium*, and *osmium*. A proportion of 3 per cent. of either of these in bar-iron prevents rusting, and renders the alloy capable of being tempered like steel. It is with *steel*, however, that the alloys of all these metals are the most remarkable. The same may be said, too, of *platinum*, whose alloys with steel are of great interest, and present some remarkable peculiarities, but which hardly unites directly with iron, except in the presence of carbon.

Silver does not form a real alloy with iron. Fused together, the iron will take up a small proportion of the other; which, when it is as low as $\frac{1}{3000}$ only, injures the malleability and weldability of the mass. In these effects, Karsten ranks it as very nearly equivalent to sulphur.

Tantalium does not unite with iron directly; except at a very high temperature, and in the presence of carbon. So formed, it is tenacious, without ductility, and readily scratches glass.

Tin and iron have a great affinity for each other; unite in all proportions, and at last so permanently as not to be separated by fusion. The alloys in which tin predominates are without the peculiar characters of this metal, while they have gained none of the properties of iron; and the same may be said when the proportions are reversed. This does not apply at all to that superficial alloy which takes place in what is known as the *tinning of iron*, and which is manifested both with crude and malleable iron. The particulars of this art will be given under the article TIN-WARE.

The alloy of *titanium* will be spoken of in connection with the so-called *titaniated* iron-ores.

Tungsten behaves like molybdenum; and its principal effect is to increase the hardness of the alloy. Even when the tungsten is 37 per cent. (which is equivalent to 1 atom of tungsten to 6 of iron,) the physical characters of the alloy are very much those of *white iron*.

When *zinc* is kept in fusion in iron vessels, it gradually corrodes and dissolves them; a proof of the capacity of these metals to form alloys. At the high temperature, however, required for the fusion of iron, the zinc is volatilized; and so is never found, even in trace, in the metal from high-furnaces where iron-ores containing zinc are used. It is the opposite when the ores used for the extraction of zinc contain iron; this last is very hard to be gotten rid of, and even in small proportions injures the malleability and embarrasses the lamination of zinc. There is also a superficial alloy, like that mentioned just now in the case of *tin*, which is produced when clean sheets of iron are plunged in a bath of melted zinc. The preparation of this zincked iron, known in commerce as *galvanized iron*, is a late application of art, which will be particularly described under Zinc.

Iron is one of the few metals which do not form an amalgam with *mercury* directly. It is possible by the medium of a third metal, as zinc or tin, to produce indirectly amalgams which are of no interest in the arts.

Mineral characters and geological occurrence of productive ores of iron.—1. *Native iron, bolide, meteoric iron, &c.*—Although these are not strictly *ores* of iron, yet, as they are both workable and productive when they occur, it is proper to include them here. The means of distinguishing with certainty those which are terrene from those which are formed in, or at least fall from, the atmosphere, are yet so vague, that the two classes are here counted together. The occurrence of *nickel* is generally held to mark a meteoric origin. The most remarkable specimens are those of Siberia, discovered by Pallas; of Louisiana, sent to New York by Gibbs; and of Buenos Ayres, found by Rubin de Celis. This last more than doubles the size of any of the others; weighing about fifteen tons. Besides these, Africa, near the Cape of Good Hope; North America, at Canaan in Connecticut, and Randolph County, North Carolina, and in Bedford County, Pennsylvania; South America, along the eastern cordillera of the Andes, and in Brazil, and Peru; Asia, in Hindostan; Europe, from Bohemia, Croatia, France, Italy, Saxony, and Switzerland; and the Esquimaux settlements near Davis' Straits, (which belong to no continent,) have all contributed specimens. The color of these varies from silvery to bluish white; their hardness may be taken at between 4 and 4·5 of Kirwan's scale; they are all magnetic. Their specific gravity varies from 5·95 to 7·34, according to the associations, which are principally, and sometimes wholly, nickel, apparently in definite proportions. Arsenic, chrome, cobalt, copper, and molybdenum have also been found united with the iron, as well as a small proportion of carbon in the shape of *graphite*.

2. *Magnetic iron-ore, octahedral iron-ore, fer oxidulé, black oxide of iron, loadstone, &c.*—This is the only ore of iron acted on by the magnet without application of heat, except the titaniferous iron grains of Brazil. Its geological occurrence is in primary formations; and it is apt to be accompanied with quartz, hornblend, calcareous and fluor spars, and asbestos, which modify variously its fusibility and workable properties. Its chief deposits are in Sweden and Norway, and in Siberia, where it occurs in bands; sometimes it is found in beds, as in Savoy and Piedmont, Tyrol and the Vosges; it forms the mass of considerable mountains, as at Taberg in Smoland; and is also worked, as in Naples, in small grains like sand. In the New World it is found also, as in La Plata, Brazil, Mexico, and the United States; but generally not in sufficient extent to work. The mines at Schooley's Mountain, in New Jersey, have been, it is believed, abandoned; and the new works for this ore near Sykesville, in Maryland, have not been long enough in operation to determine their reliability. This ore frequently occurs in crystals, whose primary form is the regular octahedron, and whose cleavage is perfect. Its color is black; its lustre generally metallic; its fracture generally conchoidal; its hardness 5·5 to 6·5; its specific gravity 5 at a mean. When pure, it is composed of 1 atom of iron and $1\frac{1}{3}$ atoms of oxygen. The metal from this ore, known as Swedish iron, is of the best quality in commerce; and its properties, although attributed sometimes to the methods of its treatment, are probably more owing to the materials.

3. *Specular oxide, anhydrous peroxide of iron, iron-glance, red hematite, fer oligiste, eisenrahm, &c.*—This mineral is generally found in primary formations, but occurs also among sedimentary rocks. Varieties of the species, apparently of daily formation, are to be met with amid the lava of Vesuvius, and in ancient and existing solfaterras, as of Tolfa and Guadaloupe. The most celebrated deposit of it is in the island of Elba, where it has been worked for more than 2000 years, and where the extent of the excavations and deblais attests the industry more than the skill of the ancient miners. The Elba mines are continuations, probably, of the Tuscan ores. At present there are three workings in a hill of about three miles in extent, and elevated only about 600 feet above the sea. The rock in which it occurs is a whitish talcose slate, called there *bianchetta*, easily worked, but, after all, not very productive in modern times; the whole quantity exported not long since, being not more than 15,000 tons. The ore here is often slightly magnetic, and contains, in fact, an admixture of magnetic oxide, and often titanium. The wash from the actual workings, presenting the ore in the shape of octahedral grains like sand, is also exported under the name of *poulette*. The same granular occurrence is met with at Framont in the Vosges, the only point at present in France furnishing specular oxide. There are some other striking localities, such as Gellwara in Lapland, and Sommorostro in Biscay, (where it forms the mass of large mountains,) Norberg in Denmark, and the Minas Gerues in Brazil, where it exists in very extensive beds. The crystals of this ore are varied; but the primary form appears to be a rhombohedron nearly cubic. Its color is a brilliant black, very often iridescent, with a metallic lustre. Its fracture is sometimes lamellar, but more generally irregular. Thin laminæ show a deep blood-red color. Hardness, from 5·5 to 6·5; magnetism, when it exists, attributable to admixture of magnetic oxide; and specific gravity at a mean, 5·10. When pure, it is entirely a peroxide of iron, and consists of 1 atom of iron with $1\frac{1}{2}$ of oxygen. The metal from this ore may be taken as equal to that from the former class; the Celtiberian iron of old time, and the Bilboa blades of more recent periods, were made with it; and in Sweden even, in many mines, it is not separated from the magnetic ore. The *micaceous* variety crystallizes in hexagonal tables, which are divisible into thin translucent plates. Its powder is a bright red: its specific gravity about 5·25. This is found of extreme beauty near Northampton in Massachu

setts. *Red hematite* occurs massive, stalactitic or fibrous, and mamelonated. Its color is a dark red with very often a metallic lustre and aspect. Hardness, about 7; powder, which is red, never magnetic; and specific gravity, at a mean, 5. Thomson gives the specific gravity of a specimen from Muirkirk at 6·305. It is often mixed with oxide of manganese, and is then a reddish-brown, almost black. Of this variety are the deposits in Cumberland, (Eng.,) so useful in admixture with the ores of Wales; and in this also is the principal mining about Lauterberg and Altenau in the Hartz. This is the *blood-stone* of the metal-polishers. The *compact red iron-ore* of Lavoulte, in France, occurs massive, in veins 50 to 60 feet thick. It is also sometimes found in pseudo-morphous cubic crystals. Its color is a brownish-red; its fracture uneven; its specific gravity about 4·25. *Red ochre*, which is chiefly used as a pigment, but also as an ore, may be regarded as closely allied to this last variety, in which it is principally distinguishable by a softer texture and more lively red color.

All these classes of ores, when pure, contain the iron associated only with oxygen. The others which follow contain also *water* as a permanent additional element, in the proportion of from 10 to 15 per cent. Such are,

4. *Hydrated peroxide of iron, fibrous and compact brown hematite, brown ochre, umber, ætites, limonite, bog-iron ore, &c., &c.*—This class is very extensive, and is found as well in primary formations as in newer rocks. Its principal deposits are in the oolite series and chalk equivalents. *Bog-ore* is considered of daily formation. It is sometimes found in octahedral and cubic crystals, but most generally massive. The color of the mass is in various shades of brown, but its powder and streak always yellow. Its hardness is from 4·5 to 5; its specific gravity, at a mean, 4. It does not act on the magnet. Chemically, it is composed of 1 atom of water, 1 of iron, and 1½ of oxygen; or otherwise, 1 atom of pure specular oxide with 1 atom of water. From this class (principally, the compact brown hematite) comes a great part of the iron of France; the deposits about Whitehaven in England, which are of enormous extent, are a variety (the *reniform*) of it; the *oolitic* ores, which are small globules held together by a calcareous or argillaceous cement, cover a considerable extent in Burgundy and Lorraine, and occur also in Carinthia and Styria; the *granular hydrates*, or ferriferous sand, are worked in Normandy and other parts of France, in Switzerland, in Silesia, Bavaria, and Poland; and, finally, the *bog-ores* are profitably mixed with other ores in many places, as in Silesia and Livonia, and in the coal region of Maryland, or worked alone as in the last-named state. Phosphate of iron, however, which occurs frequently in this alluvial variety, prejudices its unmixed use. *Brown ochre* is principally used as a pigment; and the *ætites*, or eagle stones as they are called, which occur along the Rhine, are almost as much used by the French shepherds as amulets, to be hung around the neck of a favorite ram, as for any other purpose. The metal from this variety, however, as well as from the whole class, is unexceptionable whenever (as is the case generally, except with the bog-ores,) there is no adventitious impurities or associations, in sufficient proportion to be injurious. Ordinarily, the associations are from three to ten per cent. of silica, alumina, and manganese, in nearly equal quantities; amounts which in nowise embarrass the smelting or the result.

5. *Carbonate of iron, brown spar, argillaceous iron-ore, spathose or sparry iron, spherosiderite, fer spathique, fer carbonaté lithoïde, stahlstein, &c.*—Under these synonyms and varieties may be included a class more widely extended and more productive than any other on earth. Two principal divisions may be made of it—the crystalline or *sparry*, and the compact or *lithoïd*—the former occurring in beds and pockets in the primary rocks, the latter belonging to newer formations, and especially stratified among the coal-measures. The facility with which the former can be reduced rendered it of abundant introduction into the smelting-houses of the ancients; it was from this ore that the Styrian works turned out the metal so favorably known before our era as the *Norican* iron; and the name of *steel-ore*, under which it has been designated, from the readiness with which it yields a *steel* at the first treatment, is not less a test of its appreciation. This variety is both massive and crystallized. In the latter case, its primary form is an obtuse rhombohedron, nearly approaching the form of calcareous spar. Its derivatives are more complex; but not unfrequently it is converted, as in the very large Cornish crystals, into regular six-sided prisms. Its color is gray of various shades, yellowish and greenish, but sometimes almost red. Fracture is imperfect chonchoidal, with a vitreous and somewhat pearly lustre. Thin fragments are often translucent. Its average hardness is about 4; its specific gravity, at a mean, 3·75. It is not magnetic. Abstraction made of the impurities, which are generally carbonates of lime and magnesia, this mineral is composed of 1 atom carbonic acid and 1 atom protoxide of iron. The compact or *lithoïd* variety occurs in nodules and in regular veins or strata; this last is especially the case in the coal-measures, with which it is always more or less associated. Its color is a dark gray, and when the allied carbonaceous matter is abundant, almost black. Its specific gravity is from 3 to 3·5. Its composition is the same essentially as that of the other variety, but with the uniform addition of notable proportions of silica and alumina, and coaly matter; protoxide of manganese is very often found with it and in the coal-measures, sulphur but in small quantities. The value of this ore is more in the facility with which it is treated than the quantity or quality of the metal produced. When in an unaltered state, it rarely yields more than 33 per cent. of metallic iron; the *altered* carbonates, which occur most generally in accidental beds among the primary rocks, may give 45 per cent. *Mushet's black band*, as it is termed, a seam of high reputation near Airdrie, in the Glasgow coal-field, returns about 41 per cent. Even when made with charcoal, the iron from this ore is inferior in its physical properties to the Swedish, to the Spanish, and to the Styrian iron, and, in general, to the metal produced from any of the preceding classes; when coke or coal is used its inferiority is, of course, more strongly marked. Yet improvements in the methods of manufacture have gradually cured these natural disadvantages to an extent which, though it still leaves something to desire, is yet sufficient for most practical purposes, and may well be balanced by the economy of production and the cheapness of the metal furnished. Indeed, without the use of coal and the association of this ore with the beds of fuel for smelting it, some of the most important contributions to the civilization of the present day would have been either impossible, or at least unattempted. From this last variety comes now nearly the whole enormous prod-

uct in iron of Great Britain; is is being extensively used in France, where, as in the departments of the Nord, Loire, and Allier, it exists in abundance; it returns a part of the metal from the Hartz; it was the earliest worked of the iron-ores of America along the Atlantic coast, when, as little more than a century since, it was seriously looked to as an available resource for the supply of crude iron for the English market, and, worked with charcoal at many points, still continues to yield a profitable return; and finally, when foreign competition is, for an interval only, set aside or guarded against, will enable the bituminous coal-fields of Maryland, Pennsylvania, Ohio, and Virginia to supply the entire consumption in iron of the whole American continent.

Such are the principal classes of available ores of iron. Mineralogists, and metallurgists even, often extend their number to include others, which should be, in theory, and sometimes may be in practice, used to advantage. So the *silicated iron-ore* of Kupferrath, the *chamoisite* of the Valais, the *garnets* of Henneberg, the *titaniated ore* of Maryland, are actually smelted; while the *volcanic basalt* of France, Germany, and Ireland, and the *jasper* of Piedmont and Siberia, contain iron enough to render its extraction hopeful. So the *franklinite* of New Jersey, which contains 46 per cent. of metallic iron, might be supposed as proper for the domain of the iron-master; but in fact, it has only been employed, hitherto, (as twelve years ago for the weights and measures of the United States,) in the fabrication of brass, and probably will ever continue to be invoked solely to surrender its zinc. As for the other mineral combinations in which iron is found—the arseniets, chromates, columbates, phosphates, and sulphurets, &c.—they may be omitted here. Some (as, for instance, the *chromates*) are worked for and applied to purposes in the arts other than the reduction of the iron they contain; others (as, for instance, the *phosphates*) yield an iron of such inferior quality, when treated alone, as not to be of desirable employment; while others, (as the *sulphurets*, &c.,) even were there no objection on this last score, require such expensive processes to effect a separation, as to be quite useless as ores of iron. The following table is of interest, as showing the normal proportion of metallic iron existing in the types of the classes and varieties that have been mentioned:

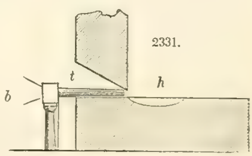
Class.	Variety.	Iron per 100 parts.
1. Native or meteoric iron		94·
2. Magnetic iron-ore	In purity	72·40
" "	Mean of seven analyses	67·47
3. Specular iron-ore	In purity	70·
" "	Red hematite	67·67
" "	Compact red iron-ore	56·50
" "	Red ochre	40·53
4. Brown hematite	Compact	59·18
" "	Fibrous	56·98
" "	Œtites	54·97
" "	Oolitic	44·45
" "	Granular	42·21
" "	Brown ochre	45·85
" "	Bog-iron ore	29·54
5. Carbonate of iron	Sparry	44·91
" "	Lithoïd; altered	40·79
" "	"	33·54

Metallurgic treatment of iron.—Under this head belong the *smelting* of the ores to produce *crude* iron; the *founding* or remelting of that product when required to be in certain forms and of metal properly termed *cast*-iron; the *refining* of crude or cast-iron, and its *forging*, so as to give malleable or *bar*-iron; and, finally, the operation, by hand, upon comparatively small masses of bar-iron, known as *smith's* work. For the first of these processes is required a *furnace;* for the second, a *foundry;* for the third, a *forge*, or *rolling-mill;* and for the fourth, a *smithy.* Under this last denomination will be included as well the manipulations—which, from the color of the work turned out, (and perhaps, also, from the soiled externals of the workmen,) are ordinarily termed *black*smithing—as the operations with the lathe, &c., which are demanded in what is technically termed a *finishing*-shop.

1. Smelting.—This is, both in theory and in fact, a chemical operation: depending, first, upon the tendency of most earthy and metallic substances to melt by heat; next, upon the affinities of the materials usually put in furnaces for new combinations, while in a state of fusion; and then, upon the excessive gravity of metallic iron, which, in this state, tends to make it separate from and sink through the melted mass. In this last regard, it may be said, that while the specific gravity of all the other solid materials likely to come together in smelting (even in a coal or coke furnace) is not much more than twice that of water, the specific gravity of metallic iron is seven times as great, and its gravitating tendency is, therefore, at least three times that of any other element. In charcoal furnaces, this average tendency downwards is still greater. The following paradigm, in which only the chief materials and products in smelting are shown, will serve to illustrate the character of the affinities that are exercised and the recompositions that result:

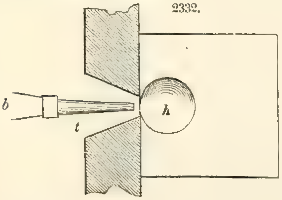
MATERIALS.			PRODUCTS. Carbonic Acid. Gaseous.	Crude Iron. Solid.	Furnace Cinder. Solid.
Gaseous	Atmospheric Air	Oxygen	——		
		Nitrogen	——		
Solid	Iron ore	Oxygen	——		
		Carbon	——		
		Iron		——	
		Silica			——
		Alumina, &c.			——
	Fuel	Oxygen	——		
		Hydrogen	——		
		Nitrogen	——		
		Carbon	——	——	
		Silica			——
		Alumina, &c.			——
	Alkaline Flux	Oxygen	——		
		Carbon	——		
		Lime			——
		Silica			——
		Alumina, &c.			——

The success of these results depends upon the means employed. Thus, it is well known that, with fuel enough and air enough, heat can be generated sufficient, both in intensity and abundance, to fuse the most refractory and voluminous materials. But as both air and fuel are costly in their supply, the task of the furnace-manager is so to admix his ores and fluxes as that their simultaneous fusion shall take place at the lowest possible temperature; that it shall be the most perfect, to allow the utmost chance for the entire separation and descent of the melted metal; and that on its continuance, and by the presence of substances suitable for taking up and neutralizing all accidental or necessary impurities, either in the ores, fuel, or flux, there should be the least possible opportunity for the iron, after separation, to enter into new and detrimental combinations. All this was expressed long ago, with great practical terseness and almost sufficiently comprehensive caution, by Rogur, the Welch founder, in saying that "In order to make iron, you must first make glass." It is to produce this glassy cinder out of all the solid materials in the furnace, (except the iron,) that the founder aims; it is by this cinder that, from hour to hour, he judges how his furnace works. In earlier times, and with many still, this task was matter of routine, or of tact, which habits of observation had rendered almost intuitive. At the present day such tact can be guided and helped by accurate theory, which, upon a nearly perfect knowledge of how different chemical elements behave towards one another, can calculate arithmetically the dimensions of the furnace and the proportions of ingredients proper to a given result. This will be better understood after some details upon the construction of the furnaces themselves, and description of their parts.

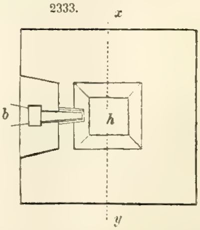


2331.

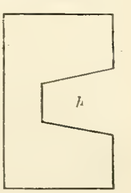
Figs. 2331 and 2332 are respectively a section and ground-plan of the hearths, or furnaces, in use about the middle of the sixteenth century, as described by Agricola. The letter *h*, in both, shows the hearth proper; *t*, the tuyère; and *b*, the bellows. This form is not unlike the blacksmith's hearth of our own times; and has, in fact, been perpetuated, with but small modification, in the Catalan forges of the present day, where a malleable iron is produced from suitable ore by the first process. More refractory ores were treated in crucibles (as it were) of a somewhat different shape, as under; where Fig. 2333 is a ground-plan, and Fig. 2334 a section through $x\,y$ of that plan. The same scale answers for all four figures.



2332.



2333.

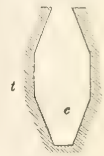


2334.

Both of these constructions belonged to a period when iron, more or less malleable, (an object of earlier utility in the arts than crude iron,) was produced direct from ores whose choice and value depended then greatly upon such a property. And both are of the kind which the Germans call *stück-ofen*, and the French *fourneaux à masse*, (in English, *pot furnaces*)—such as until very recently, and still, indeed, are used in Hungary, Carinthia, Styria, and along the Pyrenees. Both furnish the reduced metal in a solid lump, *loupe*, *stück*, or salamander, which has to be lifted by main force out of

the hearth—the fires, of course, being suffered to go down for the purpose. The second kind appears to have had, like the modern stück-ofen, a tap-hole for cinder or slag to be removed. The stück-ofen, used at present in what was formerly the principality of Henneberg, are shaped internally like the adjoining Fig. 2335. They are from seven to ten feet high, built of sandstone; but the crucible proper, *c*, is of cast-iron. There are two openings: one at *t*, where is the tuyère; the other in front, for working—i. e., removing the cinder and the metal. The cinder is always running out; the metal is kept in (it is never very liquid) by a temporary wall of brick, which is taken down when the stück is drawn. In older times, the *loupe*, which weighs from 500 to 800 lbs., and which was formed in six or eight hours, was drawn every day. The improvement of deepening the hearth left room for several loupes, which were separated in the workings by dry charges of fuel only, and were removed every Saturday evening. At present, the loupes, separated as before, are drawn whenever the hearth becomes full, but without emptying the furnace, which continues in blast several weeks.

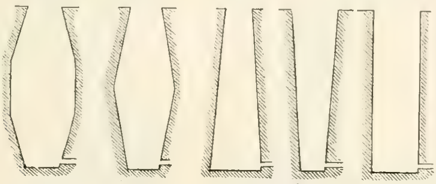
2335.



These Henneberg furnaces are types of an improvement which was beginning in the time of Agricola and is known in Germany as the *fluss-ofen*—in France, as *fourneaux à manche*—in England, as *tap furnaces*. The aim of this was to let the metal run out as well as the cinder; and the method of attaining the aim was a contraction of the crucible proper, whereby the heat became more intense and the metal more liquid. The stück-ofen—which, to be sure, always yields an excellent quality of metal—is very expensive, both in ore and in fuel: the low temperature it affords is not sufficient for the reduction and subsequent combination of divers impurities (such as manganese, silicium, &c.) in the ore, so that the iron is left comparatively pure; and as the slag contains ordinarily about 40 per cent. of metallic iron, the metal, which sinks down on the hearth after having been enveloped in this slag, becomes also partially decarbureted, and is, in fact, a mixture of crude iron, malleable iron, and steel. The fluss-ofen rendered the greater part of it crude iron; and is, therefore, the germ of the modern high-furnace. In its actual state, and like the Henneberg furnaces, only higher, (from 20 to 35 feet,) the fluss-ofen continues in use to this day in various parts of Germany, and in some places of Sweden. The Swedish furnaces were, indeed, until recently, all properly fluss-ofen. Since the intervention of Berzelius, they conform more to the models generally followed in other parts of Europe and America.

The following figures will serve to show the probable march of improvement, as longer observation, and greater range of materials that might yield iron, suggested the successive steps. For greater gen-

2340. 2339. 2338. 2337. 2336.



erality and simplicity, these figures show only the cuvette or inside section of the furnace, which necessarily regulates the externals. Thus, there is no doubt that the earliest shape was the prism, or cylinder, shown at Fig. 2336, which we know to have been in use in the time of Agricola. As it would soon be observed that, with such a shape, the materials were too heavily pressed below to allow free passage for the blast, relief in this respect would be sought by battering the sides inwards, as shown in Fig. 2337; while as, upon experience, it could not fail to be noticed that, if the materials, in descending, had more room, they would spread more easily—on this account the shape of Fig. 2338 might be preferred. The suitability of one or other of these forms would be regulated by the less or greater fusibility of the materials. But for average fusibility, as well as to combine the greatest advantage of these two experimental principles, the form of Fig. 2339 would be seen to be the best; while a slight alteration of this, and a combination, in fact, of all previously known forms, brings us to the form of Fig. 2340, which is exactly the modified fluss-ofen of Henneberg, before described. If the angles of

2341. 2342. 2343. 2344. 2345.

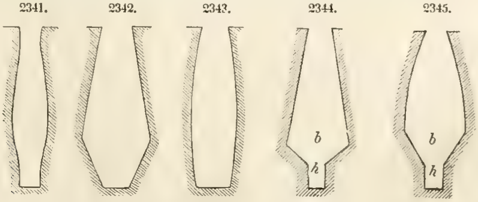


Fig. 2340 be rounded off, either designedly or by the degradations consequent upon its use, it will assume the form of Fig. 2341 which is that of the ordinary fluss-ofen of Europe. Fig. 2342 is a modification of Fig. 2339, bringing the belly, or widest part of the cuvette, nearer to the blast, as would be

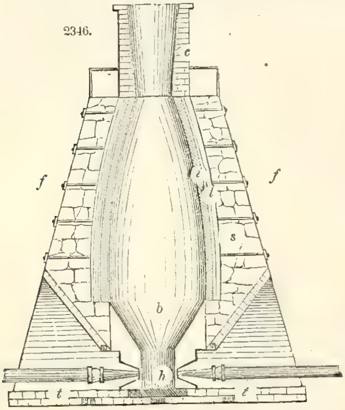
found desirable for less fusible ores; while for those more refractory, a general narrowing, as in Fig. 2343, would be resorted to. Finally, as the use of earthy ores became prevalent, it was found better to bring the top of the *boshes* (in German, *böschung*, a talus, or slope) nearer to the tuyère, and to narrow the crucible below, as shown in Figs. 2344 and 2345, which are the types of the modern high-furnace. In both these figures, *h* shows the crucible, or hearth, and *b* the boshes. The slope of these last is more or less steep according to the fusibility of the materials, and their less or greater fragility under pressure of a superincumbent. In this last regard, the height of the furnace-stack is an element in the calculation; although, for the generality intended to be illustrated by the figures, as well as for the distinction between different kinds of furnaces, the height is immaterial. It is usual to call, now, every thing above 27 feet a *high-furnace;* although, in the method of treatment, as well as in the character of metal produced, it may be, as in parts of Germany and France, a *fluss-ofen*, and although it may have no hearth proper, as in many places in Sweden. The different shape of the in-walls—straight in Fig. 2344, curved in Fig. 2345, of either of which many examples are found—arises more from caprice than from any logical conclusion. The latter is more retentive of heat, but more embarrassing to the blast; in the latter, therefore, the different stages of the process will be more distinctly marked than in the former. If the object be to gather combustible gases at the trundle-head, (as in the method of Faber-Dufaure,) the shape of Fig. 2345 is preferable.

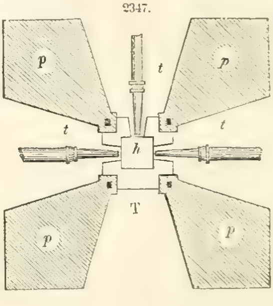
In some localities, the furnace is built upon the flat, and a veritable bridge connects with the hill. In places where there are no hills—as in Staffordshire, for instance—a long ramp is constructed, either of earth or carpentry, along whose inclined plane the materials are carried up by suitable machinery.

Figs. 2346 and 2347 are a section, parallel to the front, and a ground-plan of a blast-furnace, which may be taken as a type for all, whatever may be the materials employed. In these figures, *h* is the

2346.



2347.

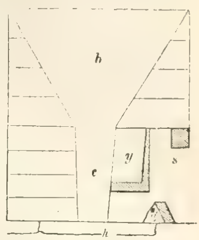


crucible, or *hearth;* *t*, *t'*, indicate the passages and *tuyères* (pronounced *tweers*) for the blast. In Fig 2346, *b* shows the *boshes*, a term applied as well to the space where the letter is as to the stones which inclose it; *s* is the general mass of masonry, called the *stack;* *i* are the *in-walls*, of refractory materials, (stone or fire-brick,) defining the cuvette; *l* is the *lining*, of broken stone, pounded cinder, &c., loosely interposed between the in-walls, to allow them to expand without thrusting more than can be helped against the stack, and also helping as non-conductors of the heat; and *f f* indicate the ties, of bar-iron, which run quadrangularly through the mass of the stack to secure it still further. In-walls are sometimes made double, with a void space between them. It is obvious that, within the limits of their general aim, the particular dispositions of these are at discretion. A chimney, generally of brick-work, is shown at *c*. On Fig. 2347, *p p* indicate the piers, connected by arch-work, for supporting the stack vertically. These piers are generally themselves still further pierced with low and narrow archways, (as shown by the dotted lines on the northeast pier,) to allow of readier communication between the *tuyère-arches*, *t t t*, where the blast-pipes are. The arch T, in front, where the working is done, is termed the *tymp-arch*—generally larger than the tuyère-arches. This plan shows *three* tuyères, which is an establishment for a furnace of the largest class; yet very many have but *two*, and smaller ones are worked with but *one* tuyère.

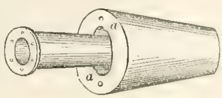
Fig. 2348 gives an enlarged view of the disposition of the hearth and boshes. Here, besides the parts already indicated by letters before used, *s* shows one of the cast-iron girders, or *sows*, for supporting the thrust of the arch; *y* is the *tymp-stone*, protected by a casting called the tymp-plate, (*tymp*, in Welch, means a *delivery*, and hence is applied to the place where the product of the furnace is *brought forth*,) both from the iron *ringards*, or long crow-bars, of the workmen, and from the adhesion of the cinder, which is very strong to heated stone; and *d* is the *dam-stone*, protected, for similar reasons, by a casting called the *dam-plate;* *h* shows here the *hearth-stone*, or sole, which is a single, large, refractory stone, and ought to underlie, in part, the dam-stone. This hearth-stone ought to have a fall of at least ⅛ inch

to the foot, towards the front, to assist the tymp of the metal, which comes out through a shoulder cut in the lower face of the dam-stone. The cinder pours over the top of this last. The place for the tuyère, which was first a square opening left in the masonry, is generally filled up now (since the use of hot air especially) with a double hollow cone, called a *water-tuyère*, made of wrought-iron, of wrought-iron with a mixture of copper, or of cast-iron, and built in with fire-clay on the tuyère-shelf. Fig. 2349 is intended to show this utensil. The openings at *a a* are intended, the one to admit, the other to let out, the water which circulates in the tuyère, and preserves it from the action of the heat in the hearth.

2348.



2349.



After stating the general principle that the hearth and boshes should be of the most refractory material possible, the choice of that material, of its position and treatment, it is obvious, depends, within certain limits, upon circumstances. Thus, they are built of sandstone, dressed or undressed; of soapstone; of fire-brick; or of an artificial puzzolana of cinder and fire-clay. The joints are always laid in fire-clay, worked up into the consistence of mortar.

Having now the nomenclature of the principal parts, some precautions as to their dispositions, and some requisites as to their proportions, may next be stated. The first thing after a *secure*, is a *dry* foundation, particularly in the vicinity of the hearth; and, therefore, too much provision of drains, active enough to take off promptly all possible moisture, can hardly be made. Under the hearth-stone should be constructed a false-bottom, with pieces of brick or stone, so as to avail of the non-conducting power of air. But currents through this are to be avoided. In some places in Sweden, it is, to be sure, the practice still to provide means for passing water under the bed of the hearth-stone, with the view of increasing its duration. But such a practice cannot be approved on any score.

The plan of the hearth is square, oblong, or circular, or elliptic. The two last forms agree best with theory; the others are more convenient in construction. With three tuyères, an oblong hearth is necessary, on account of the less resistance opposite to the third tuyère at the tymp: with two tuyères, it is still advisable, because the two nozzles should never be opposite exactly, and room for their play is desirable, as well as a better distribution of the blast. So far as the resistance to the blast is concerned, it will be in equilibrium by an addition of $\frac{1}{3}$ of the width to make up the length.

The *jambs of the hearth* are made vertical, or with various degrees of batter, from $\frac{1}{24}$, at a minimum, to $\frac{1}{6}$, at a maximum, of the height; and generally inversely as the height. This last proportion seems unreasonably great, and must embarrass the blast. But the absolute capacity of the hearth must be taken in as an element for determining the batter; as also the quality of yield which is aimed at. To make foundry-iron, the batter should be less than for forge-pig. The proportions of $\frac{1}{12}$ of the height for the former, and $\frac{1}{6}$ for the latter, seem to be warranted by the best examples.

The *slope of the boshes*, or angle which a section of their face makes with the horizon, varies from 55° to 70°. There are some instances in the Harz of less inclination than this; but it is not recommendable. A slope of 60° might be taken as a constant to present the maximum advantage; for, strictly speaking, the pressure of the blast can be regulated so as to compensate for unsuitability of slope, in any particular case, to the materials. In respect to these last, refractory ores and soft charcoal are best treated with a less slope; but fusible ores, and coke, or charcoal of hard wood, will behave better with steep boshes. The length of the boshes, which are now always circular, corresponds with the greatest diameter of the furnace, or, as it is technically called, the *width at the boshes*.

This *width*, it is obvious, must be proportionate to the *height* of the cuvette, or, it may be said, the whole height of the stack; i. e., the higher the furnace, the wider it may be with the same materials. But with a given height, the width should vary according to the materials, and *vice versa*. These two items, therefore, will have to be considered together in this respect; and, along with them, another of the greatest importance—the quantity and pressure of the blast furnished. And, after all, we can only deal in generalities, and not in arithmetical proportions, which can only be derived, for a given case, with materials of known composition and properties. The object of the furnace, at all, is to generate heat to melt some of the materials, and to melt them, also, at a proper place. This heat is produced by the combustion of others, (viz. the fuel;) and the amount of such heat depends upon the quantity of these last burnt in a given time; which quantity, again, depends upon the weight and volume of air furnished in the same time—i. e., upon the amount of blast. The greater the blast, the more fuel will be burnt, the more heat generated, and the more matter melted in a given time. Assuming, then, the blast as constant and suitable, the stack should be of such a height as that none of it will pass out unaltered at the trundle-head. It is manifest that, with a low furnace, a part of the air of a strong blast will come out at the top without having promoted combustion at all, and, therefore, at a loss With the blast constant and the height suitable to that, the next thing is to consider the effect of the width at the boshes. At this point the materials have attained their greatest extension, and are ready, some for being burnt, some for being melted. If this space is too narrow the ores will arrive too soon at a high temperature; fusible ones will liquefy in the upper part of the furnace, refractory ones will fall in fragments into the crucible, not having had opportunity to be properly cemented and reduced. If, on the other hand, the width be too great, the temperature will be insufficient, and even fusible mines will descend unaltered into the crucible. This will be especially the case with charcoal furnaces, whose fuel, more friable, does not afford the same resistance. So far as fuel is concerned, then, boshes for charcoal other things being equal, must always be less wide than for coke; and even for another

reason, that the light charcoal is easier blown aside by a strong blast, in which case it is burned against the sides of the stack, where its combustion is comparatively useless. It may be concluded, then, that the *width of boshes*, with a given height of stack and given blast, should be less for a friable fuel and for refractory ores than for a compact fuel and fusible ores.

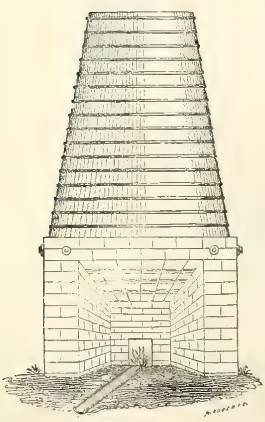
Upon the boshes rest the *in-walls*, and their junction should be effected to present the least angle possible. The materials of these, as well as of the non-conducting and elastic lining between them and the solid masonry of the stack, have been already spoken of. Their horizontal section is always circular, the vertical projection of their face sometimes a straight, sometimes a curved line. The former is more easy to build, the latter more retentive of heat, and, with a mould-board revolving round a central shaft, presents no difficulty in construction. In forming the curve of this mould-board, the shape of a common parabola is the most advantageous to be employed in respect to the distribution of heat.

The *width at the trundle-head* depends upon the quantity of blast intended to be furnished, and also, in a less degree, upon the quality of the materials. If the blast is very strong, it should be less than with a weak blast; it should be large with friable fuel, and ores that tend to stick together. The widening below should not be rapid, as if, for instance, the parabola before spoken of were cut off near its vertex, for the materials in that case would tend to distribute themselves unequally; relieved suddenly from lateral pressure, the heavier ores would descend quicker than the charcoal or cokes. The general practice is to make trundle-heads narrower than theory would dictate, under an apprehension of loss of heat; their width should not be less than 2-5ths, and in most cases might be advantageously ½ that of the boshes.

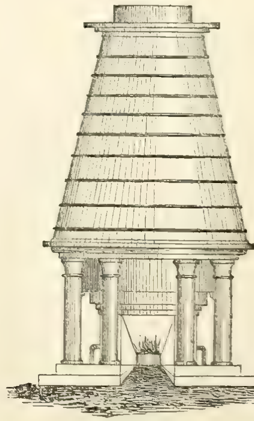
The *chimney* surmounting the trundle-head is not always adopted; in proportion to the size and temperature of the furnace it is more and more necessary. It is built uniformly of brick upon a cast-iron bed-plate, with mortar only enough to hold it together, and further retained in shape by ribs and hoops of iron. Its height is from one-fifth to one-fourth that of the stack, and its inside top-diameter is generally wider by the length of a brick than its base, the outside face of the wall being plumb.

The only remaining part of the construction which has not been mentioned is the *stack*, whose function, it is apparent, is only that of a retaining-wall to hold the cuvette, boshes, &c., in place. This function it may perform either by its *inertia* or by its *cohesion*. In the first alternative it is generally built of stone-masonry, laid dry where it approaches the lining, and mortared elsewhere; externally it will be square, the width of the base will be equal, or very nearly so, to the height of the whole stack above the foundations, and the outside face will be battered at from 2½ to 3 inches per foot, thus making the width at top about half the width of the base. These are, of course, only average and generally unobjectionable proportions. Besides this, in levels of every 4 or 5 feet, binders of bar-iron are laid in channels of 12 or 16 square inches of section left in the masonry parallel to all four sides, which binders are held at the ends by suitable *hold-fasts* that can be tightened either with a key or with a nut. When these bars break, (as they not unfrequently do,) they can be drawn out of their channels and others substituted. Besides these horizontal channels, there are vertical flues left in various parts of the stack to promote the expulsion of moisture, which otherwise would volatilize into steam, and accelerate the cracking of the masonry. This tendency to crack in the stack seems so confirmed that there is hardly a furnace of any considerable size in the world which does not show it. Except for a certain loss of heat these cracks do not injure a furnace, provided the in-walls remain unhurt. Finally, there is a dust-flue (in large furnaces) communicating from the top with the tymp-arch.

2350.



2351.



When, as in the second alternative, it is the *cohesion* of the stack that is relied on to retain the in-walls, it is generally built of bricks, circular, and tied with many vertical staves and hoops of wrought-iron. Such stacks are generally termed *cupola blast-furnaces*, but they are never of the largest

dimensions. The external proportions vary according to the fancy of each builder. Fig. 2350 shows an ordinary furnace of this sort; Fig. 2351 another, remarkable for appropriateness, ingenuity, and taste.

Blast-furnaces have universally a roof, over the ground adjacent to the front and sides, of greater or less extent, called the *moulding-house;* and one, adjacent at the top and approaching more or less near to the chimney, called the *top-house*, or *bridge-house.* The necessity of these in protecting from weather the workmen, materials, and metal, is obvious. They are also advantageous in proportion to their extent, the spouts with which they are furnished, &c., in keeping the foundation, &c., of the furnace itself dry. As far as possible, the materials used in these buildings should be iron, to avoid risk of fire.

The difference of materials in furnaces has been frequently spoken of already as entailing a difference in dimensions. The principal influence in this respect is due to the fuel; and hence there is a marked difference in size between *charcoal* and *coke* furnaces. The necessity for this is apparent, when we consider, that with equal volumes, the heating effect of charcoal is but one-half that of coke; of two furnaces, then, of the same size, the one fed with charcoal can never be raised to so high a temperature as the other, for even the most obvious steps towards equalizing them (viz. continually supplying fresh charges of charcoal) have of themselves a cooling tendency.

The following table will show, at a glance, the comparative dimensions, &c., of these two classes of furnaces, established upon what is considered a fair average of each. The particulars under the head of anthracite are taken from what may be regarded as the latest improvements for the use of that fuel

Dimensions.	High-furnaces, using Charcoal.	Coke.	Anthracite.
Stack, height from foundation	35 feet,	50 feet,	35 feet.
width at base	28 "	50 "	40 "
width at top	16½ "	25 "	33 "
Cuvette, diameter of trundle-head	4 "	8 "	6 "
height of conical in-walls	25½ "	33 "	11 "
do. cylindrical	—	—	8 "
width at boshes	9½ "	15 "	12 "
angle of boshes	55 degrees,	65 degrees,	75 degrees.
height of boshes	4½ feet,	10¾ feet,	11 feet.
Crucible, height of hearth	5 "	6¼ "	5 "
mean of length and breadth at top	2½ "	5 "	6 "
do. do. at bottom	2 "	4 "	4 "
height of tuyère above hearth-stone	1½ "	2 "	1⅚ "
Approximate capacity	1000 cub. feet,	4500 cub. feet.	
Descent of charges in about	20 hours,	40 hours.	

These dimensions and proportions undergo changes, necessarily to be accommodated to different ores, they are often arbitrarily modified besides, or follow a routine established at earlier periods of the art of smelting. Thus, in South Germany, the old *fluss-ofen* is still substantially retained; in Sweden, many high-furnaces are still erected without a crucible, *i. e.* with a continued talus from the top of the boshes to the hearth-stone; in Wales, where the product surpasses that of any other part of the world, the furnaces are lofty and vast—some (but an unsuccessful model, it is said) attaining a height of 70 and a width of 20 feet; the English furnaces of Staffordshire are lower, but, in proportion, more wide; the Scottish are more cylinder-like and squatter, still. In America, there cannot be said to be any prevailing type for charcoal works; the coke furnaces are said by Overman to be generally on the model of the first successful one,—that at Lonaconing in Maryland: while the use of anthracite as a fuel has yet received so little extension as hardly to present more than a few instances.

With these explanations of the means made use of, we can now pass to the materials employed in the smelting of iron, and their respective preparation.

1. *Fuel.* This is one of the most important materials, both in regard to quality and cost. We have already seen that it constitutes the index in a classification of furnaces; and when it is considered that there are many situations whose ores cannot be availed of because of the inconvenient supply of fuel, the propriety of placing it first in the list of materials will be apparent. The object in the use of fuel is principally to obtain heat, but it also acts in the furnace upon the other materials as a reducing and deoxidizing agent. In both of these aspects, its value is in proportion to the *carbon* which it contains; and in the last aspect, it is not mere *flame* or heat which is wanted in the furnace, but the contact also of carbonaceous matter with the materials to be reduced. *Wood*, whose chemical constitution may be taken in general at 50 per cent. of carbon and 50 per cent. of oxygen and hydrogen, in proportions forming water, contains too little carbon in its natural state to be advantageously employed in a furnace. Compared with coke, its calorific effect under equal volumes is but one-fifth of the latter; it therefore would not raise the temperature sufficiently. It has been attempted to be applied in a baked or *torrified* state, but not with sufficient success to induce a further use. The presence of *hydrogen*, which promotes inflammability, and which, although under some circumstances it acts as a deoxidizer, does not so act in a furnace further than upon the combustible itself, is a permanent obstacle to the employment of all fuel in proportion as it exists. Hence *raw* coal is, in general, improper; *turf* and *lignite*, or *brown coal*, are in the same category. The last named burn too much in the attempt to carbonize them; but pressed and charred turf is quite extensively used in France, Germany, and Russia, for the manufacture of iron. For smiths' work, it is said to furnish a charcoal of peculiar excellence. In America, where there is so much other fuel of a character as unquestionable and of supply more convenient, its consideration may as yet be left out of question; and all that will be treated of here is the preparation of *wood* and *coal*, the one by *charring*, the other by *coking*, for the purposes of the iron-master. The gen-

eral principles of carbonizing either fuel are the same: viz., the expulsion, by heat, without contact of air, of the volatile constituents of the fuel. These constituents go off in part as gases, containing more or less carbon, and, in part, as new combinations which are still liquid at a high temperature; as, for instance, acetic acid, tar, &c. The distillation of wood or coal, with a view to economizing any other products than residual carbon, does not form any part of the business of iron-working.

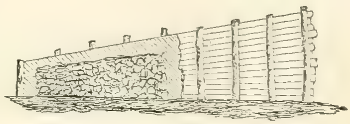
The means, too, for carbonizing either fuel for this special metallurgic use are similar, in kind, though the details of the methods vary for both considerably. These details may, however, be grouped into two great classes: 1. Where the carbonization is effected in a permanent, air-excluding *oven*: 2. Where it is done in *clamps*, or *kilns*, or *heaps*. In the general aspect of carbonization, the means employed would have to be antecedently classed according as use may be made, *first*, of other fuel than that to be carbonized, in order to generate the requisite heat, or *secondly*, of a part of the mass itself, for the charring of the other part. The type of the first system is seen generally in all the apparatus where other products than carbon are sought to be collected, and where the coke or charcoal are incidental to the operation; as in gas retorts, or the cylinders for pyroligneous acid or wood vinegar. Although a system like these might, in some localities, where fuel was abundant or in different qualities, be advantageously introduced, there is probably no iron establishment where it is resorted to; and the other classification, of *ovens* or *kilns*, remains as the only one that need be discussed here.

The relative advantages of these two methods can only be ascertained by a comparison of their products in quantity and quality. With respect to the first element, *quantity*, it may be assumed (though it is not universally admitted) that *ovens* produce a greater quantity, by weight, of carbon from the raw material. Hardly any collier can claim a yield of more than 20 per cent. of charcoal, for instance from heaps; while the best ovens, with perhaps less trouble, though not less expense in individual cases, will give about 25 per cent. Again, in the assemblage of cases, the expense for ovens is probably less; being less exposed to accidents from weather, neglect, &c., which sometimes result in the combustion of an entire kiln.

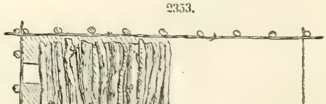
With respect to *quality* of product, the evidence is less decisive. It would seem in theory that the oven, producing a greater weight of carbon, ought also to produce a heavier material, *per se*. But such is not always, nor even generally, the case; and where the oven charcoal or coke are of the highest specific gravity, (and the economy of a high specific gravity is, in general, undoubted,) yet from some cause, such as a peculiar arrangement or disarrangement of fibres, it is not found to develop so much heat as that prepared in kilns. This point of *quality*, therefore, and, indeed, the whole question as between ovens and kilns, need a more profound and extensive investigation. All that will be done here is to describe the most usual and simple details of both methods; first, for charcoal, and then, for coke.

Charring of wood is still practised in Austria after methods which seem to have originated under the period of Roman domination, for the manufacture of the celebrated Norican iron. These may be denominated charring *in heaps*, (Germ. *haufen*,) or *clamps;* and will be understood from the accompanying sketches, of which Fig. 2352 shows a side-view, and Fig. 2353 a ground-plan of the arrangement. The ground for this may be either levelled or sloped. In either case, pipes are sometimes, but rarely, laid in the upper parts of the clamp, to carry off some of the liquid products. The length of the clamp (and, of course, the number of posts) is arbitrary—generally from 40 to 50 feet; the width depends upon the length of the logs, which, being ordinarily 4 feet, and being laid in a double row, with a very small space, to the casing of the sides, will make the width very nearly 9 feet across, from post to post. In Fig. 2353 the logs are given as if in but one length, which can very well be if the sticks are light. The casing may be of plank, slabs, or split cord-wood. The ground is well pounded; and, if in an old burning, with charcoal and dust. The logs are then piled, beginning from the upper part, to within a few inches of the top of the casing. Then it is covered with chips, twigs and leaves, and finally with sand or (better) dust, which material is also filled in against the casing, to protect it from fire. After all this is ready, fire is put in at the lower end, and some of the dust is removed from the upper end to make a draught. Draught-holes are also opened at discretion in the sides of the casing. When the smoke comes out where the dust is removed, it is necessary to throw it on again, and open elsewhere with caution. In this manner the fire is led on till the heat has charred the whole. The peculiar advantage of this method is supposed to be, that with a clamp, say of 50 feet, charcoal may be drawn from the lower end after the fire has progressed about ten feet, which it will do, ordinarily, in twenty-four hours. This is still further helped by making it on sloping ground. If well packed, a clamp of 50 feet by 9 feet, 6 feet high at the head, and 3 feet at the foot, will hold about 15 cords.

2352.



2353.

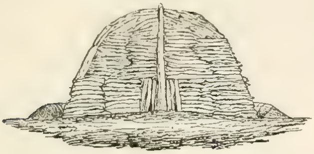


Another method, more extensively and commonly practised, is that of *kilns*, (Germ. *meiler;* Fr. *meules*.) These kilns are of two kinds, *standing* and *lying;* the wood standing on its end in the one, and lying on its side in the other, as shown in Figs. 2354 and 2355.

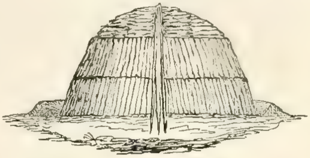
The circle, to be levelled and pounded down, for a kiln of this sort, will be from 40 to 50 feet in diameter; the driest ground must be selected for the purpose, and a place sheltered from winds. The best period for burning, in America, is from the middle of May until the middle of August; and then

again in October and November, during the season known as the Indian summer. Wood which has been felled, and lopped, and barked in December and January, will be sufficiently seasoned to char in the autumn following. After the logs have been arranged, as in the figures, around the three long stakes of ten or twelve feet in length, (which are to serve as a chimney,) and piled as evenly and compactly as possible, the whole pile must be covered to keep out the air. A site for a coaling improves

2355.



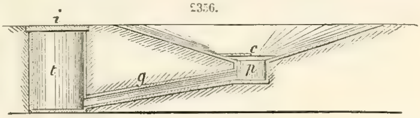
2354.



by use, for the charcoal and loam get trodden and mixed together, forming the best material for the covering. On entirely new ground use must be had of sod. When covered, fire is applied, either through the top and suffered to fall through to the centre, where provision has been made of some light wood to catch readily, or through a horizontal flue left along the ground, which is closed at its entrance as soon as the fire has taken. For the first twelve hours the kiln must be closely watched, and, therefore, it is usual to light at daybreak. At the end of that period, or a little longer, according to the kind of wood, its state of seasoning, and the skill of the collier, the fire will have taken sufficiently, and the top may be covered in with dust and loam. From that time, it is better that the operation should proceed as gradually and slowly as possible. In three or four days the cover begins to shrink and fall in, and fresh watchfulness is required to stop every opening thus made, and even new ones are made to effect an equable distribution of heat. These are points that cannot be taught by talking; they are lessons of experience and observation. When the cover sinks gradually, and the smoke grows less and less, regularly, the work is known to be going on well. Expert colliers find indications of the process in the *color* of the vapor and smoke, which varies at different stages. After all smoke has ceased, the kiln is entirely and thickly covered, and left for four or five days, less or more according to its size, *to cool.* The coal is begun to be drawn from the foot, but cautiously at first, until it is found to be too cool to re-ignite upon admission of air. If so, the drawing may be continued all round for coal that is wanted, peeling it off, as it were, like an onion; the whole contents may be hauled off to store, or it may be left (covered up again) to be resorted to when wanted. In proportion as the kiln is well piled, flues in various places are unnecessary. It sometimes happens that the fire takes in particular parts, or does not take at all. In this last event, the advantage of a horizontal firing flue is tested. A kiln of ordinary size, of this kind, holds about 30 cords; the largest contain 50 cords.

When the circumstances are such as to render it likely that the same charring-ground will be used for a considerable period, it is worth while to adapt to it some permanent accessions, as indicated in Fig. 2356; which represents the section of a basin laid in dry brick, to serve as the ground of the kiln. This basin has a pit at *p*, with a cast-iron cover *c*, to keep ashes out, and a gutter, *g*, communicating with the tank *t*, which receives the liquid products of carbonization. With resinous wood, these products are advantageously removed as soon as possible from the charcoal, and are valuable when caught. The tank has a lid, *i*, which must be laid over it and luted when the kiln is fired.

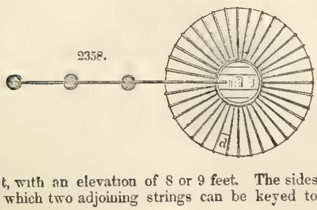
2356.



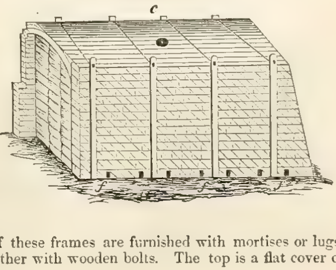
Midway between ovens and kilns comes the shroud or *abri* of Foncauld; of which a side-view is shown in Fig. 2357, and an orthographic one in Fig. 2358. It consists, in fact, of a series of trapezial ladders, made of light frames, and capable of enclosing a circle at the base of 30 feet, at the top of 10

2357.

2358.



2359.



feet, with an elevation of 8 or 9 feet. The sides of these frames are furnished with mortises or lugs, by which two adjoining strings can be keyed together with wooden bolts. The top is a flat cover of

scantling, with traps that can be opened or shut for the passage of air, and also for that of a conduit made of three pieces of light plank, for the condensation of gaseous products. The effect of these ladders is to allow of a better packing (and, as it were, thatching) of the ordinary loam covering of kilns. Fire is applied, and air furnished at first through the door *d*, left in one of the ladders. The charcoal furnished by this method is said to be of superior quality; its yield is stated at 24 per cent. of the wood, with 20 per cent. besides in crude pyroligneous acid. This yield of charcoal is about one-fifth more than from the kilns that have been described.

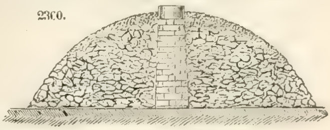
Of *ovens* there is a great variety of form; but as the most of them are embarrassed with apparatus for collecting other products besides charcoal, they are more connected with distillation than carbonization for the manufacture of iron. Only one, of the most simple and economical form, and yet yielding good results, will be described. A portion of it is shown in Fig. 2359, which is supposed to give a tolerably clear idea of the plan. The building from which this is taken is about 50 feet long, 12 feet wide in the clear, and 12 feet high, and will hold, well packed, about 60 cords, a quantity that has been found to present the maximum of convenience and economy. *c* shows the chimney-hole in the centre for firing, *f f* flue-holes for the draught, of which there are others on top which cannot be seen. At the ends there is a small door for charging and drawing. The stays are of cast-iron or wood, the horizontal binders on top of bar-iron. Wooden scantling was first used for both these, but it is neither so safe nor so strong. The arch which is sprung for the top is low, but yet, when the fire is in, there is considerable thrust against the walls. These walls are 1½ brick, and must be well laid and joined. As the acetous products in the oven are apt to attack the lime, asphalt, or a bituminous cement made of coal-tar and loam, is used instead of ordinary mortar. Coal-tar is also advantageously used for coating the outside. The wood is piled lying, as is seen in the figure. Under the chimney-hole, a chimney (so to call it) is left in the pile, at the bottom of which the fire is placed. The wood may be kindled through the draught-holes or at the doors, but less economically. When the fire is first started all air-holes are shut; when it is fairly caught the chimney may be filled up with dry wood, the hole closed, but not tightly, and air-holes opened at the ends. This will happen in seven or eight hours. The operation must now be watched, and by the emission of smoke and vapor through the air-holes, a judgment may be formed as to where they should be shut and where opened. In 45 to 50 hours the whole oven will have been heated; all openings are then closed and luted, and the concern left for three or four days to cool. On the fourth or fifth day at latest the coal should be fit to be drawn.

To what has been said, may be added some generalities as to the choice of wood and quality of the charcoal. The denser woods are to be preferred, because, other things equal, they afford a denser and harder charcoal. Decayed or doted wood will not yield a good article; and charcoal from green wood is more light, more friable, and less calorific than from dry, besides being less economical in the manufacture. The trees should be felled when the sap is down, i. e. in the winter, from December to February. Small timber is in general, and young timber always, worse than that which has attained a larger and more mature growth. Yet *very* old wood is not so good, because there is always more or less decomposition of the fibre. Branches of trees give less and a lighter charcoal than the boles, and the best of all is furnished by that part of the trunk and roots nearest the ground. In the ordinary felling of trees this part is all lost. Hence it would be better for the purpose (and the land would be left in a better state) to extract the trees at once by the roots, as is very easy, and then saw the timber instead of cutting. Heavy charcoal produces more heat, but its *reducing* effect is not in every case in proportion. There are some mines with which lighter charcoal acts better; but that it should be *hard* is an important characteristic universally. Charcoal just from the kiln burns quicker and produces less heat than that which has been kept some time in store, yet very old charcoal is admitted to be less valuable than what has not passed over one season. To what this is owing is not clear, for the affinity of the material for moisture is exercised very promptly, and after the first 24 hours, in an ordinary atmosphere and with reasonable precautions, it does not materially increase in weight. It is better to keep charcoal in store than to leave it stored in the kiln. After it has grown cool enough to handle, the sooner it is made quite cold the better; all gradual expulsion of heat, such as occurs in a kiln, is at an expense of carbon. With ovens this caution is unnecessary, for the circumstances there always compel removal of the charcoal as soon as manufactured. The product in charcoal ranges from 18 to 22 per cent. in kilns, and from 20 to 25 per cent. in ovens. By volume a cord of wood, 128 cubic feet, well corded, ought to give, at a mean, 40 bushels of charcoal. The price depends, of course, upon the value of labor in every locality, and the distance of hauling. The chopping of a cord of wood is equivalent to about one-third of a day's labor in the abstract, and the coaling of it in kilns or clamps afterwards to about a half day. The computations of the charcoal-burner are usually made upon the 100 bushels of charcoal delivered. Coaling in ovens, although in fact less laborious and demanding less experience, requires more tact, and wages there are generally higher.

The ***charring of coal***, or ***coking***, (from the German word *kochen*, to cook,) is the same in principle as that of wood, and the processes are very similar, though in some respects the considerations are different. Thus the coker does not fear, like the charcoal-burner, either air or moisture, nor is he troubled with the shrinkage and falling in of the kiln. On the contrary, for coke there has to be a large supply of air to determine combustion at all; the volume is in general increased during the process, while moisture, during the earlier stages, (but after the fire has obtained full way,) is recommended as a desulphuretting agent. It does, in fact, so act, but hardly to the extent that is claimed for it in theory, and sometimes supposed in practice; for the proportions of sulphur remaining in the coke from the same coal, treated either way, do not appreciably differ. On the other hand, coke-burning, subject to the same general category of regularity and manageability of temperature, and therefore when in the pure air liable to accidents from high winds, &c., of the same sort as occur to charcoal kilns, has to undergo constantly a greater per centage of loss from combustion. This loss is, on the average, about 6 per cent., so that coal which, on analysis, shows 85 per cent. of carbon and earthy matter, will rarely give 80 per cent. of coke, allowance being made for the quantity (from 5 to 10 per cent.) converted into slack.

Coke is made in *heaps*, in *clamps*, and in *ovens*. A suitable contrivance, and much used for heap-coking, is shown in Fig. 2360, the central shaft of which is a cylindrical or conical chimney loosely built of brick, (terminated in the sketch as in Staffordshire, with a cast-iron chimney-head,) against which the coal is piled conically, not tightly, and often with regular flues and intervals left between the masses. As with wood, the heaviest lumps are near the centre, the lighter outside. Coke-dust and slack-coal are used as a cover and for stopping. Ignited coal or coke is thrown in the chimney, and fire is sometimes introduced by the horizontal flues below. After the fire is started, similar precautions are required as with charcoal. The height of the chimney is from 5 to 6 feet, the diameter of the heap from 14 to 16 feet, and it will take from 10 to 12 tons of coal. As the process advances, slack-coal is thrown on in some places, and openings with a crow-bar made in others, according as the coker wishes to direct the heat, and water is injected plentifully, both to control the heat and desulphurate the fuel, if it is supposed to need it, and finally to put out the fire. A heap of the size given will be thoroughly coked in two and a half or three days; it is then left four days to cool, the whole operation requiring about a week.

2360.



In Wales *clamps* are more used for coking, which are long piles 5 or 6 feet wide, 2½ to 3 feet high, and in lengths varying according to the extent of coke-yard, from 60 to 100 feet or more. One of 60 feet will be of 30 to 40 tons. The coal is piled as in the other method, the largest pieces inside, loose throughout, and with horizontal flues. In place of the chimney, however, a stout stake is driven in the middle of the width and at every two yards of the length, to serve as a guide in piling. When the coal is piled the stakes are pulled out, and the space they leave becomes a chimney, into which the fire is placed as before. Sometimes the clamp is fired in its whole length at once; most usually it is fired at but one end, (regard being had to the state of the wind at the time and its probable permanence,) and even before the piling at the other is finished, so that it is a common thing to see coke drawn from one end and coal piled on the other end of a clamp at the same moment. The coke yielded by either of these methods is supposed to be better for iron-making than by any other way; but they are both costly in coal consumed, the latter especially. Where, however, as in the districts of its principal employment, coal is abundant and cheap, it presents divers conveniences which are probably cheaply purchased.

Slack-coal, i. e. coal beaten and comminuted in very small fragments or powder, (Germ. *schlag*, a *stamp*, a *blow*, and, by metonymy, a *crushing*, and the *thing crushed*,) of suitable quality, is also capable of being converted into good coke by a somewhat similar process. If the slack be from very *dry* coals, i. e. which do not contain much bitumen, it will not, however, coke at all; if the coal be too *fat*, i. e. with too much hydrogen, it will run together on the application of heat, embarrass the circulation of air, and yield a small proportion of a very friable and inferior article, if it does not defeat the whole operation. Assuming the coals to be of suitable quality, it may be treated by being mixed in small quantities, well wetted, in a kiln or clamp with larger coal. But the best method is to screen it first, and thus separate all the egg and nut-sized lumps from the mere slack, or pure powder. This last is mixed with water abundantly, and can be beaten from within against a wooden mould or shroud. Provision must be made by laying smooth and somewhat conical tampers of wood horizontally and vertically through the mass, for air-flues. These tampers are afterwards drawn out, and some larger than the rest, towards the top, leave the means of introducing already ignited coal to fire the mass. It is better to fire at the top than below.

Fig. 2361 will give an idea of the arrangements proper for this method, which, preserving the main principle, are of course susceptible of many variations in detail. Thus they are sometimes made circular, but the most usual form is, as in the figure, an elongated prism, 50 to 60 feet in length, from 4 to 8 feet wide at the base, and from 2½ to 6 feet at the top, and 3 or 4 feet high. A greater width, up to 15 feet, has been tried, but not to advantage. Of course a mould and cores of the whole length are not necessary, but after a portion has been finished the shrouds and tampers can be discreetly moved further on and the clamp extended. Iron rings are indicated at the end of the tampers, through which a lever is passed to assist in their removal. The quantity and quality of coke made, due care being taken in the process, is in proportion to the quality of the coal, and about 80 per cent. of the quantity yielded from the same slack in ovens. A clamp of the size mentioned will take about ten days to coke and cool. It is better, on divers accounts, to leave it to cool, rather than extinguish it by cold affusions.

2361.

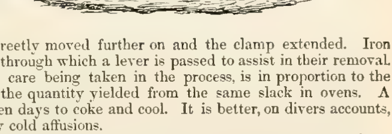


Fig. 2362 is an elevation and plan of two ovens of a series, especially applied to the coking of slack, but also capable of being used as well for lump-coal. It is supposed that the sketch makes it quite intelligible, without further description. The doors at each end render the emptying of the oven very convenient. The average dimensions are about 16 feet long, 8 feet wide, and 4 feet high to the arch The diameter of the chimney (which is generally a cylinder of a single brick, or refractory pottery) is ordinarily 16 inches. The hearth and arches are best made of fire-brick. The foundation of the hearth may be of stone or common brick, with a filling of a foot at least of sand or furnace-cinder interposed between it and the floor of the hearth proper Such an oven will hold from 10 to 12 tons, and the

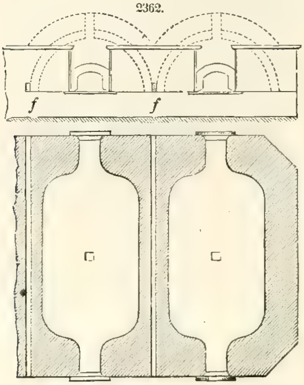
coking, including cooling, is done in from 40 to 50 hours. It is not well to let it cool too long, or to such a degree that the slack will not be speedily ignited on contact with the hearth. In this respect, the oven, like a common bake-oven, works better for longer use. The first yield of coke from the cold oven is inferior to what is made afterwards. There can be no doubt of the greater economy of *ovens* fo• slack-coal.

Another sort cf oven suitable for slack-coal resembles very much the *bank-ovens* for lump-coal that will be spoken of presently. The ground-plan is circular, the roof slightly arched, the only mortar used fire-clay. Flues are carried all round, communicating at generally three points with the interior. There is but one door for drawing, and the filling is done through the top; for greater convenience in which, they are generally built against a bank or sloping ground.

2362.



2363.

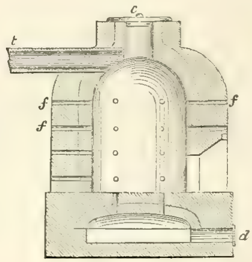


Fig. 2363 shows an oven of a different construction, much used in Silesia, both for coking and also for *coal-tar*. For the former purpose alone the ash-pit and damper *d* may be dispensed with, sufficient draught being furnished through the flues *f f*, &c. The opening in the section shows the door through which the fire is introduced, and which is afterwards bricked up. The filling is done from above through the throat, whose cover *c* is, after firing, luted down. The flue for the escape of the *tar* is shown at *t*.

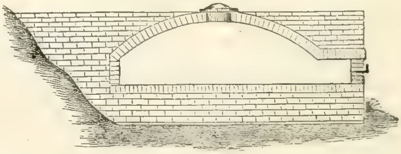
The oven in most general use, both on the Continent of Europe, in England, and in America, has a circular or ovoid ground-plan, with a low, arched roof, to allow for the swelling of the coal. The draught is regulated by a damper in the door, and sometimes by flues communicating with the interior; the filling is in part effected by the door, and in part through the chimney, the fire applied generally through the last. The backing of the arch is filled up square, and, to save masonry, the building is generally made against rising ground, whence they have the name of *bank-ovens*.

Fig. 2364 shows a section of one of these ovens, for holding about two tons of coal. In England they have generally more or less of a chimney, and not unfrequently two more smaller apertures in the same axial plane to assist the draught. Also, there, the doors are usually of iron, sliding vertically in a frame and balanced; in America, the doorway is generally bricked up, and as this is always but temporary masonry, in such case iron staples are let in on each side for receiving a bar that may resist the thrust from within of the expanding coal against the brick-work. For economy of building and heat, several ovens are generally ranged in one stack.

2364.



One of the most simple and at the same time serviceable forms of oven is that employed at Newcastle and its neighborhood, which serves equally for lump or for slack coal. It was devised, indeed, principally in the view of economizing the last. The ground-plan of these ovens is rectangular, 13 feet by 10 or 11 feet, covered with a low elliptical arch, (a parabolic one would be better,) whose crown is about five feet above the hearth, clear inside measurement. They have but one door, sliding in a close joint, as before mentioned, about 2 feet high and $1\frac{1}{2}$ wide, with a register-door in its centre of 3 inches square for admitting or shutting off the air. The draught is further managed by three chimneys in the arch, the main one, of about 1 foot square, in the middle, the others, about 4 inches square, at equal distances from the central one. This last has, as usual, a cast-iron cover; the others are closed with a brick. The coke from these ovens is supposed to be very good.

In regard to the advantages of the two methods of coking, in the open air or in ovens, it may be said that there is less loss and less labor of attendance with ovens, but more skill is required in managing

the temperature. Thus, for instance, if the heat is got up too quick, (as it is very apt to be,) the coke with *fat* coals is spoiled by burning out too swoln, light, and friable; with *dry* coals, it burns up and causes loss. Also, ovens yield, on an average, about 10 per cent. more coke, but generally of less specific gravity and more friable. Whether less care is taken in the selection of the coal for ovens, as is probable, it is certain that the almost universal experience of iron-masters is in favor of coke made in the open air on the score of useful effect. Again, the yield from ovens is more uniform, and less subject to accidental discounts. Besides, ovens allow more readily the use of slack or refuse coal, to produce an article of the same value. The oven-coke, then, charged, too, with the greater labor required in drawing and the higher average wages of the cokers, is the cheaper in actual outlay; but its final cheapness, in which the quality of the product is an element, because of the varying degrees of its inferiority, which depend too much upon the constitution of the coal used in different places, hardly allowing a satisfactory comparison. Coke made in retorts is undoubtedly the *cheapest* of all, but its quality unfits it for use in the smelting of iron.

So great an effect has the physical constitution of the coal upon the coke produced, that experience shows the quantity of coke ranges in different places from 45 to 90 per cent. of the original weight of coal employed. About $\frac{5}{8}$ths of coke would be, most likely, a fair average of all known results on the large scale. Experiments made in small, or calculations upon the chemical analysis of coals, are no further admissible or of use, in this respect, than to stimulate the manufacturer to an investigation and economization of his actual results.

Regard being had to *volume* yielded, most coals expand in coking; some are unaltered, and some, even where a large proportion of earthy matter is principally aluminous, shrink. The resulting volume with the swelling coals is nearly, but not quite, nor always, in proportion to the loss of weight. Thus, Johnson, in his report to the Navy Department of the United States, in 1843, states, for a specimen of coal from Allegany County, Maryland—

Loss in weight, $17\frac{23}{100}$ per cent.; gain in bulk, $42\frac{25}{100}$ per cent.

The physical properties of this coal are stated by the same observer as under:—

Sp. grav.	Weight of a cubic foot. Calculation.	Experiment.	Per centage of Volatile matter.	Carbon.	Earthy matter.
1·337	83·3 lbs.	54·3 lbs.	12·67	74·53	10·34

The water and loss on the analysis appear to have been 2·46 per cent., and the proportions of the ingredients in the earthy matter is not stated.

No average increase of volume can be taken, in the present state of our information, to be of any practical utility; for, 1st, the result depends so much upon the methods employed; and, 2d, it is not the aggregate of the volatile matters which determines the expansion, but chiefly the proportion of oxygen and hydrogen to one another, and also to the earthy matters present. In regard to the first point, Berthier has shown the proportions of volatile matters existing in coke prepared on a large scale for blast-furnaces, to vary from $2\frac{7}{10}$ to 18 per cent.; in regard to the last, while analysis alone could satisfactorily determine it, yet for the practical purposes of the manufacturer it may be borne in mind that in general great lustre, but deficient hardness and elasticity, indicate the presence of hydrogen, (the element promoting fusibility,) while great lustre, with an intensely black color and much hardness, show a predominance of oxygen, associated with a large proportion of carbon. These last-mentioned indications, assuming the earthy matter in constant proportion, characterize the class of *dry* coals, which may be, with more or less advantage, employed *raw* in the smelting of iron. In general, it may be added, that coals containing more than 20 per cent. of volatile matter cannot be expected, *prima facie*, to be advantageously used in the furnace, either hot or cold blast, without coking.

From what has been said, it is obvious that the final efficiency of any coke must depend on its ultimate constitution. Thus the coke of Luxemburg, just now mentioned, with its 18 per cent. of volatile matter, is substantially but *dry* coals. The average composition of good coke may be represented as of

Carbon	82	per cent
Earthy matters	15	do.
Volatile matters	3	do

It is also obvious that the earthy matters in coke answer no useful purpose in smelting—they are only absorbents of heat. In proportion to their occurrence, therefore, they embarrass the operations of the furnace. It is difficult to fix a limit to which there will not be individual exceptions; but in general, coke containing more than 15 per cent. of ashes is not fit for the iron-master's use. Karsten places the excluding proportion far lower than this.

The absolute or relative efficiency of coke, then, can only be determined upon analysis; and external characters by no means give a conclusive result, though they are often valuable as an approximation. Good coke may be inferred from its not having undergone great alteration of *volume*, or change of *shape*; from its *color*, an iron-gray, or more nearly that of graphite; from its *lustre*, more *silky* than metallic; from much *hardness*, *elasticity*, and *resistance to impact*; from a uniform *fracture*; from a *texture* more fibrous than compact, and which imparts a peculiar *sonorousness* to a mass when struck; and, finally from a specific gravity which should, if any thing, somewhat exceed that of water.

These details upon fuel may be concluded with the following table, showing the probable consumption of fuel per 100 of crude iron produced with ores of different sorts

Denomination.	Per centage of Metal in Ore.	Per centage of Fuel consumed.	
		Charcoal.	Coke.
Fusible ores, (Class 4, in part, and 5,)............	25 @ 30	66 @ 90	110 @ 150
do.	30 " 35	90 " 110	150 " 180
do.	35 " 40	110 " 130	180 " 220
Ores of mean fusibility, (mixed mines,)...........	30 " 40	110 " 140	180 " 240
do. do.	40 " 50	140 " 180	240 " 300
do. do.	50 " 60	180 " 210	300 " 360
Refractory ores, (Class 2, 3, and part of 4,).......	30 " 40	160 " 200	275 " 350
do. do.	40 " 50	200 " 250	350 " 400
do. do.	50 " 60	250 " 300	400 " 500

Anthracite has been omitted in the discussion of fuels, mainly to save room, and also because, in one aspect, it may be considered as coming under the category of coals capable of being used *raw* in furnaces; whose employment, (whether bituminous or anthracite,) however interesting to particular districts, has not yet received actual extension enough to be treated on the ground of uniform or average experience. In another aspect, it may be regarded as belonging to the class of *hard-coked coals*, whose constitution its own very much resembles, as will appear from the following average, viz.:

Carbon	88·7	per cent.
Earthy matters	7·4	"
Volatile matters....................................	3·9	"

It is on the respective proportions of the ingredients in these earthy and volatile matters that its treatment and behavior depend; the principles of calculation must be precisely the same as those which govern in the case of average coke, and the results accordant.

2. *Ores, and their preparation.*—The methods of *extraction*, or *mining*, practised for different ores, according to differing circumstances of position and association; of *picking*, (Fr. *triage*,) *washing*, and *stamping*,—processes used according to circumstances for separating the ore proper from a more or less indurated gangue, and cleaning it,—will not be considered here; according to the distribution practised in extensive iron-works, at least, the ores do not come properly under the hand of the furnace-manager until the last of these processes is achieved; and they belong, therefore, to the article MINING, which see.

The *roasting* of the ore is the beginning of the furnace processes. The objects of this are to diminish the aggregation of the mass, and thus leave more room for other chemical affinities to act, and for new combinations to take place; to drive off such impurities and admixtures (water, carbonic acid, and sulphur, principally) as can be volatilized at a red heat; and, as some suppose, to present the mine in a higher state of oxidation. The methods followed should be in subordination to these aims.

In point of fact, all of them are partly answered with many ores by continued exposure to the atmosphere, under which a spontaneous disintegration takes place, together with a partial absorption of impurities and a peroxidation. But with some ores, these effects are not manifested till after a long period, (as, for example, with magnetic and specular oxides,) and with all they are vastly accelerated by a due application of heat. It may even be said that all ores are the better for being roasted and then exposed for as long a time as convenient to the macerating influence of the atmosphere. The *red hematites* of Lancashire are hardly an exception to this; for, though used habitually raw, it is only for intermixture with other ores, and in small quantity; while the custom, in some districts, of only *weathering* the sparry carbonates, which are afterwards used unmixed, arises only from the difficulty of so managing the heat as to roast and not fuse them.

This management of temperature is more or less necessary with all ores. Thus, magnetic and red oxides, quartzose sparry carbonates, argillaceous carbonates containing a suitable proportion of silica, and generally all the silicated ores, are easily vitrifiable. As a general rule, the roasting should be as prolonged and at as low a temperature as possible, with free access of air and moisture.

The roasting may be done in *kilns*, or *clamps*, or *ovens*. The first is the most simple of all and the most extensively practised. The shape of the kiln is indifferent; it is sometimes conical, sometimes a square or rectangular pyramid. Its size is equally indifferent. The whole method consists in interstratifying the ore and fuel, (in an average proportion of about five of the former to one of the latter,) from the base, where there is a sufficient accumulation of combustible, and certain rudely made flues or prolonged cavities, to insure the fire taking throughout. The smaller pieces of ore are put outside as a cover, and ashes and cinders, coal, coke, or charcoal dust, or loam, used afterwards, where necessary, as a stopper or damper of the fire. After piling and starting the fire, it is, in good weather, only looked at from time to time. In most of the English, Welch, and Scottish furnaces, as well as at many in America, they appear to overlook the importance of keeping a large stock of roasted mine ahead, so as to give it the further benefit of atmospheric exposure.

Clamps are, in principle, very much the same with those already described for making charcoal. Three sides of a parallelogram, of width and length indefinite, are built round with a dry wall in stone, having draught-holes left at intervals of five or six feet in the base, and carried up to about three feet in height. Chimneys are built loosely, of brick or stone, along the middle of the clamp, and corresponding with each one (or, sometimes, two) of the flues. The fuel is laid, in the beginning, at the bottom, and is more or less interstratified with the pile of ore according to the greater or less presumed fusibility of this last. Sometimes there is no interstratification at all, but fuel is supplied as wanted to the draught-holes in the base.

The *ovens* used are of almost infinite variety in shape and dimensions. Their general types are a cylinder, an inverted cone, or a combination of an inverted and a right cone, and a truncated ellipsoid; they vary from 6 to 18 feet in height, with an average diameter of 3 feet at the grate and of 5 to 10 feet at the trundle-head. They are like *lime-kilns*, either perpetual or periodic; and, in fact, the description of a lime-kiln is also that of a roasting oven. The temperature to be maintained in the last is lower than in the other. *Reverberatory* ovens have been tried, but unsatisfactorily, for the roasting of ores.

It is to be supposed that the larger the oven, the more regular and economical will be the work. For refractory ores, the oval shape is, perhaps, the best; while the more simple cone or cylinder is better suited to fusible ores. Ores generally pass, with but short (if any) interval, (and in so far disadvantageously,) from the ovens to the top-house, where they are *broken up*, and immediately charged into the furnace.

This *breaking* is effected upon a stone or (better) a cast-iron floor, sometimes with a beetle, one or two handed; sometimes with iron-shod stampers, moved by machinery; sometimes the mine is crushed between fluted cylinders made to revolve. But the best of all methods is to break by hand with an ordinary stone-hammer.

The size to which the mines should be reduced before charging ought to vary directly with the hardness of the ore and the height of the furnace. From one to three inches, average diameter, inside, will be the limits. Larger than the one, they leave too much to be done in the furnace; smaller than the other, they embarrass the blast.

3. *Fluxes.*—The reducing effect of the carbon of the fuel upon the metallic oxides in the high-furnace has been already spoken of, as well as that of the potassa and soda contained in the earthy matter of charcoal; but these are rarely sufficient, with most mines, to cause at once fusion and reduction; and it becomes necessary, then, to add other matters, sterile in metal, to promote fusion: these are known as *fluxes*. *Silica*, indeed, which is a constant association in all ores of iron, is, of itself, a sufficient flux in some cases; but, even in those, it is more apt to be in excess, when it both embarrasses the working of the furnace and impairs the quality of the metal. It would be proper, then, to neutralize this excess by the addition of some other substance; and such addition becomes still more proper when (the practical problem in the furnace being *to effect fusion at the lowest possible temperature*) both theory and experiment show that it not only cures such excess, but also promotes fusibility. In fact, we know that while of each of the earthy bases most ordinarily accessible, viz., silica, lime, magnesia, and alumina, is almost (and one of them entirely) infusible, *per se*, yet in combination, two and two, three and three, and, still more, four and four, they melt readily at easily attainable temperatures. The addition, then, of suitable proportions of these sterile matters, is the means to economical fusion of the materials in the furnace.

Without dwelling, however, upon the theory of their action, (which has been explored more or less profoundly by a host of chemists and metallurgists, and has been experimentally examined by Achard, Alexander, Berthier, Descotils, and Lampadius,) and regarding only the practical maxims that fit the question, it may be said that in addition to the silica and alumina, always present in the ores and fuel, and to the lime, magnesia, manganese, and potassa, sometimes present, too, the positive flux most usually added is *lime*, in the form of marine shells, limestone, or chalk. The proportion of this addition varies in almost every case; but, at a mean, it may be taken, for charcoal furnaces, at one-fourteenth of the other solid materials by weight; and at one-eighth, for coke furnaces.

Although lime is the flux thus almost universally employed, it is not always the one that best suits the case. With an excess of silica, it is the proper one. But when the ores are themselves *calcareous* in any considerable degree, the best addition is of aluminous or magnesian earth, or both. In some cases, where the ores and fuel are highly aluminous, the addition required (though with great caution) is *silica*, in the shape of quartz, &c. In such cases, the best avail has been taken of *siliceous* matter containing also a low proportion of iron. It is thus that amphibole, basalt, and garnet have been applied. This is, in fact, the use of a *poor* material instead of one utterly sterile.

In general, it may be estimated, that of the whole solid materials introduced into the furnace, (the *metallic iron* excepted,) the

Silica may range from	45 to 60	per 100.
Lime "	20 to 35	"
Alumina "	12 to 15	"
Magnesia "	12 to 25	"
Oxide of manganese	15 to 20	"

If all four first named are present together at once, the most fusible proportions in which they can exist (without regard to the fluxing action of metallic oxides that may be there too) are,

Silica	35·2 per 100.	Lime	19·1 per 100.
Alumina	31·7 "	Magnesia	14·0 "

The solid material of the fluxes should be, like the ores, broken up into fragments of similar and uniform size. When oyster-shells are used, it is not necessary to treat them further than by a slight previous calcination. They do not always receive that.

The artificial fluxes, (such as *salt*, *potash*, *saltpetre*, &c.,) either singly or in combination with alkaline earths, which have been suggested at various times in the last twenty years, do not appear to have met with as much practical success as the theories of those who recommended them seemed to warrant. It is probable that this will be always the result; owing not so much to mistake in the principle as to a difficulty, inherent in the blast-furnace, of applying these highly fusible and reducing agents just at the point where they are wanted.

4. *Gaseous material—atmospheric air.*—The remaining material in blast-furnaces, besides those that have been considered, is the *atmospheric air*, which is regularly blown in to keep up the combustion.

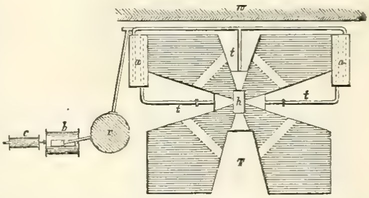
It is, therefore, in this aspect, one of the most important to be duly managed; and when the enormous quantities of it that are required are taken into view, its probable influence and collateral effect can be still better appreciated. The following average statement may be derived from the practice in this particular.

	Charcoal Furnaces. Solid.	Charcoal Furnaces. Gaseous.	Coke Furnaces. Solid.	Coke Furnaces. Gaseous.
Volume of materials, in cubic feet, per minute	0·295	900·	1·06	3000.
do. proportionate................	1·	3050·	1·	2830·
Weight of materials, in lbs., per minute................	24·82	75·	102·12	269·
do. proportionate................	1·	3·022	1·	2·634.

Taking the mean of the proportional quantities, it appears that, in round numbers, the *volume* of the air injected is 3000 times larger than that of all the solid materials in any given time; while its *weight* is three times greater than theirs. The elements used above would show also that on the average there is consumed nineteen tons of *air* for one ton of *iron* made.

In order to illustrate the means of managing this vast supply, Fig. 2365 (a sketch, with more attention to distinctness than proportion of parts) shows the arrangements suitable for a furnace of the first class. The power used is assumed to be *steam;* though the method of its procurement and application is not carried further back here than to the steam-cylinder *c*, worked horizontally by the same piston-rod that goes through and works the cylindrical bellows *b*. It is obvious that other sources of power, or other methods of geering, may, under suitable circumstances, be resorted to. From *b*, the bellows, the air is driven into *r*, the *regulator*, whence it passes into *a a*, the furnaces for heating it, and then transmitting it along *t t* into *h*, the hearth or crucible. T indicates the tymparch as before; W a retaining wall against the hill-side, and connected by an arched bridge above with the stack; while the blanks left in the piers show the passage-ways before spoken of, left for more convenient access between the tuyère and tymp-arches. Such being the general arrangements, the parts and their requisites will be spoken of briefly in order.

2365.

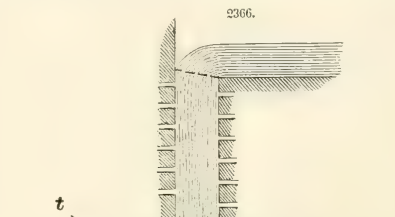


Bellows, or *blowing machines*, have been constructed of *leather*, of *wood*, of *stone*, and of *cast-iron*. The first material, on account of its expensiveness and the narrow limits which it imposed upon both the volume and density of the blast, is no longer used except for smiths' fires. The second, whether made with hinges or (as afterwards) worked with a piston, left much to be desired. The use of the third, in an instance or two, can only be justified by necessity, or applauded as a conquest over circumstances: while the last, in the shape of a double-acting cylinder, furnishes the only satisfactory and sound means to the end.

Before describing these, however, mention must be made of a method on a totally different principle, which, under variously modified forms, is still employed in parts of Italy and the districts of the Pyrenees. This is the *trompe* or *water-blast*, of which Fig. 2366 shows the principle.

In this, a vertical tube of wood or iron, cylindrical or prismatic, of length and diameter suited to the fall and quantity of water intended to be used, connects with a cistern below, made air-tight except for the opening *t*, to connect with the tuyère. Through this tube a stream of water is allowed to fall, drawing in the air as it descends through openings that are indicated by broken lines in the sides of the column, and breaking upon an altar below. The air thus carried into the cistern has no means of escape except the tuyère *t*, and its quantity and pressure delivered through that depends upon the absolute size of the column of water, and the proportions of the various parts. Venturi has already satisfactorily investigated the relations of this machine; which will not be dwelt on in that aspect further here than to say, that although very cheap and convenient in its construction, it uses more water for a given effect than a water-wheel would do, and that its effectiveness is quite limited. Karsten refuses to admit that the *dampness* of the blast it affords, injures the quality of the iron; although it is probable that most metallurgists would conclude, in the face of general theory and experience, that the good quality of iron made by this method exists *in spite of it.*

2366.

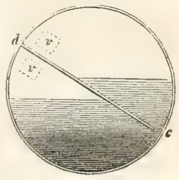


The *chain-blower* of Henschel is an improvement upon this machine. In it, a more complete separation of the air and water is effected, by means of an endless chain of floats or pistons, worked by the descending water itself; but its effect is not such as to take it out of the general category of objections.

The *hydraulic bellows* of Baader is, in fact, but a single-acting piston air-pump, in which the surface of a reservoir of water is made to take the place of the otherwise solid end of the pump. It cannot be made to furnish blast either of large volume or much density, and is mentioned here only because it is actually used with satisfactory effect in suitable cases; but it can only be recommended in districts where water is plenty and the labor of the artisan dear.

The *oscillating cylinders* of D'Aubuisson are an extremely ingenious blowing-machine, cheap to construct, and worked with little power and at small expense. Although not giving a blast of sufficient amount or density for the smallest high-furnace, except with the most fusible materials, they answer very well for chafery and finery fires. Fig. 2367, which is a section of one of the cylinders, will afford an illustration of their action. A diaphragm, central, through the entire length and nearly the whole diameter, is shown at *c d*; *v v* are two valves, alternately aspiring and expiring. In its normal position *d d* is vertical; the barrel is filled half full of water, through a bung, and is then set in oscillation, through an arc of 90 or 100 degrees, by a connecting-rod and crank geered on near *c*. It is manifest, that in different angular positions of the diaphragm the content of water in the two semi-cylinders will come to be unequal, as shown by the shaded lines; and the air will be respectively rarefied and condensed accordingly.

2367.



All these methods, however, imply more or less contact of the air with water, and the consequent immission of more or less moisture with the blast; which is objectionable. But this oscillating method leads to speak of a *rotary* method for delivering dry air—at least, air of the ordinary atmospheric humidity only. This last is the *fan-blast*, in which fans, radiating from an axis, are caused to revolve rapidly in an appropriate disk, receiving the air at the centre of rotation, and delivering it on the circumference into a chest, with or without a valve. The volume of air furnished by this means is not, without considerable expense in construction and power, sufficient for a high-furnace of the first, or even of the second class; but the density that can be obtained leaves nothing to desire. For cupolas, refineries, &c., it is very convenient and appropriate. It is, in practice, of two kinds: one acting *impulsively*, in which the air is aspired and at once diffused in a common chamber, whence it is driven out by the fan-wheel; the other *centrifugally*, in which the fan itself is a hollow wheel, receiving the air at openings near its axis, discharging it first, at openings in its circumference, into the chamber or casing, and then driving it out from said chamber by fans fixed upon its own periphery. The chamber of the outer casing is kept from communicating with the external air, as it is inspired, by a portion of the internal revolving disk, which is made to work air-tight as possible in the outer casing. Here is exactly the embarrassment of the arrangement, which imposes a higher cost upon the apparatus in the beginning, and is difficult of maintenance. When it fails of being maintained, however, the machine does not, on that account, lose its value—it merely passes over into the other class.

2368.

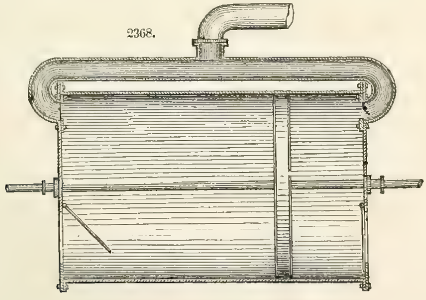


Fig. 2368 is a section of a horizontal, double-acting, blowing-cylinder, in cast-iron; which may be taken as the type of a class that fulfils all desirable conditions. The details, it is supposed, sufficiently explain themselves. There are some advantages in a horizontal cylinder rather than a vertical one; principally, it can more readily secure a good foundation, with less waste room from valves, which, in the others, are more or less necessarily in the sides. By carrying the piston-rod through both heads, the weight of the piston is equalized upon the collars, and there is left but little risk of the cylinder's wearing out of shape.

The *size of the blowing-cylinder* depends upon the volume of blast wanted. As the length of the stroke is generally somewhat limited by the conditions of the other machinery which supplies the moving power to the piston, and as the maximum speed of the stroke, or number of revolutions in a given time, is, in like manner, determined by general mechanical considerations, it has been found necessary, in practice, to give these cylinders a large diameter, disproportionate to the length of stroke

The blowing-cylinder at Dowlais, for instance, (which is the most extreme case that could be cited,) has a stroke of 10 feet and a diameter of 12 feet.

To determine the volume of blast, and, consequently, the size of cylinder, the best rule is, when the constitution of the materials to be used is known, to allow air enough to *peroxidate all the materials* in the furnace at any one moment. This will be the outside limit. In ordinary practice, the machinery will be worked at a slower speed; and in emergencies, there will be still a margin to go upon. In calculating the supply of air, it is to be remembered that the best-executed blowing machines do not deliver into the furnace more than $\frac{3}{4}$ of their theoretical capacity: it would be even safer to take, as an average, $\frac{2}{3}$ of such capacity for the actual supply.

If the constitution of the materials is not known, but the size of the furnace is, and thence the number of charges that it ought to bear in a turn, we have another rule: *One-fifth of the weight in pounds of fuel* (either charcoal or coke) *charged during one turn of twelve hours, is the number of cubic feet of air, under the pressure of the atmosphere, to be furnished in one minute.*

This allows for the average discount on the working of the machine, leakage of pipes, &c.; and gives, therefore, at once the capacity of the cylinder.

Regulators are of two general classes: 1st, of *variable* capacity; and, 2d, of *constant* capacity. Those of the first class are either *dry*, or *wet*, or (as these last are called) *water-regulators. Dry regulators* are merely cylindrical air-chambers, in which a piston works air-tight, which is loaded to the pressure desired at any time. These cylinders have, of course, an inlet and an outlet pipe for the air, neither of which needs valves: the valves shown in the air-chest above the cylinder, in Fig. 2368, answer all the purpose of isolating the air in the regulator from that under the piston, on the one hand, while, on the other, the blast-pipes and tuyères are regarded but as continuations of the regulator. In fact, in every case, long and large blast-pipes (although density is lost in proportion to length) serve, in a measure, to assist in uniformity of blast. The *capacity* of these *dry regulators* should be, in theory, *twice* the capacity of the blowing-cylinder; in practice, they will answer to be *one and a half* times as large.

Water-regulators are oblong chests without a bottom, or *receivers*, let down in a tank containing water, and balanced after the manner of gasometers. The weight of the chest, and the additional load put upon it, cause it to sink; the influx of the air, and its elasticity, cause it to rise. As the air beneath the piston is under much greater pressure than in the regulator, and thus every stroke of the piston causes a slight fluctuation, the capacity of these regulators (whose minimum is the same as in the former kind) is generally governed by other considerations, and made as great as convenient. The adjutages and pipes for receiving and discharging the blast are, in practice, very much varied in position, &c.; but the general principles of their arrangement are too obvious to require description here. Very convenient and suitable in most regards, this kind of regulators is liable to all the objections accruing from access of moisture.

The second great class comprehends air-chambers of *constant capacity*. These, which long ago were built under or above ground in masonry, or for which even subterranean caverns, sedulously rendered air-tight, were resorted to, have, in the most modern times, come up again, (as in Wales,) only in a material more suitable and manageable. Sheet-iron is now most generally resorted to; strengthened, when thought necessary, with ties. Their form is generally cylindrical or spherical; one of the latter shape exists with the enormous diameter of $25\frac{1}{3}$ feet. The most convenient form appears to be that of a right cylinder, of thin sheet-iron; with a base solidly supported, and a head, either of cast-iron or sheet-iron, stiffened with wood, carrying a safety-valve, (which acts here also as an equalizer of pressure,) and admitting of an aperture, large enough for the entrance of a workman, and capable of being closed air-tight.

Of course, the larger such a chamber is, the less will it feel the pulsations of the piston; but there must be an economical limit in this respect. In practice, the regulator is made from nine to fifteen times as large as the blowing-cylinder; in theory, its least capacity, to furnish a uniform discharge, should be in the same proportion to the blowing-cylinder as the pressure of one atmosphere is to the pressure desired to be maintained. Thus, if the pressure be assumed at 2 lbs. per square inch, the regulator must be at least $\frac{15}{2}$ or $7\frac{1}{2}$ times the size of the blowing-cylinder.

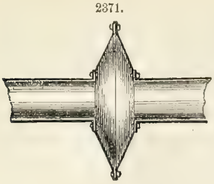
From the regulator the blast-pipes were traced, in Fig. 2365, to *the hot-air furnaces;* but the considerations belonging to these will be postponed for a moment, and the furnace considered as working (as all did, in fact, until 1827, the epoch of Mr. Neilson's improvement, and as many prefer to do still) with *cold-blast.* What remains to be spoken of in advance is the *blast-pipes* and *nozzles;* the water-tuyères, which are indispensable with hot air, and advantageous with cold-blast, have been already mentioned.

Blast-pipes are made of sheet or cast iron; for first-class furnaces, where the pressure is required to be considerable, generally of the last-named material. As they cannot be made in one piece, they are jointed either by flanges or by a muff, (what is called the *faucet and spigot* joint,) as in gas and water pipes. When cold air is employed, the packing of the joints is *lead;* with hot air, an iron cement must be used. This cement is made of 99 parts of iron filings, sifted fine, and 1 part of powdered sal ammoniac, intimately mixed, dry. When used, as much water is added as will make a stiff paste. Flowers of sulphur, sometimes recommended, in no way contributes to the efficiency of the mixture, but rather to the contrary.

The pipes are sometimes laid under ground and covered over; but this mode is not to be recommended; they should be always accessible. If hot air is ever expected to be used, provision should be made in the laying for expansion and contraction by resting them upon rollers, (short pieces of three-inch iron pipe answer very well,) on a smooth foundation. It is impossible, in the conditions of application, to avoid flexures; but these flexures should, of course, to save friction, be made as gentle as possible.

When the straight lengths are so great that there appears to be danger that the pipe will break, a

2371.



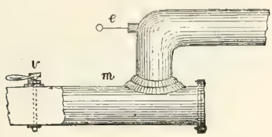
compensation-joint is inserted; this frequently consists of an end of a pipe movable in a stuffing box. The plan represented in fig. 2371 is preferable to it. This is a compensation-joint, consisting of two round dishes of sheet-iron, or copper, 20 or 30 inches in diameter, according to the size of the pipe, riveted air-tight at their periphery, and screwed to the two flanges of joining pipes. The sheet iron may be from $\frac{1}{8}$ to $\frac{3}{16}$ of an inch thick. The large diameter and flexibility of the sheet-iron allow the two pipes which are joined to it, to move longitudinally, independent of each other. Wooden blast pipes are sometimes used, but are useless where a dense blast is to be conducted.

The capacity of the pipes, *i. e.* their *diameter*, should, other things being equal, be as large as possible. But, as other things (to wit, the expense) are not equal, they should be proportioned to the quantity of blast to be delivered. A reasonable unit may be taken, in allowing a nine-inch pipe to 1000 cubic feet of blast per minute. Then, as the quantities vary with the squares of the diameters, 4000 cubic feet per minute will be accommodated by pipes of eighteen inches.

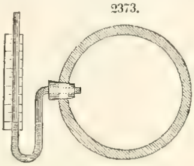
Whether the pipes are laid under or on the ground, the level of the tuyère will still be above them; two elbows, therefore, are necessary to bring the nozzle into the tuyère. The junction of these elbow-pieces should be always with a ball and socket joint for giving play to the nozzle. With cold-blast, this play can be, and frequently is, attained upon fixed elbows, by connecting the nozzle and the blast-pipe proper with a leather hose or bag; with hot-blast, the leather is inadmissible.

Various forms, of more or less complexity, are used in and about the termination of the pipes for shutting off the blast entirely (as has to be done at every run-out) or partially, measuring its intensity, &c. Fig. 2372 shows one of the most simple and satisfactory. The ball and socket and fixed elbow

2372.



2373.



joints are both seen. At v is a trundle-valve of sheet-iron, elliptical in shape, with alternately bevelled edges, and worked by the winch above. When this winch is parallel with the axis of the pipe, the valve presents nothing but its thickness to the blast; when it is at right angles to the axis, it shuts up the pipe entirely, and with a tightness proportionate to the accuracy of its fitting. It can be made (so to speak) perfectly tight. Some furnace-managers have a plate-collar fastened beneath the winch, divided angularly on its circumference, and read by an index that moves with the winch, to show either the absolute or relative quantities of blast in the different positions of the winch-handle. At e is an *eyelet*, closed ordinarily with a conical iron plug, as shown. When this plug is out it allows the founder to look into the hearth and observe the aspect of the tuyère. With hot air, this has to be used discreetly. Between the valve and the elbow, somewhere about m, is placed (with cold-blast) the *manometer* or *pressure*-meter of the blast. Fig. 2373 shows a section of the pipe with the apparatus attached; which is only a glass tube, $\frac{3}{8}$ inch bore, containing a few inches of quicksilver, and open at both ends. When there is no pressure from within, as when the blowing-machine is at rest or the blast shut off, the mercury stands, of course, at the same level in the two branches of the tube; when there is pressure, the column in the long arm rises, at the rate of 1 inch in height for every $\frac{1}{4}$ lb. of pressure. The best scale to put on it is a piece of card, divided in equal parts, sliding up and down by friction, and capable at any moment, by shutting of the valve, of proper adjustment. With *hot-blast*, the manometer has to be placed in the regulator. Otherwise the actual density of the air is more accurately measured as near as possible to the *nozzle.*

These *nozzles* or adjutages are conical sheet-iron tubes, made to fit as tight as possible upon the cylindrical blast-pipe, and tapering off to an orifice from 1 to 5 inches in diameter. Furnace-managers do not generally trouble themselves much about the laws of pneumatics, and hence we find a great variety in the shape and proportions of these utensils. Several of them are provided of larger and smaller orifices, to be used as circumstances require. Ordinarily they are in two joints, of which the one fitted to the blast-pipe is the more permanent. The elliptical shape of the orifice sometimes found, is a disadvantage, as well as the great length of the cone; both lessen the discharge that would follow a shorter and more acute cone. The following table (which is strictly accurate under the conditions for which it was calculated) is sufficiently so to be relied on for giving the discharge of blast into a furnace in any case likely to occur, the pressure being that in the regulator, and the diameter of nozzle being measured at the extreme point of discharge.

A table like this is indispensable to a furnace-manager who wishes to be cognizant of what is going on in the furnace, in connection with changes, accidental or designed, in the blast. Its application in the present shape is both direct and inverse, and in either method is very simple. Thus, having ascertained the actual pressure of the blast to be, say $1\frac{1}{2}$ lbs., while we are using a nozzle of 2 inches; if we wish to know directly what is the quantity actually going into the furnace, we enter the table, under the first column, and opposite to that we find 122·61 cubic feet, which is the quantity that would pass through a 1-inch nozzle. Then, as the areas of circles are as the squares of their diameters, the quantity

passing through a 2-inch nozzle will be four times as great as through a 1-inch; therefore the quantity in question will be 122·61 × 4 = 490·44 cubic feet per minute, through one tuyère. If the furnace has *two* tuyères with the same sized nozzle, the whole quantity discharged in one minute will be, then, 980·88 cubic feet. We have, then, as a general rule, to *enter the first column of the table for the given pressure, ranging with which, in the second, is a number that, multiplied by the square of the diameter of nozzle used, will give the actual quantity blown in by the single tuyère.*

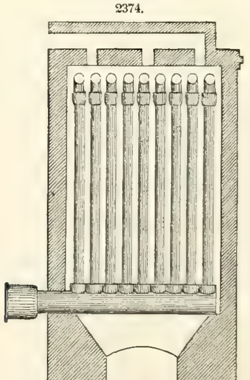
It may be applied, again, *inversely*, to find the diameter of nozzle that will discharge any required quantity per minute under a given pressure. Thus, if the question be, what diameter of nozzle will keep up a pressure of 1 lb. on a discharge of 800 cubic feet per minute through one tuyère?—we have only to divide 800 by the number (101·66) standing in the second column opposite the given pressure; the square root of the quotient $\left(\sqrt{\frac{800}{101\cdot66}}\right)$ or $2\frac{8}{10}$ inches is the diameter sought.

TABLE *showing the Volume and Weight of Blast discharged under various Pressures and at ordinary Temperatures.*

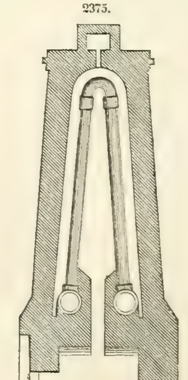
Pressure per square inch.	Quantity in cubic feet per minute, through a 1-inch nozzle.	Weight in lbs. per minute.	Pressure per square inch.	Quantity in cubic feet per minute, through a 1-inch nozzle.	Weight in lbs. per minute.
½ oz. av'd.	18·54	1·43	2 lbs. avd.	139·48	12.14
1 " "	26·20	2·02	2¼ "	146·86	12·97
2 " "	36·97	2·86	2½ "	153·70	13·77
4 " "	52·07	4·07	2¾ "	160·06	14·55
6 " "	63·51	5·	3 "	166·01	15·30
8 " or ½ lb.	73·04	5·80	3¼ "	171·61	16·03
10 " av'd.	81·33	6·51	3½ "	176.88	16·75
12 " "	88·74	7·16	3¾ "	181·86	17·46
14 " "	95·47	7·76	4 "	186·58	18·15
1 lb. "	101·66	8·33	4¼ "	191·07	18·83
1¼ " "	112·78	9·38	4½ "	195·35	19·50
1½ " "	122·61	10·36	4¾ "	199·43	20·17
1¾ " "	131·44	11·27	5 "	203·32	20·82

If, instead of measuring the discharge by *volume*, we have occasion to know the *weight* of the blast, the third column, treated in the same manner, gives that element.

2374.



2375.



The effects of a more or less dense blast, i. e. of more or less pressure, appear to take place in two ways principally. First, *mechanically* upon the quantity of discharge in the same time; and, secondly, *chemically* upon its constitution, and upon the materials in the furnace. The air, at the instant of expiring, is of the density it had in the blast-pipe, although it very shortly afterwards assumes its normal

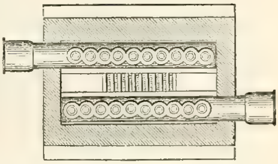
volume. But as far as the melted materials in the hearth are concerned, it is, at the moment of entry richer in oxygen in proportion to its density. Thus, under

Pressure of	Volume of air.		Weight in oxygen.
1 lb.	100 cubic feet give		1·88 lbs.
2 "	do.	do.	2· "
3 "	do.	do.	2·12 "

By increasing the *pressure*, then, we support combustion more readily, and generate a *m intense degree* of heat. By augmenting *volume*, we support combustion more extensively, and produce a *greater quantity* of heat. These considerations apply to and solve the question often mooted among founders, as to whether the best effect is obtained by increasing *the pillar of blast*, (as they term it,) or using larger nozzles, and thus furnishing more air under a constant pressure. With fusible materials, sufficient air should be furnished under low pressure; with refractory ones, it is better to increase pressure rather than volume.

The apparatus used for *heating the blast* is very varied and multiform, the aim being in all to furnish the utmost extent of heating surface with the greatest economy. Instead of mentioning all the modifications that have been suggested, or figuring the contortions that hot-air pipes have been made to exhibit, Figs. 2374 and 2375 give vertical sections, transverse and longitudinal, and Fig. 2376 a horizontal section of the most convenient and best arrangement, either for separate furnaces near the tuyères, or for ovens on the trundle-head. In the latter case, the horizontal flue shown in Fig. 2376 (which communicates with a vertical one in the stack itself, or back-wall) is replaced by a short chimney. So far as outlay is concerned, to heat the air at the trundle-head is the cheapest, for there is no extra fuel required. But to realize all the benefits of the system and the greatest absolute economy, separate furnaces below are much preferable.

2376.



For the *dimensions* to be given, in either case, iron-masters are yet without any rule, not so much from any difficulty in investigating the principles that should govern, as from want of actual experimental knowledge on the rate of cooling, &c., which prevents any general formula from being applied. Calculations made upon the quantities and velocities of blast under pressures between the ordinary limits, (of 1¼ to 2½ pounds per square inch,) result in 18 and 28 square inches respectively of heating surface for every cubic foot of air per minute. The mean of these, or the 1-6th of a square foot, may be taken as a safe allowance (if the pressure does not exceed 2½ pounds) for raising the temperature of the air, at the instant of leaving the oven, to *half* that of the pipes. What will be its temperature at the nozzle depends upon the distance it has to go, the thickness and size of pipes, &c. With a higher pressure than 2½ pounds, the heating surface ought to be enlarged directly in proportion, at least; for in the very fact of being heated the air acquires a great increase of velocity, and therefore is exposed so much shorter time in the heated pipes.

There are a number of interesting points, chemical and mechanical, in the employment of hot-blast, for which there is no room here. All that can be said is, that, in general, with hot-blast the furnace works easier, carries a greater burden, with, of course, a higher yield, and reduces materials too refractory for cold air. A notable economy of *fuel* and *flux* follows. With regard to the former, the saving of fuel, upon an extensive comparison of results, may be stated for

Coke-furnaces at 32 per cent., from an average temperature of 330° F.
Charcoal do. 20 do. do. do. 390° F.

Besides this, certain *raw* coals that would not be admissible with cold-blast, are capable of being used with hot.

As to the *quality* of metal made, it is generally *gray foundry-iron*, with a more uniformly cubic crystalline form than cold-blast foundry. There is a general prejudice against it, as being less strong, but this opinion is more exaggerated than actual experiments warrant. The following table shows the proportionate strength in various aspects, from numerous trials:—

	Resistance to				
	Stretching strain.	Crushing strain.	Transverse or oblique strains.	Impact.	Stiffness.
Cold-blast iron	1000	1000	1000	1000	1000
Hot-blast iron	913	1033	963	1005	935

These statements upon the quality of metal lead naturally to the next class of considerations, which must be taken up, viz., upon the *products* of the blast-furnace.

These *products* are, like the materials, both solid and gaseous. To the former belong the crude iron and the *furnace-cinder*, as the melted slag of earthy matters is termed; to the other the various elementary and compound gases which arise from combustion and decomposition, and pass off at the trundle-head.

The first solid product, the crude iron, has been already sufficiently treated of; the other, the *cinder*, is reciprocal with it, and is one of the important tests which the founder has in judging of the progress of his work and of the issue that he may reasonably expect.

Furnace-cinder, chemically, is chiefly a *silicate of lime* in various proportions. In charcoal works it is a bisilicate, in coke-furnaces a single silicate. This appears from the following statement, which represents the average of good cinder, i. e., when the furnace is doing good work:—

	Charcoal cinder.	Coke cinder.
Silica	53	43
Lime	22	35
Alumina	16	14
Magnesia	5	4
Protoxide of iron	4	4

The charcoal cinder is, in its proportions, a more fusible compound than the other; but abstract *fusibility* is not so much to be considered as *fusibility at the temperature employed.* Coke-furnaces, having a higher temperature, require a more refractory material, in order that the cinder may answer its proper uses.

These *uses*, in general, are to assist in fusion and reduction; with very fusible ores, to retard fusion until the deoxidation of the metal has occurred; and after reduction, to protect the metal in the hearth from contact with the blast. In this last aspect, especially, the *degree of fusibility* of the cinder is of great practical importance. If it be too thick and pasty, it embarrasses the separation of the metal; if it be too thin and liquid, the iron is exposed naked to the blast. These properties, as they may exist within the furnace, are judged of by the *consistency* of the cinder during its flow. If liquid enough to flow readily over the dam-plate, and *slowly cooling* afterwards, it is of the proper character; but whatever its liquidity may be, if it tends to cool *rapidly*, the presence of metallic associations is to be inferred. Such association, as far as iron is concerned, may be inferred also from its *color*, which, with an admixture of iron in notable proportions, is always brownish or black. The most satisfactory color for the mass, on a fresh fracture, is whitish gray. Blue and bluish-green shades and streaks are almost always to be met with. The proper way to judge of color, however, is only upon a pulverized specimen. The *fracture* of cinder is always conchoidal, and its specific gravity, at a mean, 2·6. The aspect of good cinder, from charcoal works, is *glassy;* from coke-furnaces, it is more *lithoid*, or stone-like. When cinder becomes *earthy*-looking, it argues deficiency of heat; and if the furnace on the preceding cast has given gray iron, more blast may be put on without fear,—if white iron, the blast should be augmented cautiously. A *cavernous* or honeycombed cinder appears to originate in the same defect of heat; while one like *enamel*, although by many founders attributed to the same cause, arises more from elements in the materials—chiefly *phosphate of lime.*

The *gaseous products* of the furnace may be taken to consist, on an average, of

Nitrogen	56	Carburetted hydrogen	2
Carbonic acid	19	Vapor of water	7
Carbonic oxide	16		

The watery vapor most likely arises from the moisture of the materials freshly put in, and is, therefore, hardly a *product.* If the fuel had all been fully consumed, the sole products would be nitrogen and carbonic acid. But this full combustion has not been, and, with the methods followed, cannot be attained.

These gases, as they are, pass off at the trundle-head at a high temperature; so high, that the oxy and hydro carbon combine there with the oxygen of the atmosphere and inflame. This flame furnishes, among other things, a sign to the founder of the state of the furnace. If it is small and weak, it is presumable that the blast does not pass through sufficiently; and the materials, which from the moment of charging ought to be undergoing a preparation for fusion, are in fact descending more or less raw. The remedy for this is not always to increase the blast; on the contrary, a discreet founder will first take into consideration the nature of the materials, their friability, and liability to become *packed* in the cuvette. Too little slope to the boshes, too, is always more or less involved in the result, where the materials are constant.

If the flame is, as sometimes, on one side, it is a sign that the charges are not descending equally. If this is permanent, there is reason to suppose that the in-walls or boshes, or both, have degraded out of shape. If occasional, it is rather to be attributed to an accidental choking of the furnace, caused either by a bad state of materials, or, what is more common, bad filling. Of course, the flaring from atmospheric causes must not be confounded with this phenomenon. In a well-going furnace and a calm atmosphere the flame should rise cylindrically, with life, and with a certain whistling cry the founder likes to hear.

A *flame at the tymp* is a sign that the blast is not going in the right direction; in this case, it is better to alter the charges, by putting on less mine, than to change the blast.

The high temperature at which the gases pass off at the trundle-head is an unavoidable consequence of the process; it is, nevertheless, *waste-heat.* This waste-heat has been turned to account, as already mentioned, in the case of *hot-blast.* It has also been used for burning lime, for carbonizing wood, for coking, and for generating steam. For all these purposes, except the first and last, it is rarely convenient to apply the inflamed gases; and as, in leading off to a distance what is only inflammable air there is more or less loss of heat, these applications have been limited. For roasting ores, it is a perfectly appropriate means.

M. Faber du Faure, as far back as 1837, conceived and very ingeniously executed a very brilliant idea of leading off the gases, without contact of air at first, to suitable points where, by mixing it with highly heated atmospheric air, it could be burnt, and the heat thus produced applied not only to the generation of steam, but also to other processes (refining, puddling, and reheating) in the manufacture of the crude iron yielded from the blast-furnace. The progress of his experiments led to investigations upon the actual constitution of the gases at different points of the stack; and to the conclusion that the oxide of carbon existed as a maximum at a level below the trundle head, about one-third of the height of the stack. About this level, therefore, one or more flues are made in the stack, through which the gas ascends into a reservoir around the trundle-head, whence conduits of masonry or metal take it off into

an air-chest; from which, after mixture with a hot-blast, it issues through a suitable number of nozzles or burners into the hearth where it is destined to be burned.

This discovery and application excited a good deal of attention shortly after it was made public—in this country, about 1840, and large expectations were formed as to the revolution it was destined to cause in the manufacture of iron. But, either from some intrinsic difficulties, not at first apparent, or from bad management, its subsequent development has not been so extensive.

Faber's method, if confined to gases existing at or very near the trundle-head, would be perfectly unexceptionable; when, however, they are drawn too low down from the body of the materials, there is reason to apprehend that the train of the furnace will be disadvantageously embarrassed. At least, such seems to be the conclusion of those most practically conversant with smelting. This *train* is, as we know, very easily, and sometimes unaccountably, deranged; and there are few processes in the arts, where large masses are in action at once, so liable to the influence of apparently slight causes, and so much under the domain of what may be called the *working*. Before leaving the subject of smelting, then, some particulars must be mentioned in regard to the *working of the furnace*.

For working a single coke-furnace of the first class, the following statement may be taken of the hands usually found necessary, with their respective occupations: viz., *two* keepers, who take turn and turn about, every twelve hours, in the tymp-arch and below; two fillers, who are engaged in a similar manner about the trundle-head and top-house above, each with a boy to help; two cinder-fillers, in turn, to clear away cinder below; one cinder-hauler; one engineer and helper at the blast-engine; one weigher of pigs: all these (together, 9 men and 3 boys) are engaged, day and night, in and about the stack. Besides these, for ore-roasting are required one man and two boys; for coking, two men and eight boys; for breaking limestone, two boys; for hauling material from the yard, (which is done on a rail-track,) a man, a boy, and a horse. These 4 men and 13 boys are occupied in the yards adjacent, where, and about the stack, &c., there is always miscellaneous work enough for four laboring hands by day. This enumeration excludes the furnace-manager or founder, and underground agent; for the first can superintend the smelting, as the other can the mining, for several furnaces as well as for one.

Of course, where the furnace is smaller, as it is where charcoal is the fuel, there is not so much work to be done, and, in proportion, fewer hands can do it; where wages are high, more work might perhaps be got out of each hand, or it may be satisfactory if done in a less perfect manner; but the statement above is from establishments where ultimate economy has been a principal object.

None of the work that has been mentioned can advantageously be done by *contract;* the fuel and mine should always be prepared under the supervision of the furnace-manager. But a plan used in all large works to a greater or less extent, is to have a tariff of wages for all the hands named; which is rated and paid per ton of metal made, according to its quality. It becomes, thus, the direct interest of all hands that the furnace should yield the most possible of the best iron.

The number of hands given above may seem large, but in reality, there is a good deal of work to be done, and that of a sort at intervals so hard, and under such variations of temperature, that workmen about furnaces are generally short-lived. Thus, the duty of the keeper, for instance, besides moulding the pig-bed, which is done at spare times, and watching the tuyères, &c., which is a frequent duty, is to do the heavy work sometimes required for breaking into the furnace either at the fore-hearth or at the tuyères, putting in grates, &c. These, which are extraordinary demands, are done under the direction of the founder; who also himself bears a hand when necessary, or calls down the filler too. The *tapping*, which, when the furnace is in regular train, occurs twice in the twenty-four hours, (and, from old habit, at 6 A. M. and 6 P. M.,) is generally done by the founder, except in extensive works of several furnaces.

As a general principle, a furnace works best when most let alone; care having been taken in the selection and proportion of the materials and blast. But, in the best managed, accidents will not unfrequently happen, the repairing of which is a serious task upon the physical energies of the workmen.

The *filler*, with less demand upon his reasoning faculties, has not less labor to perform; and its proper execution is one of the most important items about the furnace. Upon regular and suitable filling depends more than is often supposed. Various methods have been proposed and tried, in this respect, to promote a mechanical accuracy; some very plausible, but none unexceptionable. The old, and most habitual method, is to fill by hand; the fuel, if coke, being upset from two wheelbarrows—if charcoal, thrown in from baskets. Ore and flux are generally filled from sheet-iron trays. Later, a more judicious practice has grown up of *weighing* all charges instead of *measuring*, for which the barrows, baskets, &c., served. Sometimes, after being weighed, the materials are kept separate; sometimes they are mixed and charged together. This last, if well done, is undoubtedly the best.

When furnaces are built on a plane, with the yards around their base, the labor of the filler is sometimes much increased. With such furnaces there is often an inclined plane, along which a separate engine generally winds up the trucks containing the charges; or the blast-engine is geered for the same purpose. In both cases, the different diameters of the fore and hind wheels keep the platform of the truck horizontal. The filler takes passage along with his freight. Sometimes a vertically elevating machinery is employed; as the equilibratro water system of Staffordshire, where the counterpoise to the charges ascending is a bucket filled, *pro hac vice*, with water, and discharging itself when it strikes the ground. Empty, it is overbalanced by the platform for the baskets; which, upon being cast off, again descend to be filled, &c.

The number of charges per turn, of twelve hours, varies with the work that the furnace is doing from 20 to 48. As soon as made, each one is scored by the filler upon a board for the inspection of the founder; who thus sees at a glance what the furnace is bearing, and can direct accordingly.

The business of keeping the tymp-arch clear of cinder is, with a first-class coke-furnace, no little occupation of itself. It is dragged off with long hooks, in large masses, to a suitable place in the moulding-house; where, if necessary, it is quenched and broken up in order to being loaded on a cart. Mixed with broken stone, or even by itself, it forms one of the best materials known for road-metal.

The breaking off, weighing, and piling the pigs, sows, and runners, (as the different moulds in a pig bed are called,) is another task in a large furnace. The number of pieces in a day will amount to about 400, from 50 to 60 lbs. each.

The moulding, &c., of castings, which are not unfrequently made at the blast-furnace, belong more properly to the next division of the subject, that of *founding.*

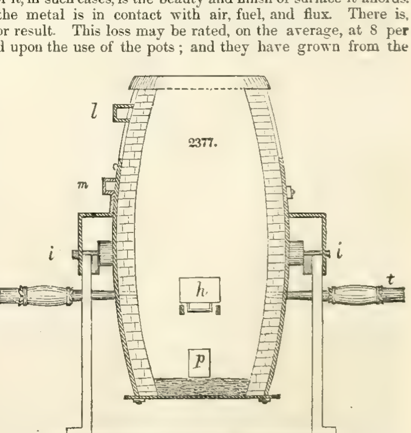
II. *Founding*, or casting crude iron in fusion into hollow moulds, no doubt followed, historically, the working of the metal in a more or less malleable state; but, in the chronological sequence of processes, it comes, as here, directly after the production of the crude iron itself. Indeed, for some objects, this crude iron answers very well itself, without a second fusion; but, in the general business of casting, particular qualities of metal are required for particular objects, and certain characters are attainable only by a mixture of different sorts of metal at once. It is obvious that these conditions are not attained with a single or even several blast-furnaces. Further, in the casting, care has to be taken to have the metal entering the moulds of a suitable temperature; this would be more difficult in metal that is *run out*, as generally it has to be, from blast-furnaces, than in that which is first received in a ladle, where it is kept till of a supposed suitable temperature to be poured. Finally, it is often necessary (as for blowing-cylinders, &c.) to have a greater weight of metal than the hearth of even a large blast-furnace contains; resort must be had, in such case, to several separate furnaces, whose united contents may suffice. But wherever *rough* castings, as they may be termed, viz., tram-rails, railroad chairs, hollow-ware, &c., are to be made in quantity, where the shape and dimensions of the moulds will allow uniform cooling, and where the highest quality of metal need not be possessed, or at least such quality as is attained by mixtures, it is the best economy to put the blast-furnace upon a proper train for the purpose, and to cast at once, either by run-outs or pourings, from it.

There are general principles about moulding and casting which govern in all metals and alloys. These should have come under a special article, FOUNDING; but, in default of that, will be found under METALLURGY. All that will be given here, will be such principles, precautions, and practice, as belong particularly to iron-founding.

In general, the metal suitable for castings is *gray* crude iron; for certain cases where the surface is of no great consequence, (i. e., the perfection of the casting,) and where the resistance is to a crushing force, *white* iron may be used. The effect of a remelting is to consume the carbon, both free and combined, to a greater or less degree; and the aim is to produce a metal which shall contain the least quantity of free carbon, and at the same time retain the octahedral crystalline structure that characterizes gray iron. This structure, other things being the same, appears to be chiefly affected by the capacity of the metal for heat, its radiation, and the circumstances under which it cools.

Iron may be melted either, 1st, in *crucibles* or *pots;* 2d, in cupolas; or, 3d, in reverberatory furnaces. The first are made of sand, as the Hessian crucibles, or of black-lead, like the blue-pots of commerce. They are of various size; but the largest will not hold more than 35 lbs., beyond which they become unmanageable. They are set upon some refractory stand or shelf, in a suitable oven. Not in contact with air directly, the loss in remelting ought not to be more than five per cent. In fact, however, it is much greater; and experience seems to dictate, as the best economy, rather to burn away a portion of the iron than to use a vitrifiable flux. Where the temperature is not at command, it is better to use a flux, both as an economy of fuel and of metal. It is obvious that the application of this method is limited to small articles. The advantage of it, in such cases, is the beauty and finish of surface it affords.

In the second method, that of *cupolas*, the metal is in contact with air, fuel, and flux. There is, therefore, both a greater loss and an inferior result. This loss may be rated, on the average, at 8 per cent. The introduction of cupolas followed upon the use of the pots; and they have grown from the little portable furnaces of France (about the year 1700)—say two feet in height, in parts—into miniature blast-furnaces, 10 and even 15 feet in height. To show that this is no limit in economy, although it is, perhaps, in the labor, may be adduced a case in Prussia, some years ago, where a blast-furnace 34 feet high, which worked in hollow-ware, had become so encumbered with scraps, that it became a serious matter to disembarrass the establishment. For this, they built inside of the stack somewhat in section like a fluss-ofen before described, narrowing it to 22 inches at the trundle-head; 4 feet at the boshes, which received a slope of 45°; with a hearth 15 inches in diameter at top, and twelve inches below. With this was remelted, in 21 weeks, very nearly 240 tons of metal; the fuel (charcoal) was 34 per cent. of the yield, and the loss of metal was 8 per cent.

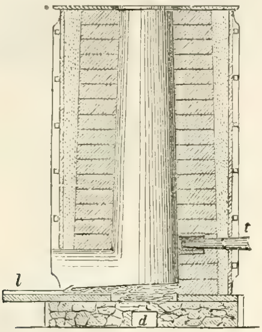


The little furnaces of 1½ to 2½ feet are, except for special purposes, very much out of use. Fig. 2377 shows, however, a small swinging furnace in section, like those still employed in Sweden. The dark parallel lines show the barrel-shaped casing of stout sheet-iron, or boiler-plate, inside of which the fire-brick are laid. The whole concern rests, and can be made to swing, on its

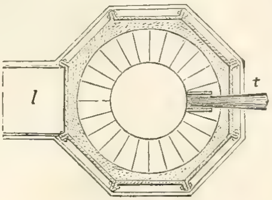
journals, $i\ i$, which work in an appropriate gallows-frame, seen below At $l\ m$ are staples, in which iron levers can be thrust to tilt the furnace over and pour through the tap-hole h, which is furnished with projections on which a clay *lip*, or runner, can be moulded. This tilting is still further helped by placing the centre of motion an inch or two below the centre of gravity when the hearth is full. The ash-hole, for cleaning out, is shown at p, and $t\ t$ represent the two tuyères used. Over the throat is fixed a hood, or mantle, connected with a chimney-flue. These cupolas are about 8 feet high; the tuyère, from 14 to 16 inches above the hearth, which, as shown, is made of fire-clay, well packed and beaten on the iron bottom. The diameter at the bottom is 18 inches; across at the tuyères, 30 inches; at the throat, about 2 feet: on the average containing about 1000 lbs. of metal.

Figs. 2378 and 2379 show a section and ground-plan of a neat and convenient form of cupola. The exterior is of cast-iron plates, with flanges that bolt together; the in-walls of fire-brick; the space between the casing and in-walls filled with coke, dust, or ashes. The bottom is an annular plate, upon

2378.



2379.



foundation of masonry, which should be well drained, as shown at d. The hearth itself is made of fire-clay, sloping outwards to the lip in order to make a clean run-out. The height of such a cupola is from 8 to 10 feet; the *tymp*, as it may be called, (i. e., the *tap*,) is 12 by 16 inches high. (This is made large purposely, in order to get at the hearth for cleaning it, and, when the cupola is working, is stopped up.) The tuyère can be varied from 16 to 20 inches above the hearth.

The hearth in this figure is represented as very large—the object being to save metal and repairs, rather than fuel. In general, a narrow hearth saves fuel; but it is at the expense of metals oxidated and in-walls worn. The comparison for ultimate economy must be made in each case; and the result will differ according to the locality. Where fuel is dear, the hearth may be narrowed to advantage.

The internal shape of cupolas does not appear to have been much studied, if one may judge from their variety. These rules, however, may be safely taken; that, with charcoal, the height should be greater than with coke, on account of the greater friability of the material, and the greater tendency of the crude iron to descend too soon. A cupola for coke ought not to be less than 6 feet in any case; nor, with charcoal, less than 9 feet. The English cupolas for coke are ordinarily 8 feet high, and about 3 feet wide, holding between 3 and 4 tons. The best form for economy is that of a small blast-furnace, proportioned as for refractory materials.

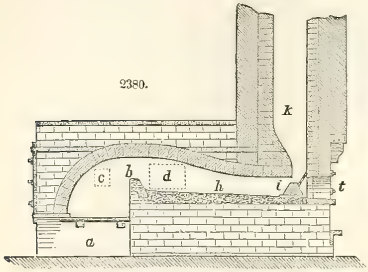
According to the size, the quantity of blast, under a mean pressure of $1\frac{1}{2}$ lbs., will be from 250 to 550 cubic feet per minute. The fuel consumed under a good train will be, with the best coke, about 30 per cent.; with coke of inferior quality, 50 per cent.; and with charcoal, 75 per cent. of the yield, which, in the best cupolas, is about one ton per hour. If the pigs are not very clean, no flux need be used; if scraps are to be worked up, limestone (chalk is preferred in England) or oyster-shells must be added in small quantities. If the average loss of metal, in remelting, is more than 8 per cent., it must generally be attributed to some error in the building, or in the management.

When a cupola is connected with a high-furnace, the blast is generally taken off from the blowing-engine. Otherwise, the fan-blast, already described, is the most convenient. It is also well, in cupolas for large work, to have three or four tuyère-holes at different elevations, to which the nozzles can be successively applied as the hearth fills.

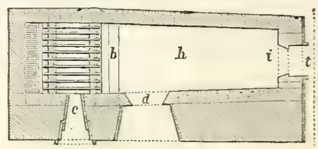
The third method of remelting is by *reverberatory* furnaces, where the metal, not in contact with fuel, is fused by the heat of the flame that, from the peculiar shape of the roof, is reflected and *reverberated* down upon the bottom, or sole. With a reverberatory furnace proper, there is no blast or impulsion of air—it is all *aspiration*—and the necessary draught is created by the height of the chimney. Figs. 2380 and 2381 show a vertical and horizontal section of one of the best forms of reverberatory furnaces; in which a indicates the ash-pit, with the grate-bars over it; $c\ c$ the charging-door for fuel; $b\ b$ the bridge dividing the fuel from the metal to be melted; $d\ d$ the charging-door for the metal; (both c and d are balance-doors, that slide vertically, shut tightly, and, when the fire is to be most intensely urged, must be luted;) $h\ h$ the hearth, or sole, on the upper part of which, near the bridge, the metal is charged, and along whose inclined surface it, when melted, runs; $i\ i$ the dam, whose function is as well to narrow the chimney-throat, as to retain the fused metal; k the chimney; and $t\ t$ the tap, where the metal

is run out through the dam, and which is stopped with clay till needed. This tap is sometimes placed in the side, but disadvantageously. The inner parts of this furnace and chimney are built with fire-brick; the sole, which needs frequent repair, laid of fire-clay, resting either on massive or arched

2380.

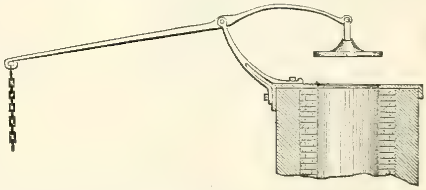


2381.



masonry, or on castings; the external parts of common brick, well tied with iron bolts and plates; the chimney, which, in the figure, is represented fragmentary, should be, at a minimum, 40 feet in height, and is terminated with a damper, as shown in Fig. 2382. The flue in this figure appears cylindrical which is the best for the draught, although it is generally made square. In no case ought its section to be less than a square foot. The damper, which is worked with a light chain or wire, as shown, should always be provided with a register-scale below, calculated for different degrees of opening and draught.

2382.



The dimensions of such furnaces are at discretion: some hold hardly a ton, others three and four tons. But the *proportions* of the principal parts—viz., the fire-grate, the hearth, and the chimney—must be subject to the laws of Pneumatics and Heat, and are, therefore, not arbitrary. The following rules, which are far from having the generality and exactitude that would flow from a fully explored theory, may be taken as in accordance with the best practice:

1. The higher the chimney, the better and more manageable the draught, other things being equal. If the section of the chimney be too narrow, the draught will be choked; if too wide, it will be weakened. When one stack is built for several furnaces, each one, then, should have its separate flue.

2. The sections, respectively, of the narrowest part of the throat (about *i*, Fig. 2380) and the widest part of the shaft, (near *k*,) may vary between the limits of $2\frac{1}{2}:1$ and $3:1$. This variation can be made from time to time, according to the nature of the fuel and of the metal to be melted, by packing more or less sand upon the dam.

3. With a given capacity of hearth and given fuel, the areas of the throat and fire-grate must be in constant proportion. This is easily ascertained by observing how the furnace works. If fusion takes place the soonest near the *bridge*, it may certainly be concluded that the area of the throat is too small; if fusion occurs sooner near the *dam*, the throat is too large. The numerical ratio will vary according to the strength of the coal and the length of the hearth: it may be assumed, as a mean, that the aggregate of the open spaces between the bars should be $3\frac{1}{2}$ times the area of the throat.

4. The absolute capacity of the furnace is, of course, determined in advance by the work it is intended to do. Its relative capacity should be such as that it goes on continually contracting itself the further from the grate; so that there should be an equal degree and quantity of heat in every part.

5. The length and width of the hearth, two of the elements of the capacity, should vary according to the fuel. On an average, the length may be *twice* the width. With coal that gives much flame, it may be $2\frac{1}{2}$ times the width; with a dry coal, and especially anthracite, it should not be more than $1\frac{1}{2}$ times the width.

6. The area of the hearth should not be more than $3\frac{1}{2}$ times the area of the grate, bars and all.

7. The height and width of the hearth should be such as that a vertical section through its widest part, near the bridge, should be $\frac{3}{4}$ the horizontal section of the grate.

8. The slope of the hearth need not be more than $\frac{1}{2}$ inch to the foot, which allows the iron to run out freely. If the inclination be great, there is no chance for yet solid fragments to be soaked (as it were) in already melted metal, and thus be facilitated in their fusion; while there is also a greater liability to decarbonization, and consequent formation of *carcase*.

9. The height of the bridge above the hearth depends upon the fusibility of the iron to be melted. If easily fusible, it may be from 8 to 10 inches in height; if refractory, not more than 4 or 5 inches.

10. The section of the grate has been given already in terms of the other parts. The space between

the bars may vary from 0·5 to 0·75 inch, according to the size of coal. The depth of ash-pit may be lessened in proportion to the inflammability of the coal; but it should always be considerable enough to avoid having the air heated by transmission over fallen cinders and ashes.

Theoretically, it would hardly appear that a large reverberatory furnace should give a less intense heat than a small one; practically, however, this is found to be the case, which may arise from this—that in proportioning the size of chimney, beyond a certain limit there occurs the phenomenon of ascending and descending currents.

The foregoing rules apply to furnaces worked with *coal*, which is by far the most economical fuel for these arrangements. When wood is used, which contains less carbon and more oxygen, there has to be a material alteration in the proportions. In a successful example, the area of the grate was two-thirds that of the hearth, four times the widest section beyond the bridge, and ten times that of the throat.

Every time iron is fused it becomes more refractory, especially after reverberatory fusion. Metal of the first and second fusion should not, therefore, be mixed together; and, as far as possible, only those of the same or nearly equal fusibility. So also the fragments ought to be of the same size. If any difference is allowed, then the larger pieces ought to be charged nearest the bridge.

In charging, it is well to get the heat of the furnace well up first, and afterwards the aim should be to raise it to the full height as quickly as possible. A low temperature is only at the expense of fuel and metal. After the iron is liquefied, every care must be taken to keep out cold air; the fuel must be charged quickly, frequently, and in quantities that will just maintain a continued and active combustion. If too much is thrown on at once, the temperature fluctuates; if too little, it falls. From one-half to three-quarters of a bushel of coal, every ten minutes, will keep a grate of average size (say nine square feet) sufficiently supplied. The best test is the flame at the top of the chimney: if it does not appear there, even with a chimney of sixty feet, there is a waste of metal; if, on the contrary, it shoots out much above, there is a waste of fuel.

The average *consumption* of coal is about 60 per cent. of the yield; the waste of metal about 7 per cent., with a good train. The average effect, under equal volumes of coal to wood, is very nearly seven to one. Upon the experience in Russia, it takes, by weight, of seasoned wood, 150 per cent. upon the yield.

The *time* taken to melt down a charge is very variable, according to the fusibility of the metal, the strength of the coal, the proportions of the furnace, and the management. The average power of fusion may be rated as equivalent to one ton per hour, and the furnace can be tapped, according to circumstances, (size, &c.,) every two to four hours.

If the scope and practical appliance of these three methods of founding be compared, it may be said that,

1. The employment of crucibles, very costly in materials, though not in construction, is limited to small objects, whose price bears no comparison to the weight of metal out of which they are made.

2. Cupolas, which are rather the most expensive in construction and maintenance, are yet worked more regularly with a less proportionate expense for wages, and are the most universally applicable for all objects of ordinary demand; and,

3. Reverberatory furnaces are especially required for castings of the heaviest sort, where the maximum resistance of the metal is demanded.

In all, the same general principles apply in the management of the metal before and after fusion. Thus, the *mixture* or charge of different kinds of crude iron is a point of great importance, both as regards fusibility, and the properties of the cast-iron run out. Castings will hardly ever be made from one sort of pig only; at least two, and often six or eight sorts are charged together. This is a matter dependent upon the practical experience and judgment of the founder, for which no written rules serve.

So also the *pouring* of the iron, or conveying the melted metal to the flasks, is independent of the kind of furnace in which it may have been fused, and is determined by the quantity required to be poured at once, and the character of the casting, whether it is to be *open*, or in *close* moulds. Very large objects, with plane surfaces, (such as girders, plates, &c.,) are generally cast open in sand-moulds, and the metal runs through a gutter (frequently itself of iron) lined with sand, after the same fashion with the sow and pig casts from the high-furnace. But when the surfaces are curved or re-entering, (as cylinders, &c.,) it is best to pour from ladles. These ladles vary in size, and, of course, in management, according to their purpose. A hand-ladle, which is wielded by one man, will contain from 50 to 60 pounds; a double hand-ladle, or *shank*, managed by three or four men, carries from 200 to 400 pounds; ladles holding four or five tons travel in a crane. The handles or pivots of all these are placed a little above the centre of gravity of the ladle when charged, so that they may be easily tilted. With the smaller ladles, accidents, either to the workmen or the contents, are rare; the largest are now so improved with tangent-screws, worm-wheels, and skimmers, as to render their management even easier than that of the smaller ones.

The whole business of making patterns and moulds is the same in principle for all metals, and belongs to the article Moulding. Only such particulars will be summarily mentioned here in which the casting of iron differs more or less from the founding of other metals.

The *patterns* for iron-castings, besides being made so as to draw readily from the mould, are made larger than the intended casting, by an average scale of $\frac{1}{8}$th inch per foot. This is to allow for the contraction of the metal in cooling. In strictness, every particular mixture has its own proportionate contraction, and when a foundry is running upon the same mixture and article, the pattern is dressed to suit; but the proportion which is given is the one generally adopted. The pattern-maker, in getting the proportion, simply uses a *contraction-rule*, whose divisions of feet and inches are everywhere 1-96th longer than the true measurement. In this way he works directly from the measurements given, without any trouble of calculation. In making a pattern of wood from which to cast an iron pattern, to be used afterwards, a double shrinkage is to be allowed for, and a double contraction-rule, with divisions 1-48th in excess everywhere, is employed.

Patterns for iron-castings require to be more carefully designed as to symmetry and equality of parts, and distribution of material, than for any other metal, partly because of the heavier stress upon the objects in use, and partly because of the peculiar behavior of the metal itself in cooling. It is easy to see that a small external stress, coming upon a material already strained by its own shrinkage, will cause it to give way. Inattention to these considerations is the frequent cause of breakages in the wheels for railroad cars. In planning a pattern other than for simple prismatic figures, regard should always be paid as to which parts are to endure extension, and which compression. The latter may be made thin, and be allowed to chill; but the parts to resist extension should be, as far as possible, compressed in the mould, and escape chilling. For instance, a T-shaped cast-iron joint is a bad shape at best for strength, but its resistance is still less when the vertical leg is downwards. In general, patterns for castings, if at all complicated, should be regarded as systems of *framing;* and in combining the several parts, it should be remembered that the strength of the whole can never exceed the weakness of the weakest part.

In taking impressions from these patterns, or *moulding* the object desired to be produced in metal, the processes are the same for iron as for other metals, regard being had to the heavier masses required of the former, and also to its different affection by heat. In this last particular, moulds for cast-iron need not be so dry as for other metals. The sand employed is also coarser, and less adhesive. Sand for partings in the mould is generally that which is scraped off from former castings, and which, having been once exposed to a full red-heat, and mechanically triturated in the rough processes of scraping, has become less sharp. The best facing-sand is charcoal and coal-dust in equal parts, ground fine, and intimately mixed. For small articles of luxury, the best facing is graphite.

Cores, which are prismatic or cylindrical pieces inserted in the mould, to produce the *holes* and openings in the casting, and in general intercept the flow of the metal, may be made of any material which does not alter its shape or volume materially when exposed to heat. The best for iron-castings are made of sand, horse-dung, and a little loam. After being shaped they are dried, and then put in a crucible and burned for ten or twelve hours, in order to consume all the vegetable matter, and leave them in a proper porous condition, both for their own permanence, and also the escape of air.

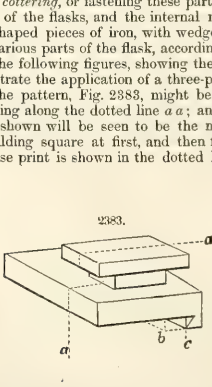
Castings of ordinary objects are made in iron moulds or in sand; very heavy objects, such as cylinders, &c., are moulded in loam. Of the use of *iron moulds*, the running of bullets is a familiar, but perhaps the best illustration, though it is ordinarily exemplified with other metal than iron. This kind of mould is applied advantageously to the casting of heavy shot and shells, (which will be treated of more particularly under the title PROJECTILES,) to tram-plates and chairs for railway bars, and to railway wheels. In these last the outer rim only is often made of iron, and the nave and spokes cast in sand upon an iron-core, the object here being chiefly to chill the tire of the wheel. Another object, *plough-shares*, are advantageously cast in iron moulds, so also are cylinders for rolling metal, forge-hammers, ore-stampers, &c., and in general all objects which have a sufficient mass of matter to resist impact or compression, and require in use the hardest and least wearing surface.

Sand-mouldings (we do not speak here of those objects, plates, joists, &c., which may be run *open*) are made in *flasks*, which, for iron-founders' use, are best made themselves of iron, but in other respects like the wooden ones used in foundries generally. The bottom flask or *drag* has generally plain, flat cross-ribs, to serve instead of a bottom-board; the top flask has deep cross-ribs cutting it up into compartments five or six inches wide and twenty to thirty inches long, with little fillets on their sides to lock in the sand more effectually; middle flasks have no such compartments at all. Of these middle flasks the iron-founder makes frequent use. They constitute the three or four part flasks, which are much more convenient for many objects than two-part flasks only, which might have to be of excessive depth. The *cottering*, or fastening these parts together, is easily effected by transverse wedges in the steady-pins of the flasks, and the internal mass of sand is retained firmly, or *gagged*, by means of *lifters*, or T-shaped pieces of iron, with wedge-shaped tail, and set head downwards. These *gaggers* are placed in various parts of the flask, according to the objects to be moulded, and the discretion of the founder.

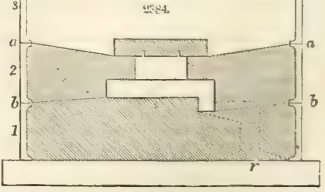
The following figures, showing the pattern and mould for the top of a sliding-rest for a lathe, will illustrate the application of a three-part flask.

The pattern, Fig. 2383, might be moulded in a two-part flask of sufficient depth by making the parting along the dotted line *a a*; and indeed there are several ways in which it might be cast, but the one shown will be seen to be the most convenient. The chamfer at *c* might also be cast, either by moulding square at first, and then filling in sand and working it to a gage, or by means of a core whose print is shown in the dotted lines terminating at *b*; but the most usual and the best way is to

2383.



2384.

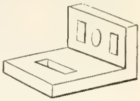


cast it square, and plane it to the required bevel afterwards. That being the case, Fig. 2384 shows the flasks 1, 2, 3, after they are put together. In working them, 1 and 2 are first set, nearly filled with

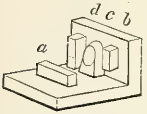
sand, and the pattern knocked in as shown, the whole well rammed, and the parting made along *a a*. The flask 3 is then added, filled and rammed, levelled, covered with a board, and all three turned over, so that 1 becomes the top, which is now taken off, a parting made along the line *b b*, and the runner-stick put in to make the runner or in-gate, as shown by the dotted lines near *r*. To prepare for casting the runner-stick is taken out, flask 1 is lifted off, and the part of the pattern (shown white) is taken out from the middle flask; the middle flask is then removed, and the shaded part of the pattern (which has been fitted by pins or lugs, as shown) is taken out from flask 3 or the *drag*. The flasks are then united, and the pouring made through *r*. It is manifest that the same system would be pursued with a flask having a greater number of parts.

The iron-founder has, from the vast variety of works which he is called on to execute, greater occasion than others to use a variety of methods of *coring*. The following figures will illustrate some of these, and will indicate how others, more complicated still, are met and accomplished. Thus, Fig 85 shows the finished casting which is desired to be produced, and Fig. 2386 tne pattern, with its core-prints for producing it. The horizontal print *a* delivers itself, but one made like the left-hand vertical one *b*, would tear up the sand in the attempt to remove the pattern from the mould. The right-hand print *d*, therefore, shows the proper shape and length, reaching down to the bed of the pattern. The circular opening has, in the same manner, a tapering print of the same length. These prints, if we suppose the pattern inverted, will leave a recess, as shown at *d* in Fig. 2387. Upon being drawn, the cores are inserted as in Fig. 2388, (a section through *d*,) the upper part of the recess is made good with sand to the general surface, and the mould is ready for casting.

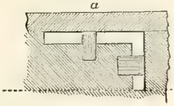
2385.



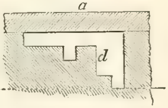
2386.



2388.



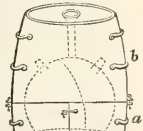
2387.



By observation and practice moulders become exceedingly expert in managing their patterns, &c., and often display remarkable ingenuity in the shifts and contrivances to which they resort for eking out or stopping off patterns, or for moulding additional parts for which there is no pattern. Indeed, as one of the heavy items of expense in a foundry is for a stock of patterns, it is not unusual, for avoiding this, to see many common articles of simple form, (grates, parts of stove-plates, &c.,) which are made upon written orders, built up with core-prints or slips of wood, and moulded almost entirely by hand. Wherever accuracy is required, however, well-made patterns are indispensable.

The objects which are moulded in sand and cast in flasks are too numerous to be mentioned. They comprehend nearly all the articles of cast-iron in ordinary or domestic use. Before leaving this branch, another illustration of flask-casting of the last-mentioned class of articles may be of interest to some readers, viz., the manufacture of *iron pots*. Fig. 2389 will give an idea of the implements in this process. The pattern for the pot (which is of metal, for wood could not be turned down well to the thinness of these vessels) exists in two hemispheres, which fit and are fastened together in the oblique dotted curve shown in the figure. The moulder takes these and places them together, mouth downwards, upon a board which has a bevel-rim just fitting the mouth of the pot. On the same board, he places symmetrically over the pattern the flask *a*, which is in two pieces, as shown. Sand is rammed down round the pattern till the flask is full, when a parting is made even with its top, and flask *b* is placed on and fastened. This is filled in like manner, prints for the feet and a runner-stick having been put in at the proper levels. The top of *b* is levelled off, a board placed on it, and the whole concern inverted. The board that originally served as the drag, and upon which *a* and *b* have been built, is removed, the interior of the pot is seen, and the flask *c* is set around its mouth upon *a*. The pot is then filled with sand and rammed to the edge of *c*, when it is all *strickled*, (i. e., levelled off,) a drag-board placed on it, and the whole reverted to its former position, as seen in the cut. In drawing the pattern, *b* comes off first, out of which the core-prints are also taken; *a* takes apart and leaves the pattern exposed, which comes out in halves. The convex and concave moulds are then dressed with tools and facing-sand, the flasks replaced, the runner-stick taken out, and the whole is ready for casting. In spite of the apparent complexity of all this, it is by no means among the costlier or more difficult works of the foundry.

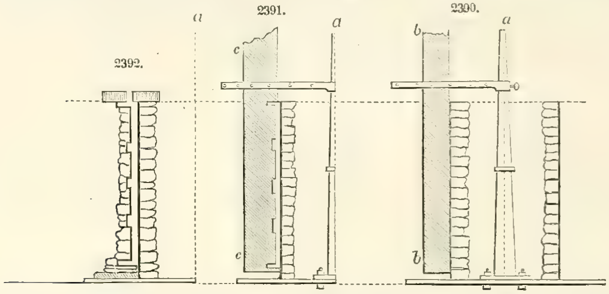
2389.



Articles that are heavy or large have to be *moulded in loam*, as it is termed; and as such things are generally required to be cast vertically, while the quantity of metal is too great to be ladled, it is more convenient to dig a pit for the mould to which the metal may be led by gutters, than to raise the furnace foundations high enough to have all the work above ground. Indeed, as works have sometimes to be executed fifteen and even twenty feet high, this last arrangement would be well nigh absurd. So far as resistance is concerned, pit-moulding is advantageous; and if due provision be made for the escape of elastic gases, it is not more objectionable on the score of danger than large flasks above ground The great merit of this method is, however, in dispensing with a solid pattern, which, for such cylinders, for instance, as are used in Cornish engines, of eight feet diameter and fifteen feet stroke, would be an

enormous expense. The following figures will serve to explain the general process of loam-moulding. Fig. 2390 shows the first stage of the mould for a steam or blast cylinder. The lowest lines represent the bed of the loam-plate, upon which the inner wall is built. This inner wall, for small works, such as pipes, is called the *core*, for large cylinders it is termed the *nowel*. The loam-plate is of iron, cast rough, and with projecting ears for lifting it. Sometimes these plates are raised from the ground, to allow of a fire for drying the loam to be made up beneath; or if the work be not too large, it is set upon a wheeled truck, by which it may be rolled into the loam-stove. Upon this truck, or on the loam-plate, or in any convenient and steady manner, a spindle *a* is fixed, which carries the templet *b b*, whose distance from the centre is adjusted exactly to the internal radius of the intended cylinder. An inner wall of brick-work is then built, whose face is plastered with soft loam, which loam is shaped and turned by the motion of the templet. When smooth it is thoroughly dried, and then brushed over with black-wash of charcoal and coal-dust, to be dried again, and serve as a parting to prevent the adherence of fresh loam. This finishes the mould for the inside of the cylinder.

The templet *b b* is then dismounted, and another *c c*, Fig. 2391, cut in profile to the external form of the cylinder, with flanges, and bosses, &c., is attached to the spindle at a distance from the centre exactly corresponding to the radius of the cylinder, *plus* its intended thickness. Fresh loam is then thrown on the nowel-mould, in order to form the thickness, which is shaped on the outside by the revolutions of the templet, carefully smoothed, dried, and black-washed as the other.



When this is finished, a loam-plate or ring is laid down to carry the outer case or *cope*, as shown in Fig. 2392. This cope is built up of brick and loam, with an inner facing of loam worked carefully to the turned thickness; it is then thoroughly dried, and lifted off carefully from the nowel. This is done by means of a crane. The *thickness* comes off with the cope, generally broken, but it has now answered its purpose. Any accidental damage to either of the moulds is repaired, the faces are black-washed and dried again, and the mould is ready to be put together, the position of the cope having been determined at first either by studs, or by marks upon the nowel-plate.

Ports at the ends of the cylinder (or short flanged tubes for attaching the steam or blast pipes) are made by working the patterns into the cope; the cores are supported either by *grains* (which are little plates of sheet-iron staid by wire, and as wide as the thickness of the metal at the port) or by sand-bearings, the holes left by which are afterwards plugged up. From the precariousness of the union of the melted metal with that of the wire and sheets, the use of grains is, when possible, to be avoided. Other passages for steam or air, either in the side or around the cylinder, can be worked in a similar manner upon the thickness, and be covered in by the cope.

When all is ready the mould is put together in the pit, the two plates bolted together, and the external space in the pit rammed hard, to resist the outward pressure of the melted metal. In very large works there are iron rings, larger than the cope, piled one on another to hold the sand; these rings are steadied by numerous stays going to the sides of the pit, which is sometimes itself walled up with brick, or even cased with iron. In such works the core too has to be strengthened by iron stays laid in diameters, and entering the brick-work of the nowel.

The metal, in pouring, is led in various ways to the mould, according to circumstances, from the sow or main runner. Sometimes there is a circular trough round the top of the mould, and the feeding is through holes in the loam-cake; sometimes the runners are sunk, and enter the mould at about one-third of the height from the bottom and tangent to the circumference. This is supposed to be a good way to keep the metal in circulation, and clear of the scoriæ or *sullage*. Sometimes, to supply hydrostatic pressure for condensation, or shrinkage in cooling, iron rings are piled up to inclose a lofty runner. In the largest works several such reservoirs or *feeds* are made in addition to the runners, purposely to provide for shrinkage. Sometimes a piston has been applied in the runners, when they are not numerous; and a still better-intended process has been proposed—that of exhausting the air from the mould, and supplying the feed from below.

Both of these methods—which have never come into general use—aim at accomplishing perfectly what the founders ordinarily obviate by other contrivances, viz., the expulsion of the air from the mould. If the air or vapor in small quantities gets entangled in the metal, it produces, of course, a bad casting, leaving cavities in the mass such as we very often see. If large quantities, especially of steam, are caught, the consequence is a greater or less explosion, sometimes attended with very disastrous consequences. The Thorncliffe accident in 1820 is still remembered in the annals of founding as one of the

saddest of such catastrophes. Upwards of 100 persons were in the cast-house at the time, to witness the pouring of a tilt-shaft of about five tons in a vertical mould. The cast was nearly finished when the explosion took place, and some four tons of melted iron shot out as from a petard, killing and wounding terribly about one-fourth of those present. There happened to be a thunder-storm at the time, and as no one knew of any mistake committed in any of the arrangements, the accident was attributed to that indefinite agent, *electricity*. It more likely arose from a sudden and explosive combination of carburetted hydrogen, a gas which is always formed in the moulds. The workmen are very well aware of this, and in casting, for example, the thick cylinders for a hydrostatic press, which are set mouth downwards generally, the air-tube or tubes which are made to come up from the core underneath to the surface are ignited for greater safety, and burn like perfect gas-torches. In small works this is not so manifest, and in these, by making openings similar to and corresponding with the runners, the metal flows *through* the mould, and drives out the greater quantity of the air and gas before it. In larger works the air-chamber is generally provided below, underneath the nowel-plate, by laying there a mass of hay-bands, with which air-tubes, leading to the surface, immediately communicate. But the use of this combustible matter cannot be recommended on the score of security.

The *temperature* proper for pouring is slightly different for every mixture; it can be judged of only by experience: at least it cannot be defined by any written rules of universal application. The *rate* of pouring, too, is in the same category. In general, *bad* castings (i. e., *blown* and spongy) are apt to be made by quick pouring of hot metal, and *imperfect* ones by slow pouring.

The necessity of providing sufficient resistance to all sides of the mould during pouring has been already spoken of. After pouring, however, the condition becomes inverted, for the metal is then shrinking into itself. The pressure from without is generally nothing; but that from within must be removed, that the cylinder be not strained, or *scored*. So, in two or three hours, according to the size of the work, the iron stays within the core are knocked away, and the workmen go down to break away the brick-work. The excessive heat renders this the most dreadful of their duties.

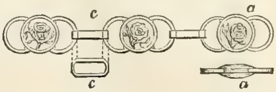
Loam-casting, suitably modified, is applied to all large works with curved surfaces, such as cylinders of all sorts, large pans, guns, pipes for water, gas, &c., &c. Guns have been cast with a core, like cylinders, but their imperfections are such as to make it more advantageous, in spite of the waste of metal, to run them solid and bore them out afterwards. The cores for pipes are usually made upon an iron tube pierced with holes, wound round with hay-bands, and revolved, while the loam is being applied, by a winch at the end, upon two iron trestles. A scraper, fixed parallel to the axis, turns off the loam, and brings the core to its true cylindric shape. This arrangement, which is susceptible of more accuracy, is the *founder's lathe*. These cores are dried and blackwashed; the thickness is laid on in loam, and also dried and blackwashed; and the object is then moulded in sand in an iron box parting in half. The core is then taken out, the thickness removed, and the core replaced, and held in place, if necessary, with grains. In establishments where pipes are cast in large quantities, it is usual to mould from wooden patterns in halves.

Within a short period, a method has been tried of casting pipes inside of an iron pattern, which is laid with a slight slope, and caused to revolve while the metal is fed. Its revolutions inspire a centrifugal tendency to the melted metal, which is restrained and shaped, as it cools, by the pattern. The precariousness of result, however, or some other cause, appears to have restricted the economical use of this method.

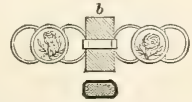
The scope of the iron-founder's art is exceedingly comprehensive, both as to the forms he produces, and the weight of metal he has to deal with. Thus, castings are sometimes required of 20 and even 30 tons in one piece, requiring the conjoint operation of three or four furnaces tapped at one time. On the other hand, the beautiful Berlin ornaments are cast in pieces of a few grains weight. The art of casting these ornaments was first developed in Prussia, and is supposed to depend, in some degree, upon the quality of the iron and of the sand employed. The latter, as well as the ores (bog-ores) out of which the former is reduced, is not only fossiliferous, but appears to be constituted entirely of the remains of animalculæ. But there are examples of successful castings of the smallest size with materials where this infusorial influence could not be suspected of operating.

The following figures exhibit one of these Berlin chains entirely of castings (many of those on sale will be found to have been connected with iron wire): its length is 4 feet 10 inches, and its whole weight 730 grains; a large and small link together weigh a little over 8 grains. Fig. 2393 shows the

2393.



2394.



chain itself; Fig. 2394 is intended to explain the way it was worked. The large links *a a* (Fig. 2393) were first cast separately. Then a pattern of the chain with core-prints *b* (Fig. 2394) was moulded. The links *a*, smoked to prevent adhesion of the metal, were laid in the mould, and then the sand-cores, *b*. The actual mould was about 8 inches long, and a separate runner was made to every one of the small links *c c*. Such things are even greater wonders of art than the larger works.

When castings are set and cooled, the next thing is to remove them from the moulds; the runners are snapped off, and all the loose sand scraped from the casting, and the seams of partings smoothed For common castings, very rough implements serve; for the finer kinds more appropriate tools are required. To these, the skin left from a sand-mould is very destructive; and therefore, if they are intended to be wrought, they are generally first *pickled* with dilute sulphuric acid—by immersion if

they are small, and aspersion if large. The acid attacks the metal underneath; and the crust that is left after a day or two is easily removed.

The skin of castings from sand-moulds is always harder than from loam. This is not so much from the siliceous matter taken up in the surface, as from the effect of a different conduction of heat, and a change of crystallization at and near the surface, which is known as *chilling*. These chilled castings have been already mentioned: it only remains to speak of the *malleable* iron castings which are produced at a few establishments.

The *malleability*, which is in some respects the reverse of chilling, in general follows the abstraction of carbon, and is proportionate to it; but the metal so produced has none of the *fibre* which is caused by forging and laminating. Like chilling, the change is external, and penetrates but a small way; the methods, therefore, are applicable only to light and thin articles. There are many such (brads, bridle-bits, coach-makers' fastenings and furniture, locks, snuffers, stirrup-irons, &c., and various vessels in domestic use) which can be cast more cheaply and conveniently than forged: to all these the method applies.

It reposes both upon the character of the crude iron and upon processes subsequent to casting. Gray crude iron produced from refractory ores, which never can be chilled, is the suitable quality; and articles cast from this, which are at first brittle, are enclosed in iron boxes, in contact with powdered oxides of iron, (either mineral, as red hematite, or artificial, as forge-cinder,) with lime, or with any absorbents of carbon. The cases, well closed and luted, are placed in an oven, and left there, at a high temperature, for a period varying from three days to a week. The temperature is then allowed to subside, and the matters to cool gradually in the ovens. When pieces of these castings are fractured, the alteration of structure is very apparent.

III. Refining, Forging, &c., of Malleable Iron.—The mention of malleable iron castings leads naturally to the account of those processes by which a malleability is imparted, higher both in kind and degree. These processes apply, 1st, to the production of iron which can be wrought directly from suitable ores; as well as, 2d, to the refining and working of crude iron which has been otherwise produced. The fagoting of scrap-iron is not sufficiently distinctive, either chemically or mechanically, to constitute a third class of processes.

1. *Of malleable iron directly from ores.*—This product undoubtedly preceded any other manufacture of iron. All the workings of antiquity were of this sort, there is reason to believe; and what has been already said in this article serves to show the gradual advance of the modern epoch of *crude iron.* The improvement in this epoch has been the utilization of many ores which, under the old process, were unavailable. Only rich and fusible mines—magnetic oxides, and some of the sparry carbonates and red hematites, and the like—admit of this treatment. This restriction will be justified in considering the general theoretical aim of the process, which, in so far different from that of the high-furnace, embraces a double task, and recurring decompositions and recompositions. In the high-furnace, our object is to drive off the oxygen from the ores; which is effected by preventing carbon in excess at a high temperature, while that portion of excessive carbon that combines with the iron after reduction is gotten rid of by subsequent separate treatment. But in the *forge-fire*, one treatment must answer both ends; carbon at the lowest temperature that will answer must be prevented to effect an *imperfect reduction* at first, till the mass consists, in fact, of a mixture of oxides and carburets of iron; and while this mixture is reacting internally on itself, additional oxygen from a current of air must be afforded to assist in the neutralization of the carbon.

To this aim, the character of the furnaces employed must conform; they must be low, so that the reduction may not take place too soon and fusion be checked; they must be wide, that the melting carburets may offer a large surface to the action of the air. Where exactly the fusion is maintained, is not of so much moment: if above the tuyère, the furnace is properly a *stück-ofen*, which has been already described; if below the tuyère, it is to be termed a *forge-fire*, of which the so-called *Catalan forge* may be taken as the type. Whether one or the other form be used, there is in either another characteristic diversity from the processes of the high-furnace, which should not be omitted. In the latter, the result depends upon the chemical action of the materials; i. e., upon the proportions of fuel and mine, and the temperature which is kept up; in the former, the chemical reactions are chiefly dependent upon the mechanical agency of the workman, whose business it is to expose successively the imperfectly reduced masses to the influence of the air. Thus the reduction and the refining are both, in a measure, mechanically effected; the formation of too much crude iron at once is checked by immediate admixture of oxide, and by a judicious management of the blast; and the result depends upon the skill with which this is done, just as in the case mentioned in a preceding part, where, to produce crude metal of a particular quality, doses of suitable materials are injected into the crucible of a high-furnace.

So much has been already said upon the *stück-ofen*, that its application need not be insisted on here, further than to remark, that their product is never entirely *malleable iron*, and requires a fresh reheating and fusion of a part. This subsequent process results in the formation of part malleable iron and part *steel*.

The furnaces used in Sweden and Norway for this purpose are also properly stück-ofen, and the result similar. In some places of these countries, they treat a roasted ore with wood in inverted cone-like furnaces, from 4 to 7 feet high, and from 2½ to 5 feet diameter at the top.

The old German method was also so far like that of the stück-ofen, in requiring actual fusion; but the shape of the hearth was different, resembling the Catalan forge-fire, and the original, apparently, of the modern *bloomery-fires* of Pennsylvania. There was also another method used still in Gallicia, of interstratifying the ores with the fuel which is broken fine and kept almost in a pasty state. The reduced metal filtering slowly through this paste is refined by the current of air directed downwards towards the bottom of the hearth.

The methods, &c., which have been applied from time immemorial in the Pyrenees, and are called

the *Catalan method*, will convey a sufficient idea of all the others, which are but modifications. This appellation comprehends, in reality, the whole arrangement of water-blasts, tilt-hammers, &c.; but the exposition will be confined for the moment only to the chemical part of the process, or the production of metal ready to be forged. The ores are generally roasted in furnaces or ovens; but in some instances a compact brown hematite has been used raw. The results, compared with roasted mine, do not appear advantageous. When the ores are tolerably pure, they are usually charged in the furnace within a month after roasting; but pyritous or phosphated mines are macerated, *i. e.*, exposed to the air, and frequently stirred and moistened with water for a twelvemonth. Before charging, they are broken up into fragments, like small nuts; red hematites are even used in powder. According to the character of the ore, earthy matter, argillaceous or calcareous, is added, to serve as a flux. Throughout the Pyrenees, the general machinery for the blast is the *trompe* that has been already described; small forge-fires are sometimes blown with leasher bellows. In this last case, to maintain a continuous blast and furnish a suitable quantity, two tuyères are required.

The following figures indicate the construction of these Catalan forges. Fig. 2895 is a ground plan on a scale of 1-40th of the actual size of the forge-fires used in the Lower Pyrenees. Such are properly called Navarrese furnaces; and while the general structure is the same for all, are intermediate in dimensions between the Spanish Catalan, which are smaller, and the Biscayan forges.

2395.

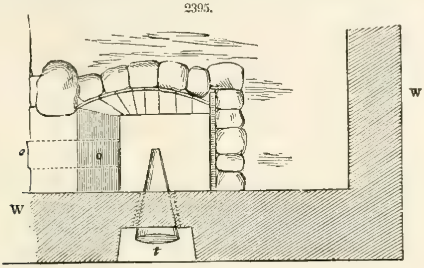


Fig. 2396 is a vertical section through the axis of the tuyère; and Fig. 2397 another section at right angles to the former. In Fig. 2395, W W represents the wall separating the forge-fire from the blast machinery, and in which is the embrasure for the tuyère. The hearth is usually lined with cast plates, and the *counter*, or side opposite the tuyère, of flat bars. Sometimes the lining of these is only a refractory sandstone; but the cinder slope (on the side *o* of the tuyère) on which the workman rests his ringers and bars, is always of cast-iron. The aperture *o* is for the discharge of cinder into the embrasure beneath; the tuyère *t* is a truncated half-cone of copper, with the orifice or *eye* circular, from $1\frac{3}{4}$ to 2 inches in diameter. The pressure of the blast varies from $\frac{1}{2}$ lb. to $1\frac{1}{2}$ lb. per inch.

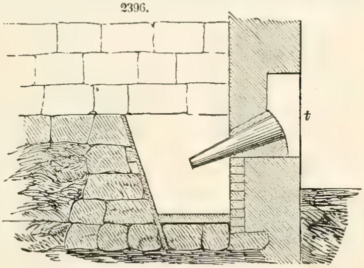
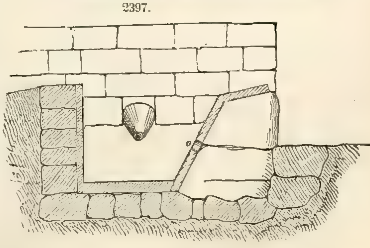
2396.



2397.



The fewest men to work one of these fires, not counting the hammer-man, is three; the greatest number employed in the largest and most active, is eight. In beginning to work, the hearth has first to be heated by keeping it two-thirds full of ignited charcoal for 4 or 5 hours. The fuel is then thrown up against the tuyère and beaten down into an inclined plane towards the counter. Upon this is thrown at once from one-half to three-fourths of the charge of mine; the hearth is heaped up with charcoal; the cinder-tap *o* stopped with clay; and the blast gradually let on, till, in about two hours, it attains its maximum. The founder, during the process, frequently wets the charcoal on top to prevent its burning too fast, and to concentrate the heat; throws on, from time to time, the smaller fragments remaining of the charge, near the tuyère; feels with a crow-bar at the bottom of the hearth for the cinder and metal; gradually brings the charge nearer the tuyère; keeps the tuyère free; and about every quarter hour after cinder has commenced to show itself, taps and lets it off. This tapping, after the whole

blast is on, has to be done more frequently: sometimes every five minutes; the other part of the work too, goes on with more activity. In three hours the whole charge is melted; a bar is thrust through the charcoal in many places to clear the metal which is thus gathered up on the bottom of the hearth, and worked and pressed with ringers into a sort of ball or loop. This takes the greater part of an hour when the heat is done, the charcoal is raked over against the counter; and the loop thus cleared is lifted by the bar to which it adheres, and, if necessary, with tongs, and carried to the shingling-hammer to be forged. In the Catalan forges, the weight of these loops (or *marsets*) is from 100 to 150 lbs.; in the Navarrese, from 180 to 250 lbs.; in the Biscayan, from 280 to 350 lbs.; and in some of the forges among the Eastern Pyrenees, as much as 425 lbs. The tilt-hammers employed weigh from 600 to 700 lbs., generally of cast-iron, sometimes of wrought; the helve and fixtures mostly of wood. Besides these are used smaller lift-hammers, for working smaller bars, called *martinets*. When the loop is placed under the hammer, it is struck at first slowly to condense it and drive out the cinder; it is then forged more rapidly into the shape of a prism, 12 to 18 inches long, and 6 to 8 inches square. This is cut in two by a chisel under the hammer; the pieces carried back to the same fire as a special chafery, there heated and successively forged again. When smaller bars are wanted, these pieces are again cut, reheated, and forged under the martinet.

The charge of roasted mine for each heat is, with the Catalan fire, from 325 to 450 lbs.; with the Navarrese, from 550 to 650 lbs.; with the Biscayan, from 750 to 900 lbs.; and with the largest fires of the Eastern Pyrenees, an average of 1250 lbs. But the economical result in metal is, as might be expected, against the large charges. The smaller fires allow six and sometimes seven heats in the 24 hours, and give about 90 per cent. of the metal found by assay in the ore: the larger ones never more than four heats in the same time, yielding about 85 per cent. of the metal. In fuel, there is less consumption with the large charges. In the smallest fires, the fuel used is, on an average, *five* for one of mine; in the larger it is about *three*.

The fuel used is universally *charcoal*. Frequent experiments have been made looking to the substitution of *coke*, both with cold and hot blast, but hitherto, and probably of necessity, always without success.

2. *Of malleable iron from pig or crude iron*—produced (*a*) with charcoal in open forge-fires, bloomeries, &c.; (*b*) with coal in reverberatory or *puddling* furnaces; (*c*) with coke or coal in a special furnace, termed a *finery*, or run-out fire, and then in a puddling-furnace. The object is the same in all these, viz., the decarburation of the metal, (as to driving off other impurities, that will be spoken of specially hereafter;) and the methods may be distinguished into two classes—first, where the metal is refined in contact with carbon, as in mode *a*; and, secondly, where it is only in contact with heated air and inflamed gases, as in the reverberatory furnaces of modes *b* and *c*. In theory, the latter method should be the best, so far as quality of metal and economy of material are concerned; but in practice, the former, though at a greater loss and expense, is the most successful in yielding a good article.

In regard to the quality of crude iron most advantageous for refining, different metallurgists have expressed different opinions. As this is no place for a lengthened discussion of principles, only such statements will be briefly made as seem to accord the best with experience.

Gray iron demands a higher temperature for fusion than white, becomes more liquid, and requires more blast and a longer time for conversion. White iron coagulates more readily, and passes sooner to the malleable state. Whether these differences arise solely or chiefly from the presence of the free carbon in the former, is not the question: it is certain, however, that some kinds of gray iron cannot be refined at all without having been first whitened by a special process. This is especially the case with coke iron; and the finery of the English method is an expedient for meeting this very difficulty. The best qualities for easy refining are white iron, produced in the high-furnace by heavy burden, gray pig, which is loose in its texture and cavernous, and broken castings from a cupola or crucible. Next come the mottled pig, the lamellar and loosely crystallized white iron, and close-grained gray coke iron. Last of all to be employed, are the compact crystallized gray pigs, especially those made with coke or coal.

No *flux*, properly so called, is employed in the fusion of refineries; but several substances are occasionally introduced, besides the air and charcoal, to act as chemical reagents. These are, for instance the rich finery-cinder, the forge-cinder, oxides of iron and manganese, sand, and water. Of the finery cinder, only that is useful which is formed after fusion is perfect, and while, in fact, the loop is about to be drawn. This cinder falls to the lower part of the hearth: rich as they are, containing from 80 to 90 per cent. of magnetic oxide, they are not displaced by the iron, and may be left in the hearth after the loop is removed. If drawn, which need only be when they have accumulated to a great degree, they must be tapped for very low down; when tapped, they run and solidify slowly, and take, of course, all forms readily. Their formation in the hearth is indicated by the silvery sparks in which they are thrown out by the blast; and they are recognizable afterwards by their weight and semi-metallic lustre. These present to the refiner the best reagent for coagulating the melted metal and bringing it *to nature*. A part of these, also, are apt to adhere to the loop, from which they are broken off and driven out by the hammer, and are very apt to be found mixed with the forge-cinder.

The oxides of iron and manganese are used mainly to save the metal which is otherwise supplied from the pig under treatment to form cinders. Sand is used sometimes (and acting then like a flux) to retain the metal in fusion; but this is bad economy, both for quantity and quality. And *water*, although its principal effect may be in saving fuel, as mentioned a while ago, yet acts as an oxidating agent too.

When the pig contains sulphur or phosphorus in any appreciable proportions, (which give red-short and cold-short iron respectively,) *carbonate of lime*, as pure as possible, may be added; and the more comminuted, the better. It should be applied when fusion is commencing, and not afterwards. In the Pomeranian forges at Torgelow, about ten per cent. of limestone is added after fusion is complete, in three different operations, each of which implies a stoppage of the blast and a stirring of the pig. It is

very successful in one respect—that the phosphorus, which exists in the pig at an average of 4¼ per cent., is reduced, in the malleable metal, to ¾ per cent.; but it is at a considerable waste of iron and fuel. Other alkalies have been tried, such as the carbonates of soda and of potash, with and without lime, but without much encouragement. In theory, carbonate of magnesia would be the best corrective.

(*a*.) The modes which are introduced under this method are, in some minute respects, almost as numerous as the localities where it is applied. Karsten has enumerated and described *sixteen* different processes, of which *eleven* are effected by a single fusion, and *five* by a double fusion. But the general type of all is the so-called *German method*, which is spread over the whole of North Germany, widely used in France, and, in many respects, exemplified in the bloomeries of the United States, especially in Pennsylvania. The hearths used for this method, except the large chimneys under which they are set, and which must, of course, have suitable foundations, so much resemble the Catalan forges, as not to need a figure. Only some of the processes followed will be spoken of.

To work advantageously, the workman must know the pig-metal he is using, for so much is dependent on management. Generally, a mixture is better than any one kind. Forge-pigs ought to be run slender, both that they may be broken easier, and that they may be proportioned more exactly. The fragments should not be too large, to waste fuel, nor too small, to run too quick. The quantity for one heat will, of course, depend upon the particular case: as an average, it may be taken from 250 to 350 lbs. The best charcoal is that from *soft* woods, (for instance, the *pinus alba*, *larix*, *strobus*, &c.,) and it should not be broken into pieces smaller than one's fist. The quantity of blast varies with the quality of metal and weight of fuel and charge, and also at different times of the operation. This last variation, unlike the high-furnace, must be under the constant vigilance and control of the workman. It is usual to put more pressure on with white than gray iron; a practice which does not arise so much from the chemical condition requisite as from the habitual mechanical arrangement—of placing gray iron nearer the tuyere. With an average charge, there will be required, while the *melting* is taking place, about 150 cubic feet of air per minute; while stirring, about 225 cubic feet; and while making the loop, as much as 275 cubic feet per minute. In cases where the loop is made by *attachment*, as it is termed, as much as 400 cubic feet is used per minute.

This word, *loop*, has been already used here frequently: it is only the French *loupe*, (a *wen*, a *lump*,) applicable to the shape of the mass. The Germans call it *blume*, (a *flower*—because it resembles the unopened corol of a campanulate flower,) from which we get our English word *bloom*—applied, in our language more particularly, to what has been under the hammer and has been forged. The term *loop* is more appropriate before forging. The French word *renardière*, by which these forge-fires are called, means, literally, a *blind ditch* through which water escapes; and the analogy may be supposed with the filtering and disappearance of the melted metal. The name has no relation to that of the animal (the *fox*) whose kennel, or earth, it also is applied to signify.

To prevent the charge from attaching itself, in fusion, to the cast-iron sides, and especially the bottom of the hearth, an arrangement is usually made by which water can be applied to the outside of these to cool them. This should be judiciously resorted to, when necessary; particularly in the case of the bottom-plate, to avoid breaking it—which would result not only in its own loss, but likewise in that of the charge for that heat. It is better to dispense with water after the fusion is complete.

The slope of the sides and inclination of the bottom, varying in different forges, and strongly insisted on by some metallurgists, appear chemically of absolute indifference. There is a mechanical advantage, only, in the ease of working and lifting the loop. But in the direction and pressure of the blast, and the size of the tuyère, (or *tue-iron*, as the American workmen call it,) the chemical results, both as to quantity and quality, are largely bound up. In former times, there were used two different tuyères, i. e., the blast was admitted through more than one orifice: a more correct observation has reduced them, almost universally, to one tuyère. The nozzle of the tuyère is frequently of cast or wrought iron, which can be easily fitted on the copper pipe. It is usually semicircular—sometimes round, or oval; and its area will not surpass 1½ square inches. The inclination of the tuyère varies from 5 to 10 degrees downwards from the horizon. Were it horizontal, it would burn away more fuel, and a part of the blast would be lost. The more depressed the tuyère, the longer the metal remains liquid; the more horizontal it is, the sooner the metal passes to the malleable state. White iron, then, which has this last tendency in itself, requires a more depressed tuyère than gray iron—although some metallurgists assert the contrary. The depth of the hearth—i. e., the distance between the bottom-plate and the upper edge of the tuyère—is manifestly correlative with the depression of the latter; and they should work together. A hearth should not be shallower than 7 inches, nor exceed 10 inches. When the proportions are established, the tuyère is fixed, by cramps or otherwise built in as firmly as the sides of the hearth, to prevent derangements that would be sure to accrue upon its accidental dislocation.

After covering the hearth with fuel, (leaving there, or not, the cinder of a former heat,) and getting up a good heat, the pigs are pushed in the hearth to about 6 or 8 inches of the tuyère, (the grayer the iron, the nearer it is placed,) covered with charcoal, the blast put on, and every thing done to promote fusion. When they have begun to melt, the workman sounds with his bar to feel the consistency of the fused mass; and he judges by that whether cinder requires to be let off, and what is the state of crudity of the metal. When the latter begins to be stiff and pasty, he draws the mass towards the counter, and, clearing away the charcoal and cinder to expose its surface, lifts it out upon his ringer. It generally breaks into several pieces, which he draws from the fire, supplies fresh fuel, and then replaces the pieces in the inverse order of their conversion; i. e., the most crude nearest the tuyère. They are fused again as before, again worked and lifted. This time, generally, they remain coherent, and the metal is sufficiently refined. Sometimes, however, a third fusion is necessary. The liftings which have been made hitherto, have only been up to, or a little above, the surface of the melted cinder; according as the workman judges it necessary to have the strongly oxidating influence of the blast, or the

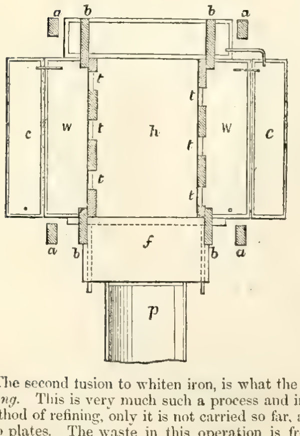
more gentle reaction of the scoriæ. But in making up the loop, it is lifted quite above the tuyère, so that the air may pass under and around it; it is turned upside down, and end for end, to expose every part of it, and then redeposited in the hearth, where the cinder is drawn to one side. It is covered with fresh fuel, the blast is strongly urged, and the loop is kept at a temperature almost of fusion, completely to decarburate and purify it. This result is judged of by plunging a ringer into the loop after the blast has been gradually diminished: if the thimble, which comes out upon the ringer, is easily detached after cooling, the metal is refined, and the loop is then taken out to be shingled.

The number of workmen required is generally *five*, including the hammer-man; the time taken to finish a loop from 3 to 4 hours. But there is always extra time lost in preparations, &c.; so that a better calculation would be to say that in the week of six days, an average forge will turn out from 4 to 5 tons of large merchant-bars, say 2 inches square; or about 3 tons of inch-square bars. The average waste will be about 27 per cent. of the crude iron; and the fuel used will be, at a mean, about 180 for 100 of bar-iron.

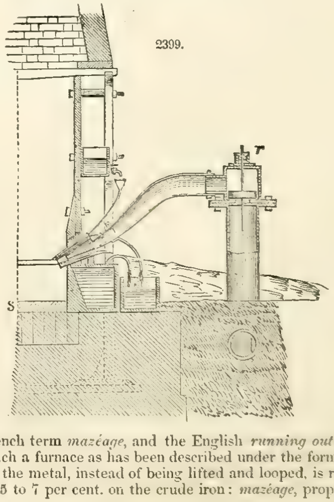
This process is, perhaps, the best for the quality of the bars produced; in respect to quantity, however, waste and fuel, it is among the least economical. In this last regard, of all the existing European processes, that of Sregen appears the most advantageous, the quantity of bar (of large size, to be sure) amounting to 9 and 10 tons per week, the average waste about 20 per cent., and the fuel, weight for weight of bar produced.

(*b.*) This, which is the method used in Champagne, and extensively in America, substitutes a reverberatory or air-furnace for an open forge-fire, urged by a direct blast; and, in fact, leaves the workman to do by manual labor what was done partly in the preceding method by chemical reagents. From a supposed analogy between the manipulations here, the behavior of the material, &c., and what was familiar in the preparation of *clay* to prevent the passage of water to foundations, &c., the process received the name of *puddling;* as the other method is sometimes called *boiling.* As in this a higher temperature is necessary, (heated air being the only reagent,) a fuel giving more heat is required, and therefore coal is used. The metal, however, was at first, and is largely still, charcoal iron; prepared in advance, both in form and substance, for the final refining it has to undergo. This preparation is a conversion into *white iron;* which is done either at the high-furnace or by a second fusion. If the first is relied on, the crude iron should be run into *plates*, or very flat pigs, to whiten it thoroughly. The Styrian method for this purpose is a curious one. The crude iron is run at once into an oval pit, or basin, in sand; the cinder is cleared off, and water is sprinkled over the yet liquid metal to chill it. In this way, plate after plate, weighing from 25 to 50 lbs. each, is formed in intervals of hardly a minute. Only gray iron, from fusible materials, will chill in this way. The plates thus made are roasted, *i. e.*, exposed for 10 or 12 hours to a red-heat, either in an appropriate oven or in an open pile; by which they are slowly decarburated. If this operation of roasting were in any case well performed, a great deal of the carbon should be got rid of; but the expense of fuel is very considerable.

2398.



2399.



The second fusion to whiten iron, is what the French term *mazéage*, and the English *running out* or *fining.* This is very much such a process and in such a furnace as has been described under the former method of refining, only it is not carried so far, and the metal, instead of being lifted and looped, is run into plates. The waste in this operation is from 5 to 7 per cent. on the crude iron: *mazéage*, proper, is done with charcoal.

The reverberatory furnace used is similar in form to what has been already figured under a former section.

(*c.*) The constant combination of a *finery*, where the plate-metal is produced with coke, and a *reverberatory furnace*, where it is puddled with coal, constitutes the method practised in England; and there,

as elsewhere, is more or less appropriate and even necessary, whenever iron is to be produced in great quantity, and fossil fuel is of course to be relied on.

Fig. 2398 is a ground plan, on a scale of 1-25th of the actual size, of an English finery, blown with six tuyères. In this *a a a a* indicate the places of the cast-iron columns on which the chimney rests; *b b* &c., are the side-plates of the forge; *h* is the hearth formed by the water-backs *w w w*; *f* is the front plate, and *p* the mould in which the plates are run; *c c* are troughs where the bars are cooled.

Fig. 2399 is a half vertical section of the same plan, drawn to the same scale, and serving to explain it. This last figure also shows the attachment of the blast, which, to save room, was left off from the other; as well as, by the dotted lines in the hatched space beneath, the mode of securing the sustaining columns in a mass of masonry. The right half-section would be a counterpart of this.

2400.

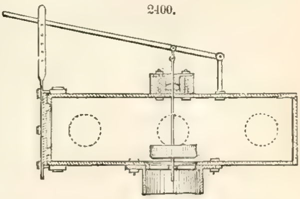


Fig. 2400 is a longitudinal section of the air-box *r*; and the dotted circles on its face are the ports by which the blast is conducted to the several tuyères. The lever-valve allows the blast (which in these establishments comes generally from the great blowing-engines of the high-furnaces) to be regulated by the workman.

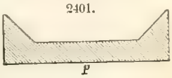
Fig. 2401 is a section, still upon the same scale, of the plate-mould *p*. The earlier fineries were blown only on one side, and with three tuyères; the modern ones, almost universally, are blown with four or six tuyères, with a cross blast. The crude iron intended for the finery should, like that for the fires already spoken of, be run into small pigs. They very frequently, however, are employed weighing from 100 to 120 lbs.

The kind of coke to be preferred varies with the quality of the metal. When this last is refractory the coke should be heavy and compact. A friable coke, and one containing much earthy matter, as well as oven coke generally, are objectionable.

2401.



The *sole* or bottom of the hearth is indicated on Fig. 2399 by the letter *s*, and by a different species of hachures. This reposes upon fire-brick or refractory sandstone; and is best made of a layer, 4 or 5 inches thick, of broken quartz, well rammed. At the first heat, this layer is partially melted and percolated by the metal, forming a bottom exceedingly hard and refractory. This property, in expediting the work, compensates fully the waste of metal in the beginning. From time to time, however, it requires replacement. The most convenient way to get it out (for it weighs often a couple of tons) is, upon the conclusion of the week's work, and after the last heat, to throw water upon it while yet red-hot. This cracks it up and renders it easy to be taken out; the water-backs may then be reset, and the bottom laid anew. The old bottom, which contains a good deal of half-refined iron, can be used up, little by little, as *scrap*.

As the object of this process is to fuse the metal, the tools and working are only fitted to that end. It is rare that any flux or reagents are added. Hard metal is heated sometimes with forge-cinder or finery-cinder. These, as well as any thing else that may be used, act in nearly the same manner as in refineries with charcoal.

The plate-mould, which can be added to, from its construction, at pleasure, should be so long in proportion to the charge, (which, for a large hearth, will be, on an average, 1½ tons,) that the plates are left not more than 1½ or 2 inches thick. After the metal is in the mould, water is thrown copiously upon the cinder which has run out with and covers it, and which, by this, is easily separated. The plate itself, after being chilled with water, is broken up for the next process.

Care must be taken, in this, to strike a proper medium between doing too much and doing too little. If the metal in the run-out sparkles little, and, after being cool, preserves its compacity, it has not been fined enough, and the puddling will be hard and long. If in the run-out it disengages, on the contrary, a multitude of faint sparks, so confluent as to become a sort of flame, and emits a white vapor, it will probably be found converted partly into malleable iron; and the puddling, in this case, will be more difficult and wasteful than in the other.

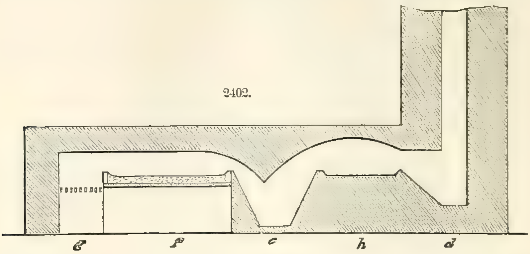
These results depend, in a measure, upon the supply of blast—which should vary according to the quality of iron, and also according to the character of the fuel with which it has been produced in the high-furnace. With charcoal iron, each tuyère should furnish from 200 to 250 cubic feet per minute, under a pressure of 2 lbs. per square inch. With coke iron, the quantity may advantageously be raised to 300 cubic feet, and the pressure to 2½ lbs.

With this supply, a finery such as described will run out rather more than a ton per hour; and ten heats may be made a turn of twelve hours. The waste should not be more than 12 per cent. of crude iron; and the coke used, about 30 per cent. of the weight of metal charged.

From the finery, the metal is ready to be passed to the *puddling-furnace*. This resembles so much, in shape and detail, the reverberatory furnaces before given, as not to require a figure. Sometimes it is used with a charging-door on each side, when it is said to be a *double furnace*. In some cases, the two doors have been placed on the same side; but, as they could not be worked exactly together, their alternations tended to produce irregularities and waste. There is a furnace of this kind, however, though with a different aim, which is affirmed to be very convenient and economical. It is a *two-hearthed* arrangement, which will be made sufficiently clear by the sketch, in longitudinal section, (Fig. 2402,) where *g* is opposite to the grate, *p* to the hearth for puddling, *c* to the cinder-pit, *h* to the hearth for heating, and *d* to the smoke-flue. On the hearth *h*, the metal undergoes a roasting and partial refining before it is removed to *p*. The external fixtures, the pulleys and counterpoises for the doors, the travelling stirrup for shifting the charge, &c., can be very easily imagined. That this furnace would save fuel is quite probable, but, in respect to other conditions, its efficacy is more problematical.

These conditions for puddling would seem to be, 1st, that a sufficient heat be obtainable to melt the metal entirely; 2d, that the heat, in whatever degree availed of, should be uniformly distributed over the hearth; 3d, that there should be no carbon unconsumed in the flame, in contact or to be combined

2402.



with the metal, which contains enough of that impurity already; and, 4th, that the metal (and this is more important for *fine metal*) should not be exposed to a too oxidating effect of the air which is aspersed through the grate.

As yet, bituminous coal is the best fuel that can be applied in a puddling-furnace. Anthracite is also used in America, with better results than have been experienced in Europe. Charcoal and wood also have been tried, but do not appear to diminish the waste or improve the quality of the metal, while the cost of fuel is enhanced. The hearths are supposed, also, to be more difficult to maintain with these last.

This maintenance is one of the points of trouble and expense; and various methods are resorted to for the purpose in constructing the hearth. It is sometimes made of cast-iron; in which case it is covered with a layer of cinder 1½ to 2 inches thick, well pounded, and melted down before the metal is charged. Others prefer to make it of sand, or broken quartz, from 6 to 8 inches thick, well rammed, and covered then with a thin coating (less than an inch) of powdered cinder, which is melted and smoothed before charging. This method is ordinarily productive of more waste, for the silica takes up portions of the oxide which is formed: with impure metal, (containing phosphorus, for instance,) the silica aids in refining it. Others, again, use cinder entirely for the hearth; stratifying it in small fragments to a depth of 5 or 6 inches, and then fusing it and smoothing down. In working only fine metal of good quality, the tendency of the hearth is to thicken itself and change shape upwards; when it is of bad quality, (and still more when crude iron is puddled by the first operation,) the hearth becomes burnt out, as it were, and hollowed downwards. Either change of shape renders repair necessary. Old hearths in sand or cinder, which have been melted out or broken up, can be used advantageously in making new ones. Limestone hearths have also been tried, to the improvement of certain kinds of metal, but to the speedy destruction of the in-walls.

Before charging the furnace, a full red heat is got up inside, principally to save the waste that would follow the oxidation by a slower fusion. Then the fine metal, broken up into pieces, which should not exceed 28 lbs. apiece, and the smaller the better, is charged—hot from the smaller hearth, if the furnace, Fig. 2402, is used—otherwise cold. Ordinarily, the whole charge is about 400 lbs. The register is then raised, and the heat urged for about a quarter of an hour, when the mass becomes pasty, as the workman can judge by feeling it with his bar. If the metal is charged hot, this ordinarily occurs in 10 minutes; longer, if it was put in cold. If it gets too liquid in that period, water is injected to cool it. The register is let down when it is at a proper viscidity; and the workman, introducing his ringer, works the pasty mass continually, to disengage the carbon. As this passes off, the metal becomes more stiff, but it still must be worked, as before, to present the oxidated portions to those that may yet be carburetted, and to prevent too great oxidation, or, as the workmen accurately term it, *burning*. Sometimes it becomes so thick as to be incapable of being worked and divided: in such case, the external air must be shut off, the register lifted, and its consistence destroyed again by fresh urgency of heat. If this misfortune does not happen, the thickened condition is followed shortly by an apparent boiling, more or less marked, and an escape of oxide of carbon, burning with a blue flame. These appearances gradually cease, and another epoch occurs, in the metal's becoming easier to work—in fact, *short*, or tending to break apart in small lumps. The departure of the last remaining portions of carbon is generally indicated by a more lively lustre, which is taken as an indication of its having become malleable iron, or *come to nature*. A continued puddling for four or five minutes more increases its shortness, and it becomes pulverulent almost—the particles of pure iron falling apart, because there is not heat enough to weld them.

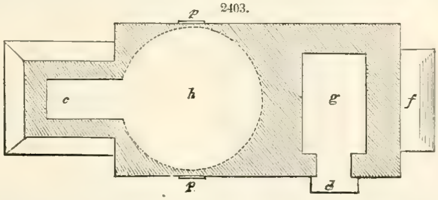
To afford this heat is the next step. The temperature, which, from the first pastiness the metal assumed, has been kept as constant as possible, is urged intensely; and the puddler judges, by his own experience, of the proper moment to commence rolling the matter into balls. If begun too soon, it would not be sufficiently welded; if postponed too long, the little fragments would have become independent, and would refuse to weld at all. Taking the proper moment, and beginning with the matter the nearest the fire, the puddler works it all up into five or six balls, (or even more, if the charge is very large,) which he draws over towards the bridge. While making the last, he rolls it all over the hearth to pick up all stray metal. This balling is done sometimes by parting the mass into as many equal parts as it may be intended to make balls, and working each separately; or, by taking a small

portion at once, and augmenting by *attachment*, (i. e., as one would roll a snow-ball,) like one of the modes spoken of before in refining with a forge-fire. The result in either case must be the same; and the care to have the balls well rounded and uniformly compact must be equal. The balls, when finished, are taken out with suitable tongs and carried to be shingled.

The operation of puddling crude iron directly does not differ materially, except in time and in the occasional addition of cinder, from puddling fine metal. The latter, if charged cold, will be balled in about 1¼ hours; if hot, in 10 or 15 minutes sooner. The former, cold, will require nearer 2 hours. Ordinarily, six heats will be made in a turn of 8 hours with fine metal, and four heats with pig. There is, of course, more waste, in proportion, with pig than with fine metal. The exact loss cannot be conveniently known, because the balls go directly to the hammer, or roughing-rolls, and a part of the measured waste occurs there. This last, however, will be tolerably constant; and a fair estimate of the waste of pig may be made at 15 per 100. With gray iron, it would be, probably, nearly 20 per 100. The loss on fine metal should not exceed 10 per 100. The weight of fuel consumed is about equal to that of fine metal puddled, and about 1½ to 1 of pig puddled. But to compare the absolute economy of the two processes in this respect, allowance must be made for the coke used in the fineries. This was before stated at rather less than one-third of a ton of coke for one ton of pig fined—equivalent to half a ton of raw coal. Allowing, besides, the waste, &c., in making this coke, we should probably conclude that, in the item of fuel, puddling direct from the pig is cheaper than from fine metal. In all other respects, however, it is dearer; and the puddled iron made is rarely of such good quality.

The use of *anthracite* as a fuel for puddling was mentioned just now. In point of fact, the furnaces in which it is applicable hardly belong to the present class of reverberatory, or *aspiring;* since, to maintain a sufficient combustion, a fan-blast, resembling what has been before described, has to be resorted to. Fig. 2403 is a horizontal projection of the principal features of one of these anthracite

2403.



puddling-furnaces; in which *f* indicates the situation of the blast; *g* the fire-grate, with *d* its filling-door; *h* the hearth, with *p p* its charging-doors, constituting a *double* furnace; and *c* the flue into the smoke-stack. The remaining details, fastenings, &c., are analogous to other puddling-furnaces, and can easily be imagined. The ash-pit is, of course, closed up, and the blast passes into it by one or two orifices. The grate is made to be about twice as deep as for bituminous coal—say 20 inches; and, for a double furnace, is about five feet long.* The hearth is about six feet in diameter; and the flue, to reach the base of the chimney, pitches very much downwards. The height of the chimney, which, for bituminous coal air-furnaces, is about 40 feet, is, in these, almost immaterial, since the draught is regulated by the fans.

Among the modifications that have been proposed in the details of puddling-furnaces, may be mentioned one (a double one) planned by Mr. Overman, the author of one of the most recent treatises on the manufacture of iron; and designed principally for economy of maintenance and repair, in cases where fusible reagents should be used for improving the iron. In this, the hearth, lozenge-shaped, is enclosed by water-backs; the sole is cast-iron, supported on pedestals, and allowing free circulation of air underneath. It is said by the expert author to have worked "exceedingly well in all cases in which inferior hot or cold short iron, from heavy burden, is puddled...... But for gray metal of small burden, particularly for all coke, stone-coal, or hot-blast iron, it is of questionable utility. For white metal it is perfectly useless." The candor of this account is an additional guaranty of its correctness.

With the puddling ends all the strictly chemical metallurgy of iron. The remaining processes of *forging*, (whether they be effected by impact, or under the hammer—by pressure, as in the squeezer, or by lamination, as in the roughing-rolls,) although necessary, to expel the remains of oxides and earthy matters admixed with the metal, and essential to the production of fibrous wrought-iron, are yet only mechanical.

The *hammers* used at the Catalan forge-fires are yet of primitive construction. A head of cast or wrought iron, or both, weighing from 600 to 800 lbs., is fixed, as well as may be, upon a helve of beech or oak. This helve, or log, is 12 or 15 feet long, and 12 to 15 inches in diameter; not squared or dressed, further than to stub off the projecting knots; and fitted with trunnions in a stout and solid wooden frame, to allow of movement up and down. This is effected by tilting the end downwards with cams placed upon the circumference of a water-wheel, usually 10 or 12 feet in diameter, but only about one foot wide. This wheel makes from 25 to 30 revolutions a minute; and, there being usually but four cams upon it, the strokes of the hammer, at a maximum, will be not more than 120. The lower face of the hammer works upon an anvil of the same surface and same material, and weighing from 450 to 550 lbs. The anvil is so inclined that the striking faces shall be parallel when in normal position. These heavier hammers are used for shingling the loops, and even for drawing down a large-sized bar. For smaller work, and for finishing, lighter hammers are used, arranged in the same manner, but weighing from 150 to 180 lbs., with an anvil of 120 to 150 lbs., and worked by a smaller wheel, of 6 to 8 feet, making 30 to 35 revolutions per minute, with, ordinarily, 6 cams; so that the

strokes amount to 180 or even 200 in a minute. The skill of the hammer-man is shown by so managing the powerful implement at his disposal as to condense the bloom uniformly; and his art, in finishing the bar to a uniform surface.

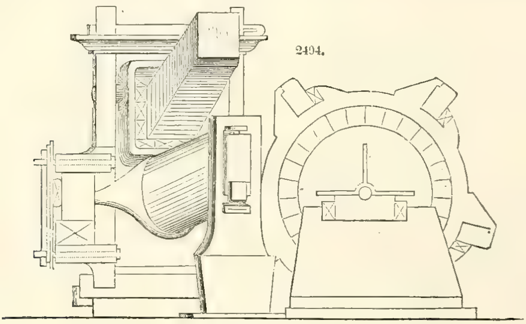
The hammers of the German forges were set with wood, in a wooden frame, like the Catalan; only they are almost universally *trip* or *lift* hammers—i. e., the cam is applied between the centre of motion and the anvil. This position has the awkwardness of sometimes embarrassing the hammer-man, and makes it necessary that the helve be set obliquely in the framing. At the present day, more or less of the framing is made of cast-iron. The weight of these hammers is from 400 to 450 lbs. only; the lift, i. e., the vertical fall of the face, from 24 to 28 inches; the wheel generally has 5 cams; and the number of strokes is from 90 to 100 per minute.

In the French forges the arrangement is the same, except that the heads are habitually heavier, weighing from 650 to 750 lbs.; the lift is not more than 20 inches; and the stroke is slower, being from 75 to 80 per minute.

In the forges of both countries, the *finishing-hammers* are *tilted*, both for convenience of access and speed. These are of different sizes, according to the work to be done and the quality of the iron. The larger ones weigh from 200 to 300 lbs., and make from 120 to 150 strokes per minute, with a fall of 18 or 20 inches; the smaller range from 60 to 100 lbs. in weight, and make from 250 to 300 strokes in a minute, with a fall of not more than 12 inches. To get up this speed, the water-wheel is furnished with more cams, sometimes as many as 32 in number. All, the largest and smallest, work against a sort of wooden spring, which checks their upward motion and imparts more momentum to the downward fall.

Fig. 2404 is a projection, upon a scale of one-thirtieth, parallel to the plane of the water-wheel, of one of the modern German hammers, in an iron frame. The faces of the head and anvil are, in this, a

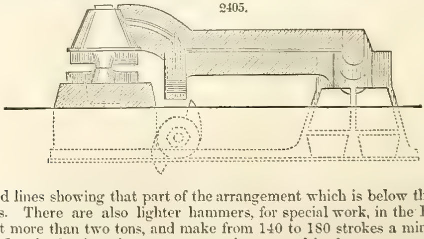
2404.



uniform plane; but often, and especially for finishing hammers, the face is like the letter T in relief, or else a full cross.

This modification is borrowed from the English fashion, whose hammers, besides, are altogether more powerful and substantial. Made of iron throughout, the hammer-head and helve weigh from 4 to 7 tons. The lift is effected to a height of about 15 inches, by cams, which seize a projecting lip in advance of the very head, and constitute a *trip*-hammer proper; sometimes by an eccentric, which works against the helve between the head and the centre of motion. The number of strokes is about 80 or 90 per minute. The power is taken off from a steam-engine, and a heavy fly-wheel is necessary to equalize the motion. The anvil weighs ordinarily from 4 to 5 tons. Fig. 2405 is a sketch of one of these

2405.



hammers; the dotted lines showing that part of the arrangement which is below the floor-line and rests upon the foundations. There are also lighter hammers, for special work, in the English forges, which weigh altogether not more than two tons, and make from 140 to 180 strokes a minute.

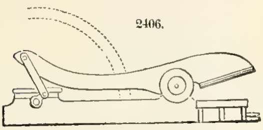
With their heavy fly-wheels, these hammers cannot be stopped in the same way as the lighter ones The usual mode is by thrusting a *jack*, or piece of iron, under the helve when it is at its highest. In starting again, a piece of wood is dexterously placed to be caught by the cam, and the jack is released.

Overman has suggested a permanent jack, (or jack-ketch,) to be worked by a piece of wire, which is undoubtedly better.

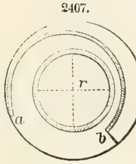
A very ingenious and useful application of steam directly to a vertical hammer has been executed by Mr. Nasmyth. Its behavior is not unlike that of a pile-driver; only, it can be worked with great rapidity, and thus, in some cases, dispenses with the number of reheatings necessary in finishing a bar. As this machine is applicable to other purposes than the forging of iron, its description will be given under a special article, STEAM-HAMMER.

The *squeezers*, which are extensively found in English iron-works, are employed for the same purpose as the heavy shingling-hammers, viz., condensing the puddle-balls into slabs: they act, as might be supposed by the name, by steady pressure instead of impact. They are supposed by some metallurgists to answer the end of expelling the cinder, &c., as well as hammers; but this is very doubtful. As applied to finishing bars, their use would not be economical. The most numerous class is of *tilt*-squeezers—i. e., the trunnions are between the power and the squeezing-jaws. The power is variously applied, by an eccentric or by cranks. Fig. 2406 shows the chief features of one of the last kind, upon a scale of one-fortieth of the actual size. The whole apparatus, which is of cast-iron, requires to be strongly bolted down to a solid foundation. The dotted circle indicates the position of the fly-wheel, by which the power is equalized on the crank; and the shaded lines show the jaws, which are separate plates of wrought or cast iron, bolted on the frame, and renewed when necessary. Such a machine, making from 80 to 90 revolutions per minute, can squeeze about 100 tons per week. Its theoretical deficiency is the want of parallel movement; its practical one, the enormous strain (especially if the loop should be too cold) upon all the blocks and journals.

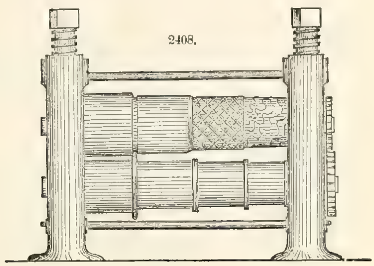
2406.



2407.



2408.



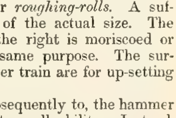
A different apparatus from this, and free from some of its defects, is Burden's patent eccentric rotary squeezer—the mode of whose action will be apparent from the projection in Fig. 2407, where r shows a cylinder with a roughened or serrated surface, revolving vertically in an eccentric drum which is permanent. The ball goes in at a, and is dragged round with it, more and more compressed in its narrowing path, until it comes out at b. The bottom is a solid plate; the top admits of a slight adjustment.

This machine has brought us round to the method, much older, and still practised in many English establishments, of squeezing and condensing between horizontal cylinders, or *roughing-rolls*. A sufficiently indicative sketch of these is given in Fig. 2408, about one-fiftieth of the actual size. The securings and couplings, &c., are omitted. The first of the upper train on the right is moriscoed or roughened, to catch and drag the ball. The next one is channelled for the same purpose. The surface-adhesion is enough to that end in the other two. The collars on the lower train are for up-setting or keeping the slab in shape laterally.

What are called roughing-rolls in America are used, not instead of, but subsequently to, the hammer or squeezer; and serve to forge the bloom into shape, rather than perfect its malleability. Instead, therefore, of being flat, the cylinders have corresponding grooves of large size, making a square or lozenge-like section. In other respects, in housing, geering, &c., they are the same with the English.

In proportion as the bloom or slab becomes drawn out by any of the condensing or flatting processes which have been mentioned, it becomes necessary to shear it up into shorter lengths, which are reheated separately or in piles, to be treated as before. The Catalan forges use a chisel under the hammer for this purpose. But rough-bar is much better severed by heavy shears, worked either by a water-wheel or steam-engine. Small bar can be cut with hand-shears. In general arrangement, the heavy shears resemble the squeezers—cutting-edges being substituted for the flatting-planes; and, like the latter, they are worked with a crank at the end of a straight or bent shank, or with an eccentric that tilts the edges. The shank and shear-block are all of cast-iron; and the leverage, from the trunnions to the crank, will vary from 4 to 10 feet, according to the work intended. The cutting-edges are of steel, bolted on to the block, and lie either in the same plane with the shank, or parallel with the trunnions. The last mode has been devised, as obviating the defect belonging to all scissors arrangement—viz., the varying angle of the cutting-planes. As suitable for thin work to be cut evenly, a sketch of this arrangement is given in Fig. 2409. The blades, which are shown by the vertically shaded lines, may be of any length—15, or even 24 inches—

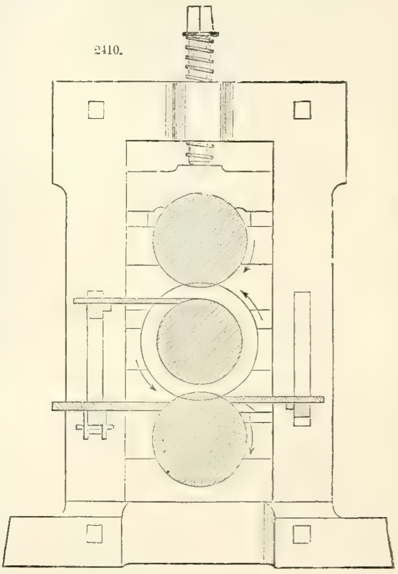
2409.



suited to the character of the work to be cut. The defect in these, as in all existing shears, is the want of horizontal slide as they come down vertically—a modification easier to imagine than execute.

The *reheating* or *piling furnaces*, which have been just now mentioned as necessary for restoring the temperature to the slabs or bars, and enabling them to be further worked on and finished, are, in the most complete establishments, separate fires. In the more primitive methods, this reheating (which is required twice or thrice) is done in the forge-fires themselves; sometimes it is done in the puddling-fire, or at the end of the puddling-furnace. In general character, these reheating ovens resemble the ordinary puddling-furnace; but they require some modifications to yield their best effect. The aim of these is to produce a welding-heat uniformly over the hearth; and, at the same time, at the expense of as little metal oxidated as possible. The last end is answered by making the grate larger in proportion to the hearth, and charging more fuel in proportion to the chimney, so that the air may be more completely deoxidized by the excess of carbon. The former is sought to be satisfied by lowering the bridge and bringing down the arch nearer to the ramp, to which, also, the hearth proper inclines a little. Wood may be used in one of these furnaces, but with a larger grate and a lower arch.

2410.



The remaining machinery to be spoken of is the cylinders or rolls for finishing the bars—flat, square, round, or in any fancy section. The housing and coupling these trains can be understood from the roughing-rolls just now given, without a special figure. All are arranged upon the same principles; only, the lighter the work the longer may be the trains, and more rollers in a train. The frames or housing for the rolls are made of cast-iron, as seen in section on Fig. 2410, which shows, on a scale of one-twelfth, an assemblage of three cylinders in a train, suitable for finishing light bars. This section also serves to illustrate Fig. 2408. These frames should, of course, be set as solidly as possible; for instance, upon a cast-iron bed-plate, bolted to a timber foundation built in with masonry. This seems better than masonry alone, because of a certain elasticity in wood. If slots are left in the bed-plate, the frames will be found of easier adjustment. The bed-plate should be open in the middle, leaving a trench that may catch the cinder that comes off from the bars, as well as the water that drips on, and that may serve as a cellar to the foundations.

For rolling flat bars, the cylinders are grooved alternately and work reciprocally in each other; for round or square bars, however, half their section is turned out of each cylinder. The diameter in the one case, and a diagonal in the other, correspond with the normal surface of the cylinders before being turned out. In turning out grooves, &c., for fancy patterns, a good deal of ingenuity is sometimes exercised, as will be seen in the descriptions and figures under the article Railroad Bars.

The reciprocal fitting of the grooves for flat bars renders a longitudinal dislocation of the rolls impossible. With the others, such dislocation is ordinarily sought to be guarded against by strong screws in the frames; but it is much better to have a groove and collar turned in one or both extremities of all cylinders. Vertical displacement is prevented by the head-screw seen in the figure; and a lateral adjustment is, in some cases, given by horizontal screws working through the trussing against the plumber-blocks. There is usually a play of about a quarter of an inch allowed in the blocks and couplings, to obviate immediate fracture in case of slight derangement; and also to throw the breakage, if an accident does occur, upon these parts rather than on the cylinders, which are the costly parts of the machinery. It is easy to see that upon the truth of all the movements depend freedom from accident, and excellence and economy of work. It is, therefore, cheapest to have every thing made of the best material and in the best manner.

In rolls for flat iron, the diameter of the cylinders is usually the same; for round and square iron, the upper cylinder is often a little (say half an inch) larger than the lower. If there are more than two cylinders, the same practice is found, in some places, of making their diameters regularly decrease (by say a quarter of an inch) from the upper to the lower. In others, and perhaps in the generality of cases, the middle of the three is the largest. Some metallurgists, on the contrary, object entirely to this difference of diameter, as causing increased friction in the machinery, and straining the iron. This objection is theoretically correct. The aim of the contrivance is to prevent the bar, as it passes through the rolls, from curling around the upper cylinder; if this last be larger, it will continue to bear on the

bar after the resistance of the lower roll has ceased, and will, of course, tend to force it down upon the apron. But this tendency to curl is best corrected by having *guards* to each groove—i. e., wedges of wrought-iron, which catch the bar as it comes out.

The diameter of the cylinders, and their bearing, vary according to the purpose for which they are intended. Roughing-rolls for puddle-balls are from 18 to 20 inches diameter, and 5 to 6 feet long; for piled iron or rough bars, from 12 to 14 inches diameter, and 5 feet long. Finishing-rolls for heavy bar will be of the same diameter with the last, but from 12 to 18 inches shorter; while for small rods their diameter need not be more than 8 to 10 inches, and their bearing about 2½ feet. The weight of a pair of roughing-rolls is from 4 to 5 tons, and of finishing-rolls from 1½ to 2 tons.

In geering up the rolls, the lower one is the driver, when there are only two; in a train of three rolls, the middle one drives. The velocity of rotation varies according to size and purpose, and even according to the state and quality of metal. Roughing-rolls should work slow: for puddle-balls 16 to 18 revolutions, and for piled iron 22 to 24 revolutions per minute, are sufficiently rapid. For finishing-rolls, this may be increased to 70 or 80 revolutions; while small rods are rolled with 120, 150, and sometimes even 200 revolutions per minute. But these high speeds are liable to frequent accidents.

The friction of the machine, and the initial temperature of the material to be rolled, heat the journals and cylinders very much. To abate this a wooden trough is laid above the train, from which water may drip on the machinery and metal under treatment. The effect is, to keep both the cylinders and metal clean.

The size of the grooves, and their proportionate spacing, varies in different countries; and the last particular even in different establishments. The methods for it are purely geometrical, and present nothing peculiar in the manufacture of iron. The constant rule prevails here, as in all lamination, viz., to place the largest grooves and the heaviest work nearest to the end at which the power is applied.

With a single pair of cylinders the bar always enters on the same side. As it comes out on the other, it is caught by a second workman, who, with the aid of a travelling-stirrup, hands it over the rolls to the first. When the cylinders are triple, the rods enter alternately first on one side and then on the other. The process with the single pair is time-consuming, but it does not seem likely to be bettered, unless by having two trains parallel to each other, which would admit of the alternation of entry as in the triple rolls. Such an arrangement would increase the first cost of machinery, but the work would be done cheaper and better.

Such are the particulars which belong to the finishing of ordinary merchant-bars. The processes by which iron is further prepared for special uses will be detailed more appropriately under separate heads. Thus, the rolling of iron for railroads—an enormous branch of trade—will be treated under RAILROAD BARS; the lamination of plates and sheets, together with the further preparations for several purposes that these undergo in the mill, will come under SHEET-IRON; the cutting up of these in making nails, hoops, &c., will be grouped under the head SLITTING-MILL; the extensive and remarkable apparatus by which this reluctant metal is shaped with chisel and drill, as if it were only wood, will be described under the articles LATHE PLANING-MACHINE, and TURNING (OF IRON;) and as far as relates to the boring of cannon, under ORDNANCE; the methods followed in drawing it out into WIRE, will be explained under that title; and, finally, under SMITH-WORK will be contained all that class of operations before indicated, which comprehend all the processes of hand-forging and welding, (as for anchors, chains, horse-shoes, &c.,) and of steeling and tempering, (as for cutlery, &c.,) practised in an art whose exercise has originated the most extensive and well-known family name in the world.

History.—There is room here only for the indication of epochs signalized by inventions that have given fresh impulses or new directions to the manufacture. From the earliest times till at least 800 A. D., the processes were either primitive, or, with unimportant modifications, gave only a more or less malleable metal direct from the ores, which were necessarily those that fused readily. The fuel, originally *wood*, had been changed, during this period, to *charcoal*—though by whose ingenuity, or when, there is no record. Some writers place about the termination of this era, which is that of Charlemagne, the introduction of crude iron. This seems an antedating by at least four centuries.

A. D. 1340. Earliest epoch of crude or cast-iron; employed as ordnance by the Duke of Normandy, afterwards John II. of France.
1490. Usual epoch of foundries.
1550. Epoch of wooden blowing-machines.
1612–19. Fossil-fuel (pit-coal) first used for reducing iron in England.
1640. Invention of *trampes*, or water-blasts.
1645–56. Epoch of foundries in America.
1740. Pit-coal and coke used in high-furnaces.
1749. Invention of rotary or fan-blasts.
1760. First cast-iron cylinder blowing-machine.
1780. Epoch of the puddling-furnace.
1784. Epoch of the rolling-mill.
1829. Discovery of the application of hot-blast.
1836. Application of the waste-gases from the high-furnace.
1837. Anthracite used as a fuel with hot-blast.

During the intervals between these dates, and since the last, divers improvements, both in theory and practice, have been suggested and executed, but none of them of palmary importance.

Statistics.—The following table, covering the last 10 years, contains what is known or can be estimated in regard to Great Britain and the United States—the two principal producers and consumers in the world:

Years.	Great Britain Manufacture.	UNITED STATES.		
		Manufacture.	Imported from Great Britain.	
			Crude Iron.	Bar Iron.
1840	1,396,000 tons.	286,000 tons.	5,516 tons.	32,829 tons.
1841	1,200,000 "	250,000 "	12,268 "	63,056 "
1842	1,088,000 "	215,000 "	18,694 "	61,599 "
1843	1,215,000 "	350,000 "	3,873 "	15,758 "
1844	1,210,000 "	490,000 "	14,944 "	37,891 "
1845	1,513,000 "	625,000 "	27,510 "	51,189 "
1846	1,675,000 "	765,000 "	24,188 "	24,109 "
1847	1,840,000 "	800,000 "	23,377 "	32,085 "
1848	1,999,000 "	750,000 "	51,632 "	81,589 "
1849	2,150,000 "	600,000 "	105,632 "	173,457 "

The following table may be of interest as showing the range and relation of value and price in the two countries for the same period:

Years.	Average Valuation in U. S. Custom-Houses.	Average Price of Scotch Pig in Glasgow.	Average Valuation in U. S. Custom-Houses.	Price, at beginning of Year, of Bar-Iron in Liverpool.
1840	$21 per ton.	$19 per ton.	$52 per ton.	$43 per ton.
1841	18 "	16 "	35 "	37 "
1842	16 "	13 "	33 "	31 "
1843	12 "	10 "	32 "	25 "
1844	13 "	13 "	28 "	24 "
1845	18 "	21 "	33 "	31 "
1846	20 "	17 "	47 "	43 "
1847	20 "	16 "	53 "	46 "
1848	16 "	11 "	45 "	36 "
1849	13 "	10 "	35 "	28 "

Sterling money is here converted, purposely, only to the nearest dollar.

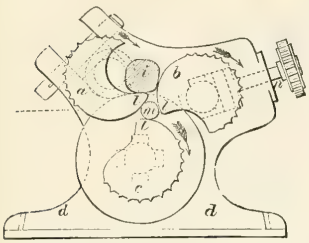
Within the past ten years, of other countries only Belgium, France, Italy, and Prussia have extended their manufacture of iron; but the statistics of these which are accessible do not warrant a continuous statement. It may be safely assumed, however, that the aggregate production of the world in 1849 did not fall short of *four millions of tons*—an increase of 60 per cent. over 1839. Such, and so growing, is the importance of this metal.

Bibliography.—Among ancient authors need be mentioned only Aristotle, *Meteorolog., lib.* iv., and *De mirab. Auscultat., lib.;* Diodore of Sicily, *Histor., lib.* v.; Strabo, *Geograph., libb.* iv. v. x.; of the Greek writers: and of Latin, the elder Pliny, Hist. Natur., lib. xxxiv. In connection should be taken Hausmann, de arte Ferri conficiendi veterum, 1820. In modern times, Agricola, *de re Metallica*, 1546; Reaumur, *L'art d'adoucir le fer fondu*, etc., 1722; Swedenborg, *Regnum Subterran.*, 1734; Bergman de Analysi Ferri, 1781; and the Swede Rinman, *Forsök till jemets-historie*, 1785, (Researches into the History of Iron, and translated into German by Karsten,)—compose a class who needed only a truer chemical theory to direct and bind up their observations. Such a theory—begun to be exemplified in the memoir of Berthollet, Vandermonde, and Monge, upon the different states of iron, *Hist. de l'Acad. des Sciences*, 1786—was more elaborated in the four quartos of Hassenfratz, *La Siderotechnie*, 1812; and underwent a final establishment in Karsten's *Handbuch der Eisenhütten Kunde*, first published in 1816, translated from a second German edition under the title of *Metallurgie de Fer*, by Culman, in 1830, and republished in a third German edition in 1844. Use has been made, in both of the last editions, of the same author's *Metallurg. Reise durch Baiern, etc.*, 1821. Other writers who since then have contributed facts or explanations, will be mentioned chronologically: for instance, Berzelius, in his *Afhandlingar i Fysik, Kemi, &c.*, (a periodical begun in 1806,) where there are several important announcements, which were subsequently collected and translated by Hervé under the title of *Chimie de Fer*, 1826; the same Berzelius in Manual of Chemistry, (*Traité de Chimie*, vol. iii.,) translated into French by Jourdan; Manson, *Traité de Fer et de l'Acier*, 1826; Pelouze, *l'Art du Maître de Forges*, 1827; Landrin, *Manuel Complet du Maitre de Forges*, 1829; Berthier, *Essais par la Voie Sèche, tom.* ii., 1834; Holland, *Manufactures in Metal, vols.* i. ii., 1834; Gueuyvean, *Nouveaux Procedés pour fabriquer la Fonte et le Fer*, 1835; Dufrênoy, De Beaumont, Coste, and Perionnet, *Voyage Metallurgique en Angleterre*, (2d edition,) 1837; Le Blanc and Walter, *Metallurgie Pratique du Fer*, 1835–38; Scrivenor, *History of the Iron Trade*, 1839–41; Mushet, Papers on Iron and Steel, (being a collection and revision of papers published many years before in Tillock's Philos. Mag.,) 1840; Johnson, *Anthracite Iron*, 1841; Alexander, *Progress and Present State of the Manufacture of Iron*, 1841, and an edition of Rogers's *Letters on Iron-Making*, 1844; Flachat, Barrault, and Petiet, *Traité de la Fabrication de la Fonte et du Fer*, 1846; and Overman, *The Manufacture of Iron in all its various Branches*, 1850. Authors who have treated of the mechanical resistance of this metal are, Duleau, *sur la Resistance du Fer forgé*, 1820; Tredgold, *Essay on Cast-Iron, &c.*, (2d edition, enlarged,) 1824, and with additions by Hodgkinson, 1842–46; Turnbull, *on Cast-Iron*, 1832; Nuvier, *Mémoire sur les Ponts Suspendus*, 1830, and *Resumé des Leçons, &c.*, (2d edition,) 1833—in the first volume of which there is a

copious collection of the results of preceding experimenters. Besides these, there are to be consulted upon the theory and practice, upon the minerals, material, and manufacture of iron, papers in various scientific journals which can only be generally indicated: for example, in the *Ann. de Chimie et de Physique* of Guyton-Morveau, Arago, Berthier, Thenard, &c.; in the *Journal des Mines* of Collet Descotils, Vauquelin, &c.; in the *Annale des Mines* of D'Aubuisson, Bunsen, Ebelmen, Thirria, &c.; in the *Annalen of Poggendorff*, of Mosander, Rose, and Seebeck; in the *Archiv. für Bergbau of Karsten*, of Berzelius, and Karsten; in the *Phil. Transact.*, and in the *L. and E. Philosoph. Mag.* of Rennie and Daniell, &c.: many of which would require examination and discussion in a complete modern treatise on iron.

Improved Machines for the Manufacture of Iron.—Various machines have been contrived for the squeezing out the cinder from the puddle ball; the best is probably the hammer, and it is generally used in the manufacture of the best iron. A common form of squeezers called the *alligator* is shown

2411.



2412.

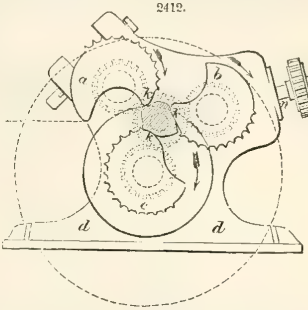


fig. 2406, an improvement over the "Burden's Patent Eccentric Rotatory Squeezers," illustrated in fig. 2407. A machine somewhat similar in its action, will be found under the head of PUDDLER'S BALLS.

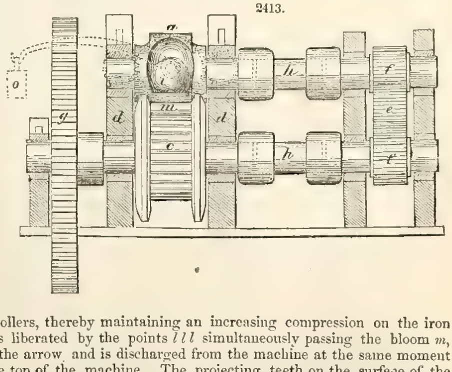
Figs. 2411, 2412, and 2413, illustrate an English machine, patented by Mr. Jeremiah Brown, and intended to serve the same purpose. The machine consists of three large eccentric rollers *a*, *b*, *c*, placed horizontally in the strong holsters *d d*, the centres of the rollers being arranged in a triangular position and the bottom roller *c*, nearly central between the two top rollers *a*, *b*: these rollers rotate in the same direction as shown by the arrows, and are driven by a centre pinion *e*, working into three pinions of equal size *f f f*, fixed on the roller spindles. In the present machine, the driving power is applied direct to the bottom roller, by means of the large wheel *g*, for the convenience of carrying the main shaft under the floor, but it could be applied to the centre pinion if preferred. The rollers are cast solid, with their journals like ordinany rollers, and are driven in the usual manner by coupling boxes and spindles *h h*. The roller faces are sixteen inches long, and the bottom roller has strong flanges at each end 8 inches deep, between which the two upper rollers work; the object of these flanges is to upset or compress the ends of the bloom, as the iron in the operation is elongated, and the ends are forced against the flanges which make them square and sound. The top roller *a* has a large hollow, in which the puddled ball *i* is placed by the puddler; and this roller carries the ball round, and drops it into the space between the three rollers, as shown in fig. 2412, this space being at that moment at its largest capacity. The three projecting points *k k k*, of the rollers immediately impinge upon the ball, and compress it forcibly on the three sides, and, giving a rotating motion to the ball at the same time, they have a very powerful kneading action upon the iron, squeezing out the cinder very effectually, which flows freely away, down each side of the bottom roller. The space between the rollers gradually contracts, from

2413.

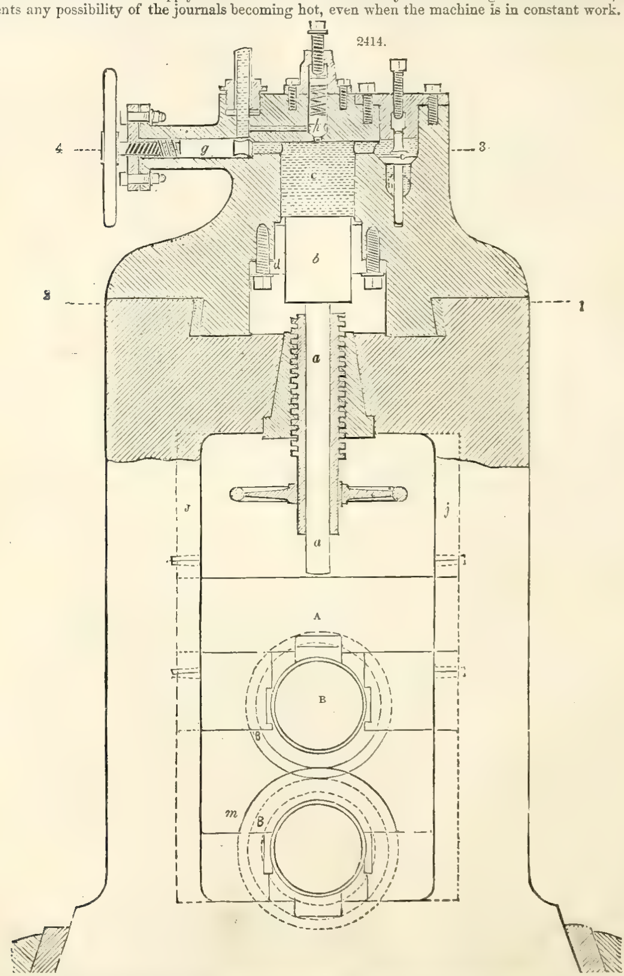


the eccentric or spiral form of the rollers, thereby maintaining an increasing compression on the iron on all sides and the ends, until it is liberated by the points *l l l* simultaneously passing the bloom *m*, which falls down in the direction of the arrow and is discharged from the machine at the same moment that another ball is dropped in at the top of the machine. The projecting teeth on the surface of the rollers assist this action, by seizing hold of the iron and kneading into it as it rotates; and these teeth gradually diminish in projection, the last portion of each roller being plain, and the bloom is consequently turned out in a smooth compact form. The space between the flanges of the bottom roller is

widened for a short distance beyond the point *l*, for the purpose of allowing the bloom to drop out readily, and admitting the fresh ball.

A provision is made to prevent risk of breaking the rollers by any unusual size of ball being put in, by means of the two large triple-threaded screws *n n*, which bear upon the journals of one of the top rollers *b*; a small pinion on the head of each of these screws works into a large pinion fixed between them, which has a horizontal lever fixed to it, carrying a balance weight *o* at the end; this weight causes a constant equal pressure on the roller, and in the case of any ball of extra size being put into the machine, the screws yield by turning back and lifting the weight to the extent that may be required, so that a large ball will be worked with the same pressure and in the same effective manner as the smaller sizes. A continual supply of water is run on to all the journals throughout the machine, which prevents any possibility of the journals becoming hot, even when the machine is in constant work.

2414.



IRON ROLLING MACHINE—CLAY'S *improvement.* We copy from the inventor's specification: My invention of certain improvements in machinery, for rolling iron or other metals, is designed to

produce, by the process of rolling, bars of taper forms, as for instance wedge-shaped bars or conical bars.

The tapering of metal bars I effect by allowing one of the shaping-rollers to recede gradually from the other, as the rolling operation goes on, and thus enlarge the space or distance between the rollers,

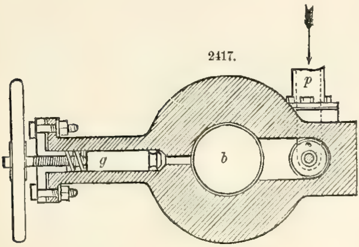
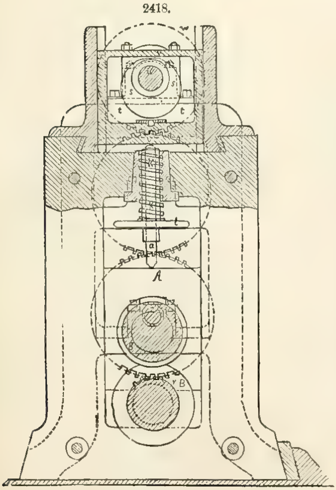
2417.



2418.



whereby the metal, in passing between them, is made to assume a gradually increasing thickness, either in a wedge, conical, or other form, according to the shape of the grooves cut in the rollers.

My invention consists in the adaptation to rolling machinery of pistons, bearing against confined columns of water, or other non-elastic fluid, the ends of the piston-rods maintaining or affording the means of keeping the bearings of the rollers from shifting their positions, excepting as the columns of water

are allowed to relax their resistance by a slow and gradual escape of the fluid from the cylinder, or chamber through an adjustable valve. The apparatus I have arranged for this purpose is shown in the accompanying drawings, in which fig. 2414 represents a vertical section, taken transversely through the head of one of the standards, wherein the bearings of the journals of the rollers are mounted, showing the piston, its rod and appendages, with the column of water against which the piston bears, and the valve whereby a small quantity of the fluid may be allowed gradually to escape. Fig. 2415 represents a partial front view of the rollers, the bearings, and part of the regulating apparatus in the head of the standard, being shown in section.

Of course, it will be understood that two such standards support the ends of the rollers. Fig. 2416 is a horizontal section, taken in the line 1, 2, of fig. 2414, showing the parts inverted, or as seen from below; and fig. 2417 is another horizontal section, taken on the upper side in the line 3, 4, of fig. 2414, showing the entrance and exit valves of the chamber of water, and the means of working or regulating the exit valve. In the rolling-mills usually employed for rolling bar-iron, the rollers are generally mounted in fixed bearings, or bearings which during the operation of rolling, are rendered immovable, by being maintained in their places by strong screws or bolts.

In my improved machinery, or apparatus, the ends of the bearing A, of the upper roller, are let into grooves in the standards, as in ordinary rolling-mills, in such a manner as to admit of their sliding up and down therein, in order that, by so sliding, the parallel distances between the rollers may be allowed to change.

The rising of the bearings with the upper roller is regulated and governed by a piston-rod *a*, which rests on the top of the bearings, the upper end of the piston-rod being connected to the solid piston *b*, of the hydraulic cylinder, or water-chamber *c*, as shown in figs. 2414 and 2415.

This cylinder *c*, is filled with water, or other non-elastic fluid or liquid, and is furnished with leather or other suitable packing, for the purpose of preventing any leakage of the water.

The packing is kept in its place by a metallic ring or plate *d*, which is firmly secured to the body of the cylinder by strong screw-bolts.

The cylinder is supplied with water from any convenient source, by a lateral tube *p*, shown in fig. 2417, through the rising feed-valve *e*, the construction and operation of which will be clearly understood by referring to the drawing.

f is the exit-valve, through which, when partially opened, the water is allowed to escape from the chamber *c*, on pressure being applied to the lower end of the rod *a*, by which pressure the piston *b* will be made to rise and partially to expel the water, as will be the case when a bar of iron is passed between the shaping rollers B B. The valve *f* is constructed in such a manner that the opening for the discharge of the water may be regulated with the greatest exactness by merely advancing or receding the plug *g*, worked by the screw at its back end, the effect of which will be to open or close the valve to any extent that may be required.

There is a slight spring behind the plug *g*, which is merely intended to push it forward and close the aperture of the valve when the upward pressure of the piston is not in action, as will be the case when the rolling operation is suspended. An additional valve *h*, is also made to communicate with the exit-passage *i*. This valve, however, is always kept closed by a strong spring, as shown, and will never allow any water to escape this way from the cylinder, except when any extraordinary pressure takes place, at which time the power of the spring will be overcome, and, by yielding, prevent the machinery from being too greatly strained.

In introducing into my improved machinery a mass of iron between the shaping-rollers, say for the purpose of producing a wedge-formed bar, having parallel edges, I employ a pair of rollers of the ordinary kind, having the grooves and flanges, as shown in fig. 2415.

The mass of iron being about to be introduced between the rollers in the first groove, I open the valve *f*, by withdrawing the screw behind the plug *g* to such an extent as will allow the escape of water from the chamber *c* in a small current, regulating the opening for the intended discharge according to the required taper of the bar to be formed, the required extent of which opening will readily be found by the experience of the workman. The operation of rolling now proceeding, the pressure of the metal passing between the rollers will cause the bearings of the upper roller to rise and force up the piston-rod *a*, in doing which the piston will be made to rise in the chamber *c*. But the ascent of the piston being resisted by the non-elastic fluid in the chamber *c*, the escape of water through the valve *f* and outlet *i* must take place to allow of the ascent of the piston, and consequently the separation of the rollers: according, therefore, to the rate of the escape of water will the taper or inclined shape of the bar to be produced be determined.

It will thus be seen that, by my improved apparatus, the process of rolling metals is carried on much in the usual manner, except that, by means of opening the valve more or less, the escape of the water from the chamber will allow the upper roller to rise, and consequently give the requisite taper form to the bar under operation, according to the rapidity with which the water is allowed to flow out of the chamber. As I do not intend to confine myself to any particular forms of bars to be produced by my improved machinery, it is not necessary to describe more precisely the shapes of the rollers. I will therefore only add, that by forming the grooves of the rollers in elliptical shapes, as at *n n*, in Fig. 4010, I am enabled, by the gradual rise of one of the rollers, and repetitions of the rolling operation, to produce bars of conical figures.

It is sometimes desirable to roll a bar taper or wedge-formed, for a portion of its length, and level for the remainder of its length.

For this purpose, it will be necessary to allow the upper roller to rise to a certain distance only, and then to stop. This I effect by means of adjusting-screws *k k*, one over each bearing of the rollers, similar to those heretofore used, except that it is through the axes of the adjusting-screws, forming guides, that the piston-rods *a* pass, as shown in the drawing at Fig 2414; and it will, therefore, be understood that

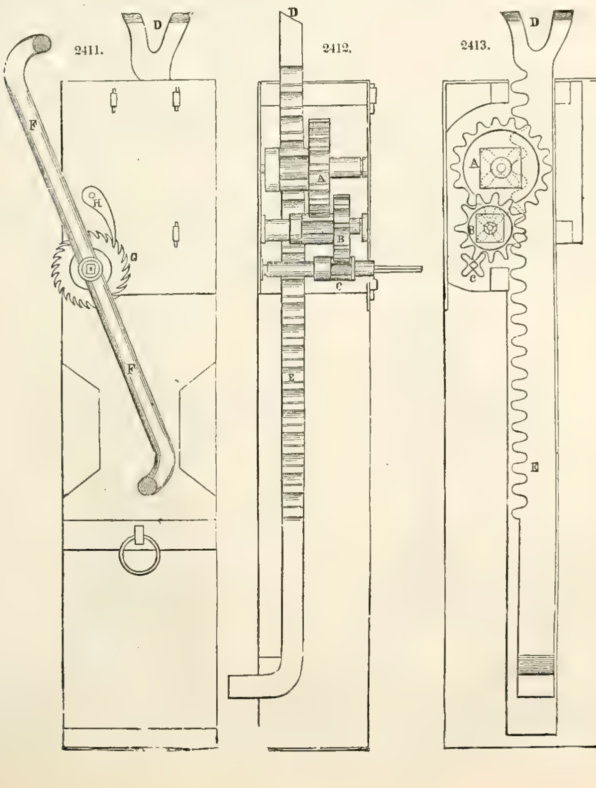
when, by the escape of the water from the chamber, the bearings of the rollers have been allowed tc force up the piston-rod and the piston a certain determined distance, that then the upper edge of the bearing A, of the top roller will come into contact with the under side of the adjusting-screw *k*, beyond which it cannot rise, and as the bearings will, for a time, become fixed, the bar of iron under operation will, for the remaining portion of the process, be rolled parallel.

The adjusting-screw *k*, passes through a hollow screw made in a socket fixed in the frame, and the screw can be easily raised or lowered, so as to limit the rise of the bearing A, by merely turning the hand-wheel *l*, attached to its lower part.

It may be as well to observe that the standards or housings may be of any convenient known pattern, and that a lever or other known balance may be used with advantage to support the roller in its rise and fall. A portion, also, of the head of the standard in which the piston works is made removable for the purpose of getting at the pistcn and packing when required, as will be seen at *q q*, in figs. 2415 and 2416.

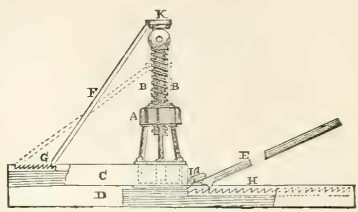
JACK. In mechanics, a sort of crane for raising heavy weights. It consists, first, of a small pinion wrought with a common winch. This pinion works in the teeth of a large wheel, on whose axis there is fixed a small pinion with teeth, working in a rack. The turning of the handle raises the rack, and of course any weight attached to it. If the length of the handle of the winch be 7 inches, and the pinion which it drives contain 4 leaves, working in the teeth of the large wheel having 20 teeth, then will 5 turns of the handle be requisite for one of the wheel. But the length of the arm of the winch being 7 inches, the circumference through which the handle moves will be about 44 inches, and for one turn of the wheel the handle must pass through $5 \times 44 = 220$. The wheel carries a pinion of, say, 3 leaves, of a pitch of $\frac{1}{3}$ of an inch, working the rack that carries the weight; one turn of the pinion will, therefore, raise the rack one inch, and as the power moves through 220 in the same time, 220 will be the power of the jack.

JACK-SCREW. Figs. 2411, 2412, and 2413 represent a plan of a jack-screw for turning large stone, used at the United States Dry Dock, Brooklyn.

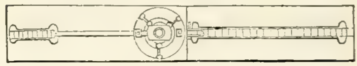


JACK, TRAVERSING SCREW. Figs. 2415 and 2416 exhibit a side view and plan of the screw modification. The screw-jack A is bolted to the plank C; at the other end of the plank is fixed the rack G, in which the toe of the strut F advances as the screw B is elevated; the strut works in a joint in the follower K: the position of the strut when the screw is depressed is shown by the dotted lines. The object of this strut is to relieve the screw of the violent cross-strain to which the apparatus is subject, when the engine or carriage is pulled over by the lever; which strain is entirely transferred to the strut, and the screw has merely to carry the load.

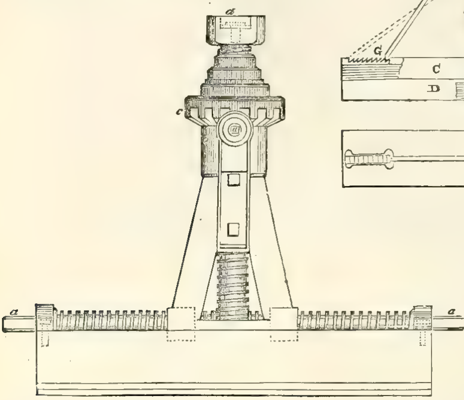
2415.



2416.



2417.

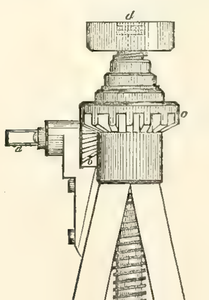


The operation of traversing the jack is as follows: By hooking the link I upon the hook of the lever E, the toe of the lever being inserted into a ratch of the rack H of the lower plank, when a man bearing down the end of the lever, drags the apparatus and engine or carriage towards him with great facility; the same lever is used to turn the screw, and to produce the traverse motion.

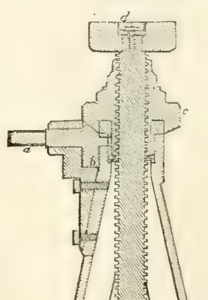
JACK, TRAVERSING. Another form of traversing jack is shown at fig. 2417, side elevation; fig. 2418 end elevation, and fig. 2419 section through vertical screw.

The lift of this jack is effected by means of a crank, or lever, applied to the axis *a*, which works the bevel-geer *b c*, the latter geer being cut on the projecting face of the nut *c*; the revolution of this nut lifts or lowers the vertical screw, and with it the jaw *d*; the screw-head moving freely in a socket of the jaw-head, permits the latter to rise or fall without side movement.

2418.



2419.



The horizontal screw *a a*, working into a nut in the foot of the upper screw-frame, effects the horizontal or traversing movement of the jack, the frame of the lower screw serving as a bed or slide for the latter movement. A ratchet-lever may be used to work either of the screws instead of a crank.

The HYDRAULIC JACK (Patent Portable Hydraulic Jack, R. Dudgeon, New York) is the simplest

and most portable in comparison with the force it is capable of exerting. This jack, or press, appears to the eye, when depressed, a simple cylinder, and when elevated, to one cylinder sliding within another. It is from two to eight or more inches in diameter, according to the power desired, with an enlarged head (attached to the inner cylinder, which is the ram), having a socket for the reception of the lever, by which the piston of the force pump is worked.

The ram, with its head, contains just so much water or other fluid as is required to fill the vacancy in the cylinder, caused by the raising of the ram in the act of lifting; and when this is accomplished the water is returned into its original recess by a valve operated by the lever that works the pump. The force pump, piston and valves are contained inside of the ram.

The lever is detached, and may be put on at pleasure. The joints in the head maintain a parallel motion for the force pump piston, which is the fulcrum of the lever. The ground-lifting attachment is an iron tube screwed into the lower side of the head, and passing down to the bottom of the press outside of the cylinder, on the lower end of which is a claw that supports the weight to be raised.

These presses are light, portable, and of easy application. A press to raise four tons not weighing more than 50 lbs., and one to raise 60 tons, not more than 200 lbs. They are all worked by the labor of one man only, which is capable of raising ten tons through a space of one foot in one and a half minutes, or sixty tons the same distance in ten minutes.

JACQUARD. A peculiar and most ingenious mechanism, invented by M. Jacquart of Lyons, to be adapted to looms for superseding the employment of draw-boys, in weaving figured goods.

Fig. 2420 is a front elevation of this mechanism, supposed to be let down. Fig. 2421 is a cross section, shown in its highest position. Fig. 2422 the same section, but seen in its lower position.

A, is the fixed part of the frame, supposed to form a part of the ordinary loom; there are two uprights of wood, with two cross-bars uniting them at their upper ends, and leaving an interval *x y*, between them, to place and work the movable frame B, vibrating round two fixed points *a a*, placed laterally opposite each other, in the middle of the space *x y*, fig. 2420.

C, is a piece of iron with a peculiar curvature, seen in front, fig. 2420, and in profile, figs. 2421 and 2422. It is fixed on one side upon the upper cross-bar of the frame B, and on the other, to the intermediate cross-bar *b*, of the same frame, where it shows an inclined curvilinear space *c*, terminated below by a semi-circle.

D, is a square wooden axis, movable upon itself round two iron pivots, fixed into its two ends; which axis occupies the bottom of the movable frame B. The four faces of this square axis are pierced with three round, equal, truly-bored holes, arranged in a quincunx. The teeth *a*, fig. 2424, are stuck into each face, and correspond to holes *a*, fig. 2427, made in the cards which constitute the endless chain for the healds; so that in the successive application of the cards to each face of the square axis, the holes pierced in one card may always fall opposite to those pierced in the other.

The right-hand end of the square axis, of which a section is shown in double size, fig. 2423, carries two square plates of sheet iron *d*, kept parallel to each other and a little apart by four spindles *e*, passed opposite to the corners. This is a kind of lantern, in whose spindles the hooks of the levers *f f'*, turning round fixed points *g g'*, beyond the right hand upright A, catch hold, either above or below, at the pleasure of the weaver, according as he merely pulls or lets go the cord *z*, during the vibratory movement of the frame B.

E, is a piece of wood shaped like a T, the stem of which, prolonged upwards, passes freely through the cross-bar *b*, and through the upper cross-bar of the frame B, which serve as guides to it. The head of the T piece being applied successively against the two spindles *e*, placed above in a horizontal position, first by its weight, and then by the spiral spring *h*, acting from above downwards, keeps the square axis in its position, while it permits it to turn upon itself in the two directions. The name *press* is given to the assemblage of all the pieces which compose the movable frame B B.

F, is a cross-bar made to move in a vertical direction by means of the lever G, in the notches or grooves *i*, formed within the fixed uprights A.

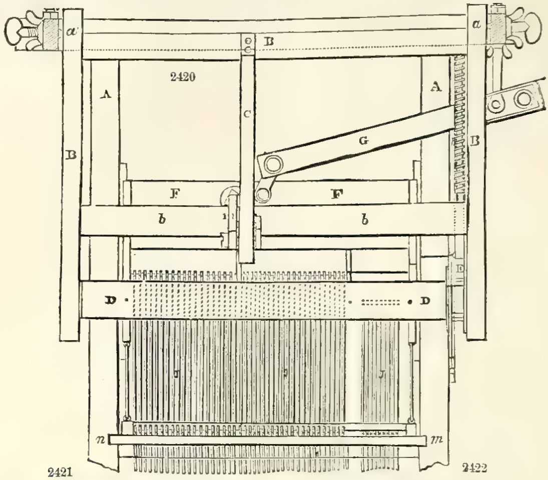
H, is a piece of bent iron, fixed by one of its ends with a nut and screw, upon the cross-bar F, out of the vertical plane of the piece C. Its other end carries a friction roller J, which working in the curvilinear space *c* of the piece C, forces this, and consequently the frame B, to recede from the perpendicular or to return to it, according as the cross bar F is in the top or bottom of its course, as shown in figs. 2421 and 2422.

I, cheeks of sheet iron attached on either side to the cross-bar F, which serves as a safe to a kind of claw K, composed here of eight small metallic bars, seen in section figs. 2421 and 2422, and on a greater scale in fig. 2424.

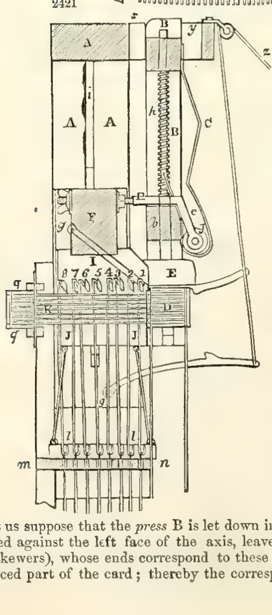
J, upright skewers of iron wire, whose tops, bent down hookwise, naturally place themselves over the little bars K. The bottom of these spindles, likewise hooked in the same direction as the upper ones, embraces small wooden bars *l*, whose office is to keep them in their respective places, and to prevent them from twirling round, so that the uppermost hooks may be always directed towards the small metallic bars upon which they impend. To these hooks from below are attached strings, which after having crossed a fixed board, *m n*, pierced with corresponding holes for this purpose, proceed next to be attached to the threads of the loops destined to lift the warp threads. K K, horizontal spindles or needles, arranged here in eight several rows, so that each spindle corresponds both horizontally and vertically to each of the holes pierced in the four faces of the square axis D. There are therefore as many of these spindles as there are holes in one of the faces of the square.

Fig. 2425 represents one of these horizontal spindles. *n* is an eyelet through which the corresponding vertical skewer passes. *o* another elongated eyelet, through which a small fixed spindle passes to serve as a guide, but which does not hinder it from moving lengthwise, within the limits of the length of the eyelet. *p* small spiral springs placed in each hole of the case *q q*, fig. 2424. They serve to bring back to its primitive position, every corresponding needle, as soon as it ceases to press upon it.

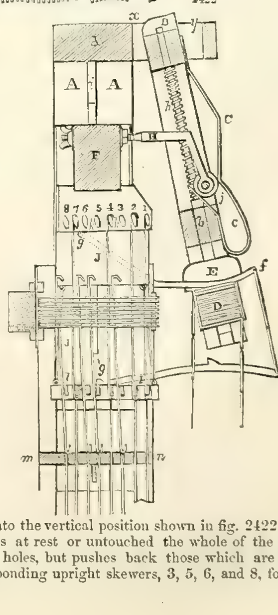
Fig. 2426 represents the plan of the upper row of horizontal needles. Fig. 2427 is a fragment of the endless chain, formed with perforated cards, which are made to circulate or travel by the rotation of the shaft D. In this movement, each of the perforated cards, whose position, form and number, are determined by the operation of tying-up of the warp, comes to be applied in succession against the four faces of the square axis or drum, leaving open the corresponding holes, and covering those upon the face of the axis, which have no corresponding holes upon the card.



2421



2422



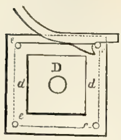
Now let us suppose that the *press* B is let down into the vertical position shown in fig. 2422; then the card applied against the left face of the axis, leaves at rest or untouched the whole of the horizontal spindles (skewers), whose ends correspond to these holes, but pushes back those which are opposite to the unpierced part of the card; thereby the corresponding upright skewers, 3, 5, 6, and 8, for example,

pushed out of the perpendicular, unhook themselves from above the bars of the claw, and remain in their place, when this claw comes to be raised by means of the lever G; and the skewers 1, 2, 4, and 7, which have remained hooked on, are raised along with the warp threads attached to them. Then by the passage across of a shot of the color, as well as a shot of the common weft, and a stroke of the lay after shedding the warp and lowering the press B, an element or point in the pattern is completed.

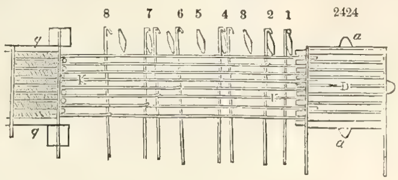
The following card, brought round by a quarter revolution of the axis, finds all the needles in their first position, lifts another series of warp threads; and thus in succession for all the other cards, which compose a complete system of a figured pattern.

If some warp yarn should happen to break without the weaver observing them, or should he mistake

2423



2424



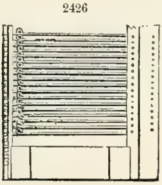
2425

his colored shuttle yarns, which would so far disfigure the pattern, he must undo his work. For this purpose, he makes use of the lower hooked lever f', whose purpose is to make the chain of the card go backwards, while working the loom as usual, withdrawing at each stroke the shot both of the ground and of the figure. The weaver is the more subject to make mistakes, as the figured side of the web is downwards, and it is only with the aid of a bit of looking-glass that he takes a peep of his work from time to time. The upper surface exhibits merely loose threads in different points, according as the pattern requires them to lie upon the one side or the other.

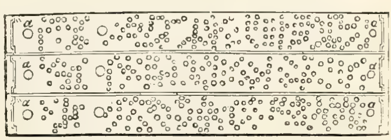
Thus it must be evident, that such a number of paste-boards are to be provided and mounted as equal the number of throws of the shuttle between the beginning and end of any figure or design which is to be woven; the piercing of each paste-board individually, will depend upon the arrangement of the lifting rods, and their connection with the warp, which is according to the design and option of the workman; great care must be taken that the holes come exactly opposite to the ends of the needles; for this purpose two large holes are made at the ends of the paste-boards, which fall upon conical points, by which means they are made to register correctly.

It will be here seen, that, according to the length of the figure, so must be the number of paste-boards, which may be readily displaced so as to remount and produce the figure in a few minutes, or

2426



2427



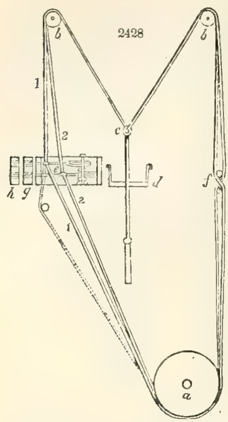
remove it, or replace it, or preserve the figure for future use. The machine, of course, will be understood to consist of many sets of the lifting rods and needles, shown in the diagram, as will be perceived by observing the disposition of the holes in the paste-board; those holes, in order that they may be accurately distributed, are to be pierced from a gauge, so that not the slightest variation shall take place.

To form these card-slips, an ingenious apparatus is employed, by which the proper steel punches required for the piercing of each distinct card, are placed in their relative situations preparatory to the operation of piercing, and also by its means a card may be punched with any number of holes at one operation. This disposition of the punches is effected by means of rods connected to cords disposed in a frame, in the nature of a false simple, on which the pattern of the work is first read in.

These improved pierced cards, slips, or paste-boards, apply to a weaving apparatus, which is so arranged that a figure to be wrought can be extended to any distance along the loom, and by that means the loom is rendered capable of producing broad figured works; having the long lever G placed in such a situation that it affords power to the foot of the weaver, and by this means enables him to draw the heaviest morintures and figured works, without the assistance of a draw-boy.

The machinery for arranging the punches, consists of a frame with four upright standards and cross-pieces, which contains a series of endless cords passing under a wooden roller at bottom, and over pulleys at the top.

Fig. 2428 represents a single endless cord 1 1, which is here shown in operation, and part of another endless cord 2 2, shown stationary. There must be as many endless cords in this frame as needles in the weaving-loom a is the wooden cylinder, revolving upon its axis at the lower part of the standard; b b



the two pulleys of the pulley-frames above, over which the individual endless cord passes; *c* is a small transverse ring. To each of these rings a weight is suspended by a single thread, for the purpose of giving tension to the endless cord. *d* is a board resembling a common comber-bar, which is supported by the cross-bars of thestandard frame, and is pierced with holes, in situation and number, corresponding with the perpendicular threads that pass through them; which board keeps the threads distinct from each other.

At *e* the endless cord passes through the eyes of wires resembling needles, which are contained in a wooden box placed in front of the machine, and shown in this figure in section only. These wires are called the *punch projectors;* they are guided and supported by horizontal rods and vertical pins, the latter of which pass through loops formed at the hinder part of the respective wires. At *f* are two horizontal rods extending the whole width of the machine, for the purpose of producing the cross in the cords; *g* is a thick brass plate, extending along in front of the machine, and lying close to the box which holds the *punch-projectors;* this plate *g*, shown also in section, is called the *punch-holder;* it contains the same number of apertures as there are punch-projectors, and disposed so as to correspond with each other. In each of these apertures there is a punch for the purpose of piercing the cards, slips, or pasteboards with holes; *h* is a thick steel plate of the same sizeas *h*, and shown likewise in section, corresponding also in its number of apertures, and their disposition, with the punch-projectors and the punch-holder. This plate *h*, is called the *punch-receiver.*

The object of this machine is to transfer such of the punches as may be required for piercing any individual card from the punch-holder *g*, into the punch-receiver *h;* when they will be properly situated, and ready for piercing the individual card or slip, with such holes as have been read in upon the machine, and are required for permitting the warp threads to be withdrawn in the loom, when this card is brought against the ends of the needles. The process of transferring the patterns to the punches is thus effected.

The pattern is to be read in according to the ordinary mode, as in a false simple, upon the endless cords below the rod *f*, and passed under the revolving wooden cylinder *a*, to a sufficient height for a person in front of the machine to reach conveniently. He there takes the upper threads of the pattern, called the *beard*, and draws them forward so as to introduce a stick behind the cords thus advanced, as shown by dots, for the purpose of keeping them separate from the cords which are not intended to be operated upon. All the punch-projectors which are connected with the cords brought forward, will be thus made to pass through the corresponding apertures of the punch-holder *g*, and by this means will project the punches out of these apertures, into corresponding apertures of the punch receiver *h*. The punches will now be properly arranged for piercing the required holes on a card.

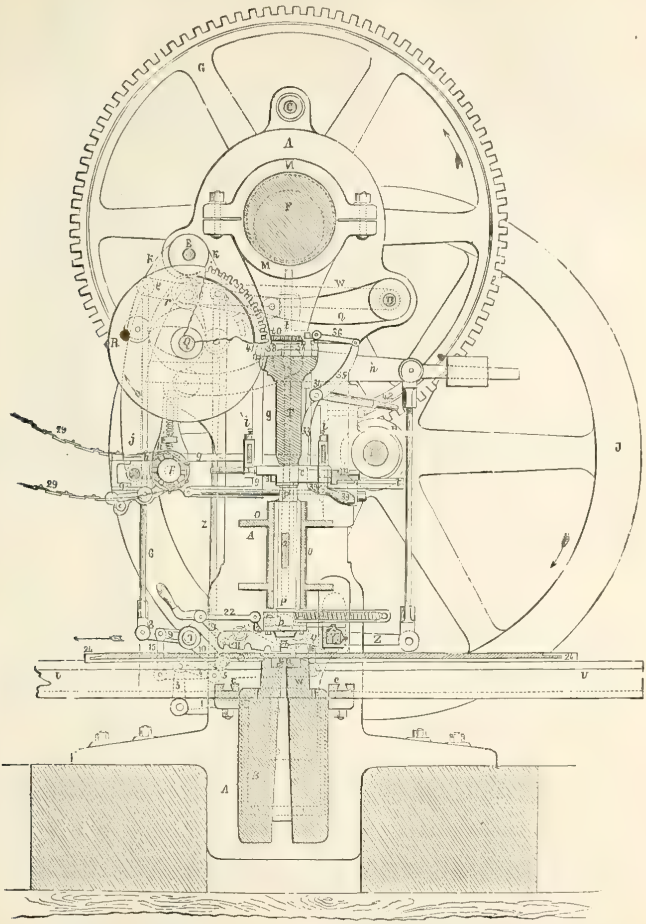
Remove the punch-receivers from the front of the machine; and having placed one of the slips of card or pasteboard between the two folding plates of metal, completely pierced with holes corresponding to the needles of the loom, lay the punch-receiver upon those perforated plates, to which it must be made to fit by mortices and blocks, the cutting parts of the punches being downwards. Upon the back of the punch-receiver is then to be placed a plate or block, studded with perpendicular pins corresponding to the above described holes, into which the pins will fall. The plates and the blocks thus laid together, are to be placed under a press, by which means the pins of the block will be made to pass through the aperture of the punch-receiver; and wherever the punch has been deposited in the receiver by the above process, the said punches will be forced through the slip of pasteboard, and pierced with such holes as are required for producing the figured design in the loom.

Each card being thus pierced, the punch-receiver is returned to its place in front of the machine, and all the punches forced back again into the apertures of the punch-holder as at first. The next set of cords is now drawn forward by ths next *beard*, as above described, which sends out the *punch-projectors* as before, and disposes the punches in the punch-receiver, ready for the operation of piercing the next card. The process being thus repeated, the whole pattern is, by a number of operations, transferred to the punches, and afterwards to the cards or slips, as above described. See Loom.

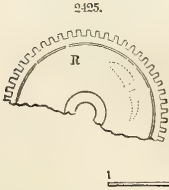
JACQUARD PERFORATING MACHINE. Machine for perforating metal plates, such as are used for steam-boilers, &c.; and employed for punching the plates of the tubular bridge at Conway, made at the Globe Works, Manchester, by Messrs Roberts, Fothergill & Co.

Fig. 2420 represents a sectional elevation of the machine; Fig. 2421 an elevation of the back of the machine; Fig. 2422 a plan view of the apparatus for putting the punches out of action without stopping the fly-wheel; and Fig. 2423 a plan view of a few of the jacquard plates. Fig. 2426 represents a front elevation; Fig. 2427 a side elevation; and Fig. 2428 a horizontal section, taken through the dotted lines A^1A^1, in Figs. 2426 and 2427. Fig. 2429 is a detached view of the traverse apparatus, and Fig. 2430 a detached view of the holding-down or stripping apparatus. A A the standards. B the bed, through which there is an opening for the punchings, or metal punched out of the plate, to fall through; this bed is inserted into the standards. C a stretcher-bar, to connect the top of the standards. D, fulcrum of the levers *q q* which withdraw the punches, and of the lever *w* which traverses the plate. E a fulcrum shaft, to which the levers *j j* and *k k* are keyed. F the main or eccentric shaft, working in bushes in the standards. G a spur-wheel, keyed on the eccentric-shaft. H a pinion, working into the wheel G. I the fly-wheel shaft, on which are the fast and loose pulleys K and L, the pinion H, and the fly-wheel J. M M connecting-rods, fitted to the eccentric necks of the shaft F. N N caps of the connecting-rods M M

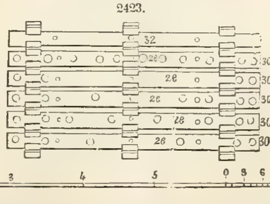
2420.



2425.



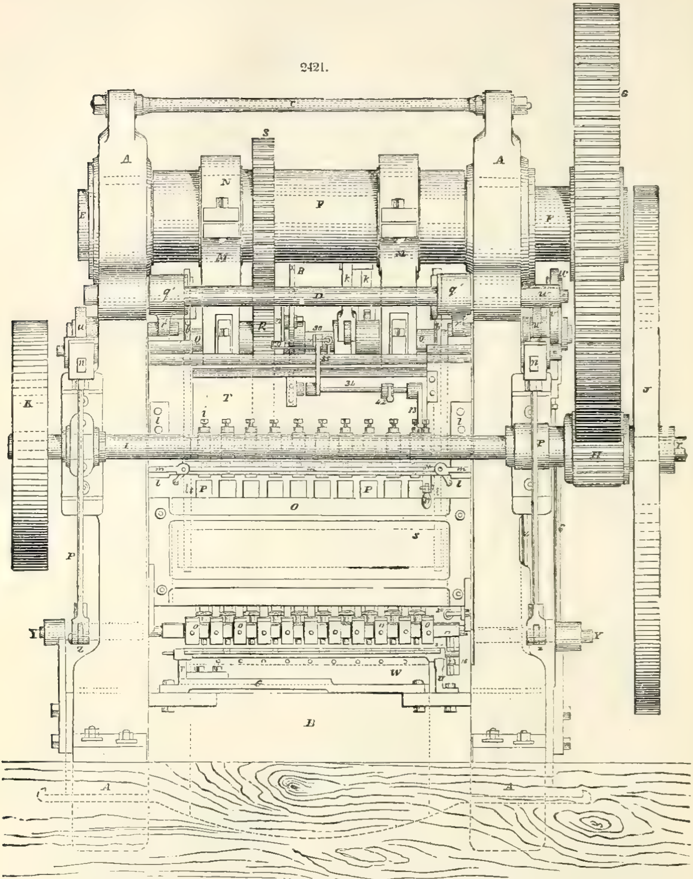
2423.



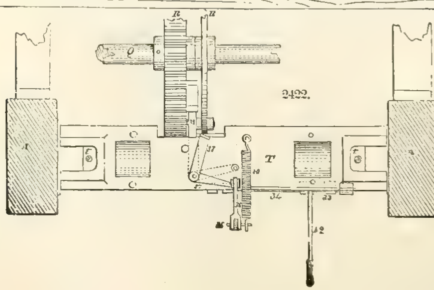
2424.

O O guide-plates for the punch-rams P P. Q the cam-shaft. R a spur-wheel, loose on the cam-shaft and having on one side two projections, between which there is an opening. R* a locking-disk or plate

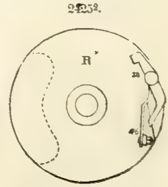
2421.



2422.



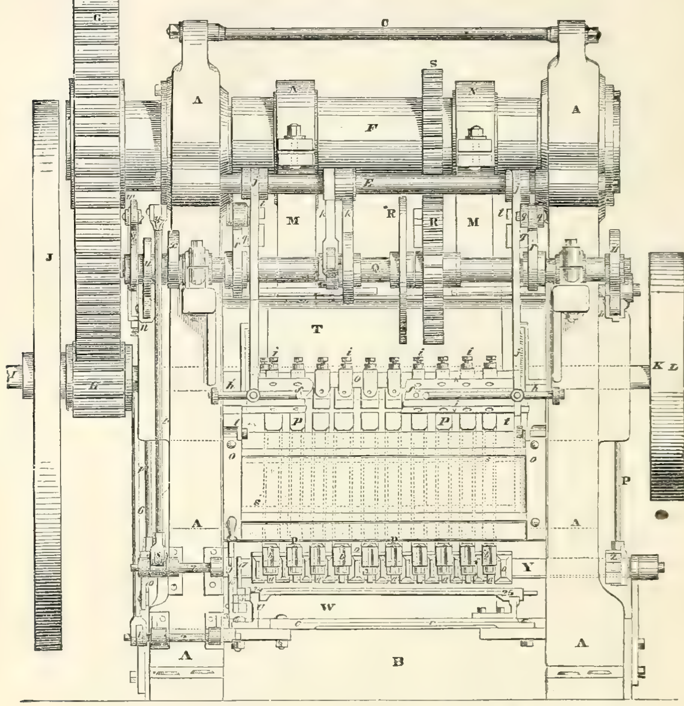
2425².



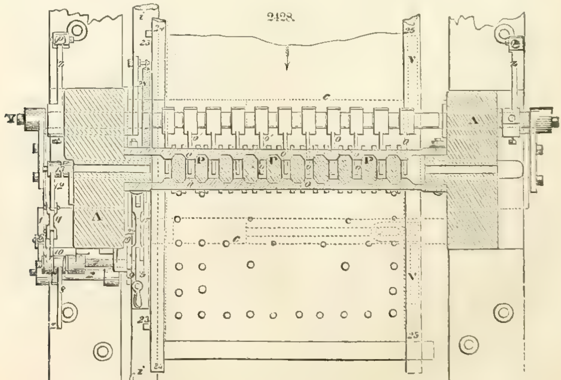
keyed on the shaft Q, having upon it a spring-catch 38, which takes into the opening between the projections on the wheel R. R and R* are seen detached in Fig. 2425,2425²: the dotted lines on R* represent a weight to counterbalance the levers *k*. S a toothed-wheel, keyed on the main-shaft F. T the punch-ram depressor, secured to the connecting-rods M M by knuckle-joints at the lower end of the connecting-rods. U a slide-bar, on which the frame traverses which carries the plate to be punched. V V two short slide-bars, to carry one side of the traverse-frame. W a block of iron, fastened with short wedges to the bed B to carry the die-plate X, into which the dies *d* are inserted, and prevented from rising by a collar at the lower end of each, as seen in Fig. 2430. Y a square shaft, carrying the holding-down levers or stripping-fingers *o o* Z Z levers on each end of the shaft Y. *a a* the punches let into the punch-holders *b b* bolted to the rams P, as seen in the detached view, Fig. 2424. *c c* pieces bolted to the bed B to carry the adjusting slide-bars V V. *d* dies inserted into the holder X. *e e*, Fig 2420, are the selecting slide-bars, which, when allowed to pass through the card-plate, enter the card roller *f*, without being pushed backwards by them; the card-roller has in this case six sides, and the belt of jacquard-plates, after passing over it in the usual manner, passes over a round roller suspended in a swing-frame, at such an angle as shall keep the belt moderately tight, whilst the roller *f* advances towards and recedes from the selectors *e*. *g g* brackets projecting from the depressor T, and carried up and down with it. *h h* sliding-blocks, in which the journals of the card-roller turn. To an upright cast on each of these blocks, is fitted a rod of round iron, thus *, with a flat foot, long enough to extend over two of the six pins in the ends of the card-roller, against which the flat foot of the rods is made to press, by spiral-springs coiled around them in the usual manner employed in the jacquard-loom, which is generally known, and need not be further described. *i i*, Fig. 2420, are two sets of guide-blocks, for the selectors *e*, one on each side of the depressor, adjustable laterally by set-screws on flat bars, extending across the machine; the use of these blocks is to carry the selecting-bars *e*, which are round at the end that enters the cards, and flat at the other end, to keep them in their proper positions; the centre portion of each selecting-bar is a solid piece of iron, projecting as much below the round stem as will, when the selecting-bar is driven backwards by a card-plate, permit the depressor T to complete its downward stroke without the selecting-bar touching the ram P under it. *j j* are levers keyed on the shaft E, and connected at their lower end by links to the slide-blocks *h h*. *k k* are levers also keyed on the shaft E and having each a friction-roller at its lower extremity. On the shaft Q are two cams, one of which works a lever *k* on one side of the shaft, and the other cam works the other lever *k* on the opposite side. One of the cams, through the medium of the levers *j j*, and the links before referred to, causes the roller *f* to approach the selecting-bars *e*, and the other cam causes the roller to recede from them, until, by a catch employed in the ordinary way in the jacquard-looms, the roller *f* is made to turn through one-sixth of a revolution, and is then retained in that position by the pressure of the spiral-spring and flat foot above referred to. *l l* are brackets attached to the depressor T at the back of the machine. *m* a bar resting on the brackets *l l*, and connected by rods with the sliding-blocks *h h*, which, on receding, cause the bar *m* to bring all the selecting-bars *e* into the position for depressing the rams, as seen in Fig. 2430. *n n* are levers having their fulcra on studs screwed into the standards; one end of these levers is connected by a rod *p* with the levers Z Z; the other end is furnished with a roller which is acted upon by a cam *u* on the shaft Q. *o o* are the holding-down levers, adjustable laterally on the shaft Y, so as to admit of one of them being placed on each side of every punch. *p p* are rods connecting the levers *n* and Z. By adjusting the length of these rods, the levers *o o* are made to press upon plates of different thicknesses, so as to hold the plates down while the punches are being withdrawn. *q q* levers turning on the fulcrum-bar D for withdrawing the punches by means of the cams *r r* that actuate levers *q q*. *s* a broad but rather thin bar, extending through the series of punch-rams P, shown by dotted lines. The punch-rams P are made with slots, through which the bar *s* passes, and these slots must be about two inches longer than the width of the bar *s*, in order to allow the punch-rams to be forced down when the bar is at the bottom of its stroke. *t t* are links connecting the bar *s* with the levers *q q*. *u u* are cams which depress the holding-down levers *o o*, through the medium of the levers *n n*, rods *p p*, and levers Z Z, and hold down the plate while the punches are being withdrawn. *v* a cam for the traversing-rack 5. *w* a lever turning on the fulcrum-bar D, and worked by the cam *v*. *x* the cam for lifting the rack 5. *y* a lever turning on a stud in the standard, and worked by the cam *x* for lifting the traversing-rack 5. *z* a rod connecting the lever *y* with the lever 8. 1 is a lever on the traverse-shaft 2; 3 another lever on the shaft 2. 4 a link connecting the lever 3 with the rack 5. 6 a rod connecting the lever *w* with the lever 1 for traversing the rack 5. 7 a shaft for carrying the levers 8, 9, and 10. 11 a link connecting the levers 10 and 12. 13 a shaft carrying the levers 12 and 14. 15 and 16 are links connecting the rack 5 with the levers 9 and 14. 17 the upper or retaining rack. 18 a stud carrying the elbow-lever 19, which is provided with a handle. 20 another stud carrying the elbow-lever 21, which is connected by a link 22 with the lever 19. The rack 17 is carried on studs in the horizontal arm of the levers 19 and 21. 23 division-studs in the bar 24 of the traversing-frame.

The plate to be punched is put into a traversing-frame formed of two side-bars 24 and 25, and two stretcher-bars secured by cottars to the side-bars, which are rabbeted to support the plate, and, when required, furnished with clamps to hold the plate down. 24 represents one of the sides of the traversing-frame, in which there is a groove to fit on the slide-bar U; into the outer side of the bar 24 is screwed a series of studs 23, represented in the engravings as being 12 inches from centre to centre apart from each other. The side 25 of the frame slides on the bars V V. When the plates to be punched are very long, rollers may be used to carry the projecting ends of the traversing-frame. In Fig. 2428 is shown part of a frame, with a plate partly perforated. The racks 5 and 17, Fig. 2429, are drawn with three teeth in the length of a foot, which will divide plates to a four-inch pitch; but it will be obvious, that for a different pitch the racks must be changed, and it may in some cases, (such as when the pitch required is not an aliquot part of a foot,) be necessary to alter the distance between the studs 23. Fig. 2429 represents the traverse apparatus, in the position it will be in when the retaining

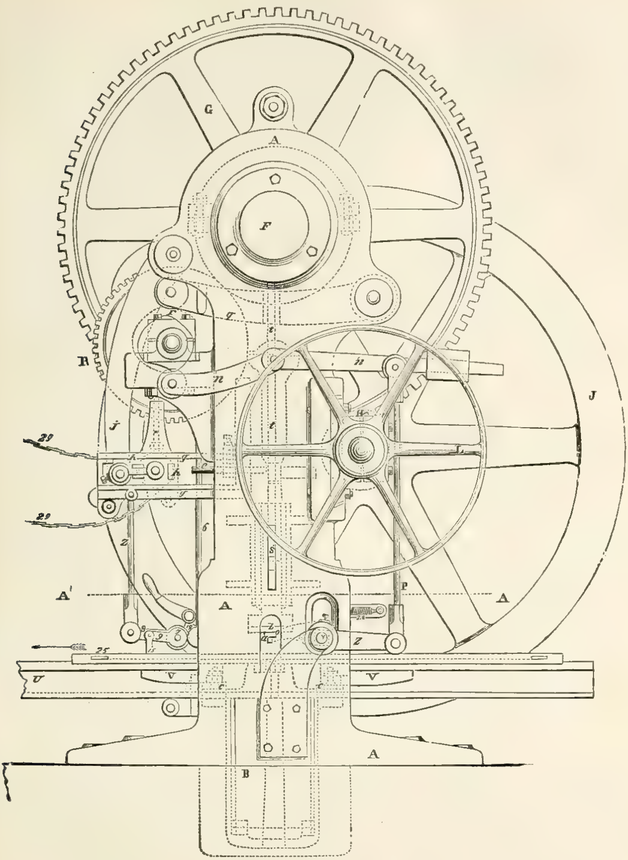
2426.



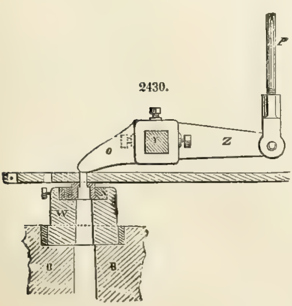
2428.



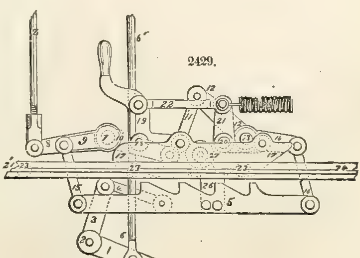
2427.



2430.



2429.



rack is down, and the punches in the act of passing through the plate, and the traversing-rack having completed its return-stroke.

When the punches are being raised, the traversing-rack will rise also; and by the side-piece 26 (which is attached to it) acting against the roller 27, on a stud in the rack 17, will raise it also, and set the frame at liberty to be advanced by the cam x, through the mechanical means already described. In Fig. 2420 this traverse apparatus is shown in the position it assumes when the plate is advancing. The spiral-spring 28 acts on the lever 21, and forces the rack 17 down on to the pins 23. For every hole required to be punched in line with the width of the plate under operation, a corresponding hole must be made in a plate of the jacquard, and an additional hole, marked 30, is also made, into which the stopping-bar 31 enters at every stroke until the punching be completed, at which time the jacquard-plate 32, which is left blank, will push all the selecting-bars e beyond the rams P, and at the same time, by pushing the bar 31, disengage the cam-shaft Q, by the mechanism to be hereafter explained, at the point where the punches and the levers o are held up, and thus will allow the perforated plate to be taken out of the machine, and another plate to be put into it. The stopping-bar 31 is provided with a projection on its lower surface, which depresses the click-lever 39 when the bar is pushed back; the lever 33 is keyed on a shaft 34, moving in bearings at the back of the depressor; on the other end of the shaft 34 is keyed the lever 35, to the upper end of which is attached the link 36, connecting it with the elbow-lever 37; the end of the other arm of this lever is inclined, for the purpose of unlocking the plate R*, and is provided with a stud, on which is a latch 38, the tail of which comes in contact with the incline on the elbow-lever 37, when it is in the position shown in dotted lines in Fig. 2422; and as the wheel R revolves, the latch becomes disengaged from the opening between the two projections cast on the said wheel, at which time the cam-shaft Q ceases to revolve. When the stopping-bar 31 has been pushed back, it depresses the lever 39, and liberates the lever 33 from behind the projection on the lever 39, when the spring 40 will pull the elbow-lever 37 into the position shown in dotted lines. To the blocks h a small shaft is attached, on which are two levers, suspending by links a plate of metal similar to a blank card-plate, except that the holes for the guide-pins are cut at the bottom edge. At each end of the same shaft is a lever-handle, held up or down by a side-spring in the ordinary way. The use of this apparatus is as follows: Should it be required to stop the machine before the plate is finished, by raising the lever here referred to, the blank plate will come in front of the roller, and will act the part of a blank jacquard-plate, and stop the machine.

Having now described the principal parts of the machine, we shall proceed to explain the manner of its working. The plate to be punched having been placed in the traversing-frame, on the sides U and V, is then pushed forward. In its progress, the first pin of the series 23 passes under the inclined end of the rack 17, until the first notch in the rack falls upon the pin. The driving-strap being now on the fast pulley K, the machine is set to work by pulling down the handle 42, keyed on the shaft 34, until the lever 33 is latched by the click-lever 39; the elbow-lever 37 is then, by the spiral-spring 40, brought into the position shown in Fig. 2422. The latch 38 being now liberated, will, by the action of the spring 41, Fig. 2420, drop into the notch in the wheel R the first time it comes round; the cam-shaft Q will now revolve at the same speed as the shaft F, and the jacquard-roller f will be drawn back and made to perform 1-6th of a revolution on its centres, after which it will be advanced, and the first card of the series will remove those selecting-bars for which there are no holes in the jacquard-plate; the other selecting-bars will remain over their respective rams P, which will then force down the punches through the plate, by the descent of the depressor T. A little before the punches have gone through the plate under operation, the levers o are made to press upon it, and are held there while the punches are being withdrawn by the bar s, which rises simultaneously with the depressor T, during one-half of its ascent.

Whilst the depressor is continuing its ascent and descent through the other half of the stroke, the roller f recedes, and draws with it the bar m, which brings all the selectors again over the punch-rams P. The roller f, while receding, having performed another sixth of a revolution, will, on advancing, bring another of the jacquard-plates against the selectors, and the operation will be repeated until all the holes are punched in the plate under operation.

JAPANNING. The art of covering paper, wood, or metal with a thick coat of a hard, brilliant varnish: it originated in Japan, whence articles so prepared were first brought to Europe. The material, if of wood or papier-machée, is first sized, polished, and varnished; it is then colored or painted in various devices, and afterwards covered with a highly transparent varnish, or lacquer, which is ultimately dried at a high temperature, and carefully polished.

An improved method of performing the above-mentioned operation is thus described by the inventor: The articles which are to be so coated, or covered, or ornamented, may be made of wrought-iron, or of other malleable metal or metals, which will withstand a strong red-heat without injury, such as brass or copper, the making of such articles being performed by any of the usual modes of cutting out of laminated or sheet metal, and hammering, or stamping, or otherwise forming to the required shape for any intended article, by aid of all or any of the various modes of cutting out of laminated sheet metal practised by the makers of articles of malleable metals, except that the more fusible metals which will not withstand a strong red-heat, such as tin, lead, zinc, pewter, or Britannia metal, are not fit to be used for making such articles or any part thereof, and, therefore, tinning and soldering with soft solder is not applicable for taking such coating, or for uniting together the parts of the said articles; but in case of an article which cannot conveniently be formed of one piece of metal, (and which is to be preferred,) then the several pieces or parts must be united or strengthened by all or any of the well-known methods of overlapping, turning down the edges, wiring, creasing, and hammering down, or by riveting or dove-tailing, as may be most suitable for the article; and in case of soldering being resorted to, it must be hard soldering with brass or spelter, usually termed brazing, and by any or all the means aforesaid the articles are to be made of wrought-iron, or of other malleable metal or metals, and in the same manner as if they were intended to be japanned, painted, varnished, lacquered, or tinned. When

made, the articles are to be subjected to a full red-heat, by placing them in an annealing oven or furnace, which may be of the same kind as is commonly used for annealing articles of stamped metal, or for annealing metal for being stamped; a number of articles of the same shape and size being piled up one upon another in such furnace in order that they may the better keep their form, and sand may be interposed between the articles so piled up for that purpose. Small articles may be heated in a muffle, such as hereafter described, into which flame does not enter, and after having been kept to a full red-heat for about half an hour, the articles are either withdrawn from the oven or furnace and allowed to cool, or else the oven, or furnace, or muffle, with the articles therein, may be allowed to cool, and the articles removed. By the said heating, all liquid or greasy matter will have been dissipated, and the surfaces of the articles will have been oxidated, and then all oxide or scale is to be removed from the surfaces of the articles by rubbing them with sandstone, for the plain and accessible parts, and with worn-out files, scrapers, or other suitable tools, for the less accessible places. Or articles of such a truly circular or elliptical form as to admit of being turned in a lathe, may be mounted in a chuck and turned; a broad flat tool being presented to every part of the revolving surface in succession, leaving the surface of the metal smooth and even, without the necessity of its being quite bright or polished. The articles being thus rendered perfectly clean, are ready to receive the first coat or covering of partially vitrifiable material, (the composition whereof is hereafter described,) and which is applied to the surface of the articles in a semi-liquid state, which state results from the materials having been ground very fine when in mixture with water, and to the consistence of a thick cream, and then strained through fine lawn. A suitable quantity of such semi-liquid is poured out from a ladle or spoon upon the surface of the article whilst it is held over a large vessel containing such semi-liquid, and by holding the article in the hands with the surface inclined, the semi-liquid runs slowly and gradually along the surface, so as to spread itself out and cover the same, the article being turned about and inclined in different directions in succession, in order to cause the semi-liquid to run over the surface until the whole is completely covered and with a coating of uniform thickness, all surplus of such semi-liquid being allowed to drain off therefrom into the basin or other vessel beneath. Great care must be taken, however, to avoid air-bubbles, specks, or defective places in the coating, and which is only accomplished by using precaution in the previous preparation of the semi-liquid, or by thoroughly grinding or straining it, in order to keep it free from lumps and from any coarse particles, and afterwards avoiding all violent stirring or splashing, so as by no means to get air intermixed with it, but using only a gentle motion when taking it up with a ladle or spoon; and such a quantity only of the semi-liquid at one time as is not materially greater than sufficient for covering the surface of the article to be coated. The operation of coating will be greatly facilitated by performing the same in a warm room, and by making the article rather warmer than the semi-liquid itself, but not so as to feel hot to the hand; and such warmth of the room and of the article will dispose the covering, after it has been spread over the surface of the article as aforesaid, to begin to dry upon that surface, and, in a short time, so far as not to run or move thereon, after which the drying is to be completed by placing the article in an ordinary japanner's stove, which should be kept heated to a temperature of about 180° Fahrenheit, the article being left therein until all moisture is gradually dried away, or so as to leave a dry whitish covering, which adheres sufficiently to the surface of the article for keeping its place thereon, but which would, nevertheless, be easily rubbed off if handled roughly, or if only touched rudely by the fingers. The composition of materials found to be the most suitable for the first coating may be prepared as follows:—

Take six parts (by weight) of flint-glass, broken into small fragments, three parts of the ordinary borax of commerce, one part of red-lead, and one part of oxide of tin. These four ingredients being brought into the state of a coarse powder, are to be well mixed together, by pounding them in an iron mortar, and then the mixture is to be fritted in the same manner as is usually done with the materials for making glass, or by subjecting such mixture to a strong red-heat in a reverberatory furnace for three or four hours or more, it being frequently stirred and turned over to expose every part to the flame, and to more effectually mix the ingredients, as well as to expel all volatile matter; and towards the latter part of the time the heat must be increased, until a partial melting or semi-vitrification has commenced, when the whole is to be withdrawn from the furnace in a pasty state, and let fall into water in order to be suddenly cooled, whereby it becomes cracked, so as to be afterwards easily broken into small fragments, or into a coarse description of powder, which is called fritt, and which is for the first body or coat, but which fritt is only one of the ingredients in the composition of such first coat. With one part (by weight) of the fritt described is to be mixed two parts of calcined bone, ground to powder; and the mixture of fritt and bone is then to be ground with water in a mill, called a porcelain-mill, such as is used for grinding the materials for making porcelain; and which operates by trituration of the materials with water between chert-stones, or other hard silicious stones, whereof some are fixed at the bottom of a tub or vessel containing water, having the materials mixed therewith; and other such stones rest by their own weight upon the said fixed stones, and are carried round thereon with a circular motion, communicated by the moving part of the mill, so as to rub over the fixed stones and grind the materials between them, which operation is continued until the materials are reduced to a state of extremely minute division in the water, forming therewith the semi-liquid (of about the consistence of cream) already alluded to, and which is ready for use so soon as it has been passed through appropriate sieves, so as to effectually separate any particles that have escaped the operation of grinding.

In articles requiring only one side to be coated, such as the hollow side of a kettle, or pot, or jug, or such as a mug, or plate, or dish, or waiter, or tray, or basin, or cup, or bread-basket, or cheese-tray, (to all which, as well as to numerous similar articles, this invention is considered as being particularly applicable,) such hollow side may be first coated with vitrified materials after the manner already explained; after which, the outside may be coated or covered by any of the ordinary methods of japanning; and in applying such first coating of semi-liquid to the hollow surface or side of such articles as those stated, it is observed that, instead of pouring out a quantity thereon, as in other cases, the vessel may be filled, or if both sides have to be coated, may be wholly immersed, and in the act of

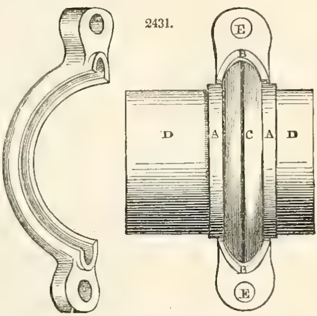
draining off the surplus the fingers of the two hands should be applied to the edges only of the article, and at the two opposite sides of its circumference, so that the weight of such article will balance itself, and render it easy to turn it over and about, so as to drain in succession from either side, extreme care being requisite in all such cases to insure a uniformity of surface. When the coating is so far dried that it will not run, the article is to be laid down upon the points of three small supports, made of burnt earthenware, and which are made to stand upon a small iron plate that serves to carry away the article which is next introduced into the japanner's stove, where it is dried more effectually. When the article is afterwards removed from the said stove, in order to be introduced into the muffle for the firing or burning in of the coating, (and in the manner hereafter described,) it is still to be borne upon the same three supports, the iron plate on which they rest being removed from the stove, and also introduced into the muffle, or with the three supports and the article upon it; and in case of any specks or deficient places appearing in the coating, such places may be mended by applying a portion of the semi-liquid thereto by aid of a brush, and in the manner of painting or pencilling, and then returning the article to the stove, and drying the same, so that every part shall not only be completely covered, but also effectually dried on, and before it goes into the muffle, the ultimate appearance of the article depending very materially upon the manner of conducting this first part of the process, and upon the care with which the coating has been applied, and upon the proper grinding and mixing of the materials, uniformity of surface in the first process being considered absolutely indispensable, in order to insure the successful result of such after-processes as have yet to be detailed. The firing next described is for the purpose of so far vitrifying the materials and hardening the coating as to fasten it on to the surface of the articles, and is performed in a furnace, of the kind used by painters in enamel, being an oven strongly heated by fire applied beneath it, and by the flame therefrom passing in flues around it, and may be called a muffle; but no fire, or flame, or smoke can enter into the interior where the articles are placed. The articles are left in the muffle, and subjected to the heat until such time as the earthy composition will have undergone so much of the commencement of fusion or partial vitrification as to render the particles of the coating firmly adherent one to the other, and also to the surface of the metal articles, and which are then to be withdrawn and laid on a flat iron bench to cool. When cold, such parts of the surface as have been coated will be found to present the dead whitish appearance of earthenware, which has been once fired only, but has not been glazed, being in that state which by potters is termed "biscuit." The time that the articles should remain in the heated muffle will vary from a few minutes to half an hour, depending upon the size and number of the articles, and upon the heat of the muffle; neither can such time be stated with precision, but the operator, it is observed, will soon find out what length of time is most suitable for any particular description of article, and also what heat should be kept up in order to obtain the required result, by observing, so soon as the article shall have become cool, whether the coating has been rendered sufficiently hard, and has or has not become firmly adherent. When cool, the newly formed coating is to be wetted, either by passing over it a sponge that has been dipped in water, or else by dipping the article itself, and a second coating is then applied over the first coat and dried thereon in the japanner's stove, and then fired in the muffle in the same manner as the first, only the composition is to be different; and the patentee goes on to state that the composition he has found to be the most suitable for such second coating is as follows: Take 32 parts (by weight) of calcined bone, ground to a fine powder, 16 parts of china-clay, and 14 parts of Cornwall stone in fine powder, and 8 parts of carbonate of potash; the latter being dissolved in water, the other ingredients are mixed up therewith, so as to make a thick paste, which is then fritted for two or three hours in a reverberatory furnace, until it assumes the appearance of biscuit-china, which is to be reduced to powder; then 5½ parts (by weight) of such powder are to be mixed with 16 parts of flint-glass broken small, 5½ parts of calcined bone ground, and 3 parts of calcined flint ground, the said mixture being afterwards ground with water in a porcelain-mill until it is reduced to a semi-liquid state about the consistence of cream, and which has to be carefully strained, as before, through sieves of lawn, when it will be ready for use in the same manner as already explained in reference to the composition or semi-liquid employed for the first coating. In firing the second coating care must be taken that the articles are kept long enough in the muffle, and that the heat is sufficient for thoroughly incorporating the second coat with the first, also for thoroughly hardening both coats. After firing for the second coat, the article, when cool, will have a stronger and whiter color, and a more decided resemblance to articles of good earthenware, but still only in the state called "biscuit."

The articles having been twice coated with composition as described, and twice fired, so as to assume at this stage the external appearance of a good earthenware biscuit, the patentee further states, that should it be desired to produce a very white color, so as to resemble the very finest earthenware or porcelain, then in lieu of the 16 pounds of flint-glass, mentioned as forming part of the last composition, proper for the second coating, he prefers to substitute a like quantity of the composition prepared as follows: Take four parts (by weight) of feldspar in powder, four parts of white sand, four parts of carbonate of potash, one part of arsenic, six parts of borax, one part of oxide of tin, one part of nitre, and one part of whiting; the mixture of these materials is to be fritted either in a reverberatory furnace (as was before described for the materials of the first coating,) or otherwise such fritting may be performed in a crucible strongly heated in a furnace, the heat in either case being continued until the materials are partially fused, and the appearance when cold will be that of a whitish enamel, which being reduced to powder, such powder is to be substituted, weight for weight, in place of the 16 pounds or parts of flint-glass formerly mentioned as part of the composition of materials for the second coating, all the other materials remaining the same. Excepting only for the purpose of obtaining whiteness of color, the flint-glass is in other respects described as being cheaper, and yet equally good. After the articles have received the second coating, (of either of the compositions described,) and have been fired and then cooled, they are to be wetted with a sponge, or by dipping them into water, as was done after the first coating, and are then ready for receiving the third coat or glaze, which is also applied in a semi-liquid state, great care being required in draining off the surplus semi-liquid glaze, so as to leave

only a thin coating or covering, equally distributed over every part of the second coating of partially vitrified material, in order that the article, after being again exposed to the heat of the muffle, and afterwards withdrawn, may present the appearance of glazed earthenware of good quality, and which will not otherwise be the case; whereas, with appropriate care, and when the composition specially adapted for producing whiteness has been employed, it will resemble earthenware, it is stated, of the very best quality. The composition found to be the most suitable for the third coat, or glaze, is as follows: Take twelve parts (by weight) of feldspar, in powder, four and a half parts of china-clay, eighteen parts of borax, three parts of nitre, one and a half parts of carbonate of potash, and one and a half parts of oxide of tin, which materials being well mixed together, the mixture is to be fritted either in a crucible or in a reverberatory furnace, and then the frit being reduced to powder, is to be ground with water in a porcelain-mill to a semi-liquid state, and strained through fine lawn in the same manner as described for preparing the composition for the first coat. Or, instead of the above composition, the following may be adopted for such third coat or glaze: Take nine parts (by weight) of feldspar, in powder, two parts of china-clay, nine parts of borax, two parts of nitre, three parts of carbonate of soda, and one-quarter part of arsenic; which materials being mixed together the mixture is to be fritted, and then reduced to powder, ground in water, and strained as aforesaid. In firing the articles in the muffle for the third coat or glaze, the heat of the muffle, and the time the articles are subjected to such heat, must be sufficient to cause the glaze to become thoroughly vitrified, and to spread over the surface of the second coat so as to become incorporated with that coat, and effectually glaze the surface thereof, as in earthenware of excellent quality; and in case there are any imperfections in the glaze after it has been so fired, then, after the articles are cold, another coating of the same glaze may be applied in a semi-liquid state and dried in the japanner's stove, and then fired in the muffle as was done for the first coating of glaze; and so in like manner a third coating or glaze may be applied and fired, if found requisite.

JOINT, CLASP-COUPLING—West & Thompson's. D D, Fig. 2431, are two pieces of pipe; A A are two flanges joined each to one of the pieces of pipe. It will be observed that the coupling parts of these flanges are bevelled, and have no bolt-holes, as those in common use all have. C is a piece of vulcanized India-rubber, or any other packing that may be thought necessary, although a pressure can be exerted in bringing the flanges so close together that the joint is made perfectly tight without any packing, but we think that it is all the better to use a little packing. B B is the clasp. This is divided into two parts, and this part is represented with the flange resting on it. By placing the concave part over the bevel of the flanges, and securing the two parts of the clasp together by bolts passing through E E, is all the operation that is required in connecting two separate pieces of pipe together. Every mechanic will perceive that the tighter the clasp is screwed up, the faces of the flanges are brought closer together, and the joint is thereby made exceedingly tight. Experience has proven this joint to be excellent for pipes that are used for conducting steam.

2431.



It will be clearly seen that this improved coupling is applicable to vessels and other articles of angular or curved forms, and that whatever may be the form, any desired and effective mode of drawing or forcing together the segments of the ground clamp may be substituted for screw-bolts or the conical rings.

In coupling angular vessels, or other articles, it will be found to be advantageous to make the grooved clamp in as many sections as there are sides to the figure, and for round couplings it will be found sufficient to make it in two parts for all articles of moderate size; but when the diameter is very considerable it may be divided into three or more parts.

This improved mode of coupling is equally applicable to the securing of nozzles, stop-cocks, bonnets, and many other articles not necessary to enumerate, and particularly to cylinder-heads, in which the edge of the head takes the place of one of the flanges.

It will be evident to any engineer or machinist, from the foregoing, that shafts and other solid bodies can be coupled together in the same manner as hollow conduits or vessels, and with equal advantage, and by a similar arrangement of parts, and therefore it is deemed unnecessary to give an example.

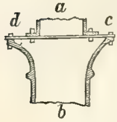
The flanges, instead of solid projections of the bodies to be united, may be made separate, and connected therewith in any manner desired, as the mode of making the flanges forms no part of the invention.

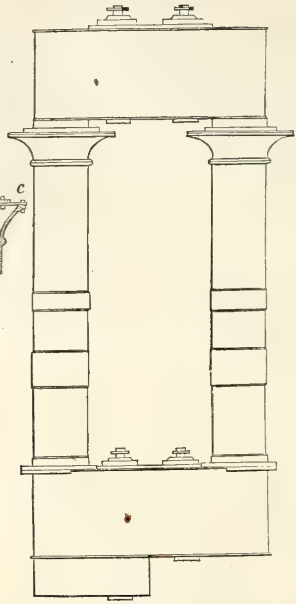
The leading advantages of this mode of coupling over the ordinary double flange and bolts heretofore and now generally used, are, a great reduction in the number of screw-bolts used, which occupy much time in connecting and disconnecting joints, particularly in the parts of steam-engines, such as cylinder-heads, and other parts, which require to be frequently connected and disconnected for packing and other purposes, and increased strength and more perfect and continuous support, as the flanges by the improved plan, instead of being reduced in strength by the numerous bolt-holes, are pressed together and supported all round by the grooved segmental clamp, and the strain on the threads of the screw-bolts, instead of being in the line of the force which tends to separate the coupling, as in the old plan, is nearly at a right angle therewith, and therefore greatly relieved. There are other advantages which, however it will be unnecessary to enumerate.

JOINT, PATENT EXPANSION. Figs. 2432 and 2433 represent a patent expansion-joint, patented by Z. R. DUNHAM, of New York, March 20, 1847.

2433.

2432.





JOINTS, AND JOINING TIMBERS. As timber cannot always be obtained of sufficient length for tie-beams, or bridges, it is necessary to unite two or more pieces together by their ends, which is called scarfing, and is differently performed by carpenters. The most common means is lapping, or halving, or, as it is sometimes called, ship-lapping. This is nothing more than cutting away a part of the thickness of one piece, and an equal quantity of the other which is to be joined to it, so as to suffer the diminished end of one piece to overlap that of the other, (as in Fig. 2434,) and then uniting them by nails or wooden pins, which are called tree-nails. This method is applied to plates, bond timbers, and others, where there is not much longitudinal compression or extension; where this kind of effect is to be provided for, the upper as well as the lower timbers should be cut and let into each other; the under piece having a tenon formed at its extreme end, with a corresponding cutting to receive it in the upper piece. That these tenons may be enabled to pass each other, it is necessary to cut away a part of the timbers in the middle of the length of the joint, equal to the length of the two tenons, so as to form a square hole, through the middle of the timbers to be joined together, and this is afterwards closed up by driving an oak key into it; this also helps to drive the tenons to their respective mortises, and prevents the timbers from being pulled asunder. The thickness of the key, in order that it may not be compressed, should be equal to a third of that of the piece into which it is inserted. Another principle is here shown, which is more simple, the joint being cut obliquely; to make these two pieces stiff, the ends of both should be cut in an angular form. To strengthen these scarfs, iron straps and screw-bolts are added; but no joining can be made so strong as the timber itself.

2434.

In making joints, it must be remembered that all timber is liable to shrink when dry, and when wet to expand; on this account, dovetail joints should be avoided as much as possible, as they are liable to draw out; and all joints should be made with reference to their contraction and expansion, which sometimes tends to split off portions of the framing. Where iron bolts or straps are introduced, care must be taken that their effect is not lost by the changes that the timber undergoes. The areas of the former should never be less than two-tenths of the area of the section of the beam; it must also be recollected in making a joint, that when force is applied to any portion, the fibres of the timber will slide upon each other.

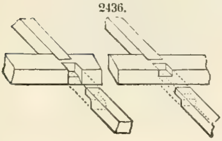
Fishing a beam is merely placing a piece of the same scantling to one side of the timber to be united, and bolting them or hooping them together. Separate pieces of timber are united either by scarfing, notching, cogging, pinning, wedging, tenoning, &c.

Scarfing consists in cutting away equally from the ends, but on the opposite sides, of two pieces of

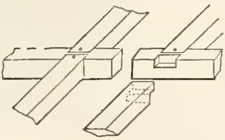
timber for the purpose of connecting them lengthwise. The usual method of scarfing bond and wall plates is by cutting about three-fifths through each piece, on the upper face of the one and the under face of the other, about 6 or 8 inches from the end transversely, making what is termed a *kerf;* and longitudinally from the end, from two-fifths down, on the same side, so that the pieces lap together like a half dovetail. Fig. 2435 is a scarf.

2435.

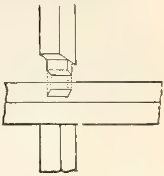
2436.



2437.



2438.



Notching is either square or dovetailed, and is made use of for connecting the ends of wall-plates and bond-timbers at the angles, in letting joists down on girders, binders, purlins, or principal rafters.

Cogging, or *cocking*, is a species of notch extending on one side, and having a narrow cog alone in the bearing piece, flush with its upper face. It is principally made use of in tailing joists on wall-plates.

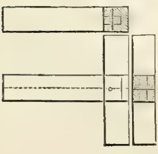
Pinning consists in inserting cylindrical pieces of wood or iron through a tenon.

Wedging is the insertion of triangular prisms, whose converging sides are under an extremely acute angle, into or by the end of a tenon, to make it fill the mortise so completely as to prevent its being withdrawn.

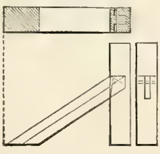
Tenon and mortise of the most simple kind is shown in Fig. 2439, in which the two timbers united are at right angles with each other. The tenon is on that which appears horizontal, while the mortise is cut in the upright timber. The tenon is left one-third of the thickness of the timber, as shown in the upper part of the figure.

The greatest strain upon the fibres of a girder is at the upper and lower parts, decreasing gradually towards the middle of the depth, which is the best situation to make the mortise. The form to be given to the tenon requires consideration. Some carpenters introduce it at the lowest part of the girder, which in a great degree destroys its stiffness: being a sixth of the depth, it should be placed at one-third of the depth from the lowest side. Horizontal timbers, intended to bear great weights, should be always notched on their supports, in preference to being framed in between them; and this rule is applicable to inclined timbers, as common rafters and braces. All the pressures to which they are subjected should be brought to act in the direction of their lengths, and the form of the joint should be such as to convey the pressure as much as possible into the axes of the timber. When subjected to a strain, a partial bearing is liable to very serious disadvantages, particularly in bridges.

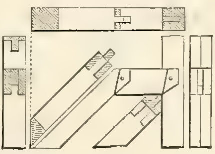
2439.



2440.



2441.



Where the mortise is to be made in the upright timber, and the tenon to be cut on another inclined, as in a brace to a partition, a bevelled shoulder, Fig. 2441, is cut on the inclined piece, and a sinking made in the upright post to receive it—the pin which secures it in its mortise passing through the tenon.

The bevelled shoulder adds greatly to the strength of a mortise and tenon joint, and should never be dispensed with: it renders the junction of the two pieces of timber more exact, and makes the abutments of all the fibres stronger and more capable of resistance.

The common method of effecting such a junction does not occupy so much time or labor, but is not so effective: it is usual to drive one or two wooden pins through holes bored for the purpose at right angles through the timber in which the mortise is made, as well as through that which has the tenon.

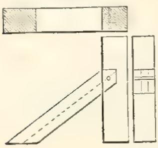
Boring the hole for the pin requires to be nicely performed, in order that it may draw the tenon tight into the mortise prepared to receive it, and make the shoulder-butt close into the joint, without running the risk of tearing out a portion of the tenon beyond the pin. Square holes and square pins are preferred to round, as they bring more of the wood into action, and there is less liability to split.

Foxtail wedging, adopted by ship-carpenters, is made with long wooden bolts, which do not pass completely through the timbers, but take a very fast hold: they are subject to be crippled in drawing if they are too nicely fitted: this is remedied by placing a thin wedge into the hole previous to the

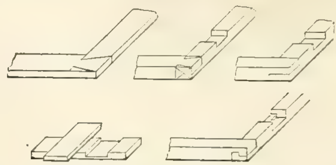
insertion of the wooden bolt, which, when driven, is split by the wedge, and thus squeezed tight to the sides of the hole.

Bond-timbers and wall-plates require to be carefully notched together at every angle and return, and scarfed at every longitudinal joint.

2442.



2443.



To make a good tie-joint requires great attention on the part of the carpenter; and, for uniting wall-plates, the dovetail joint, Fig. 2444, is sometimes adopted. If the effects that shrinking may produce be taken into consideration, the more usual system of halving, Fig. 2443, is decidedly preferable. Whenever this joint is employed, a stout pin of tough oak, or an iron bolt, should be driven through to render it secure; and, where there is the slightest tendency for one piece to slide from the other, iron straps must be used.

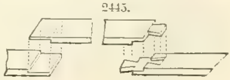
2444.

Timbers which are laid upon the plates, and intended to act as ties, should be cut with a dovetail and let into the timber it is to secure. Generally, where they cross at right angles, *halving* or cutting away the moiety of each is adopted, and one is let into the channel cut in the other.

For joining two pieces of timber together, *notching* is the most common and simple method; for, when four angles are to be formed, the surfaces of one piece are both parallel and perpendicular to those of the other. A notch may be cut out of one piece (Fig. 2444) the breadth of the other, which may be let down on the first; or the two pieces may be both notched to each other, and then secured by an oak pin: this is the best practice when each of the timbers is equally exposed to a strain in any direction. When one piece has to support the other transversely, the upper may have a notch cut across it, to the breadth of two-thirds the thickness of the one below, which must also have a similar notch cut out on each upper edge, leaving two-thirds of the breadth of the middle entire, by which means the strength of the supporting or lower piece is less diminished than if a notch of less depth were cut the whole breadth. Such joints are particularly adapted for purlins, when let down upon the principal rafters.

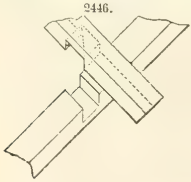
Lapping is performed in a variety of ways—either by simply halving the end of each timber, or by halving and dovetailing, as in Fig. 2445. In the latter case, the timbers act as a tie, and cannot be readily pulled asunder.

2445.

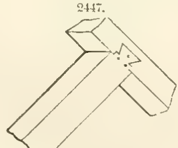


In these joints the greatest attention is required to make the several parts abut completely on each other, as the least play or liability to motion at once destroys their efficacy. The butting joints, being slightly tapered to one side of the beam, require very moderate blows with a hammer to force them into their place: if driven too hard, the parts will be liable to strain, and the abutments to split off. It is better, sometimes, to leave the abutments open, and afterwards drive in a small wedge, which, if made of hard wood and not likely to

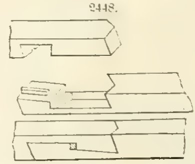
2446.



2447.



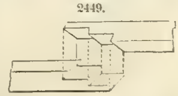
2448.



compress, is an excellent substitute. Iron has been said to injure the fibres of the timber, from its too great hardness; otherwise it is well adapted for the joggles and wedges.

Two pieces of timber may be united in such a manner that they preserve the same breadth and depth throughout, which is of great importance in the construction of beams for bridges or roofs of considerable span. The length to be given to the scarf must depend upon the force that will cause the fibres of the timber to slide upon each other; and that for oak, ash, or elm should be six times the depth of the timber; in fir, twelve times: but where bolts are used so much is not required in either case. The simplest method for uniting the ends of two timbers is by cutting away an equal portion of each, and letting one down upon the other. Fig. 2449.

2449.

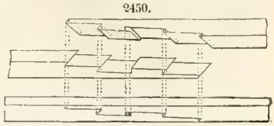


Timbers united together by a number of such cuttings, afterwards united and bolted through or hooped round with iron, are capable of sustaining great resistance: a stirrup-iron at each end

holds the timbers in their places, and one or more bolts are sufficient to prevent their being drawn asunder.

The carpenter frequently exercises great ingenuity in joining timbers of considerable scantling, Fig 2450; and, by the introduction of iron or small cubes of harder wood into the joints, can prevent their being thrust or drawn out of their position either longitudinally or laterally.

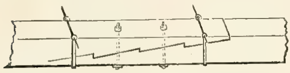
2450.



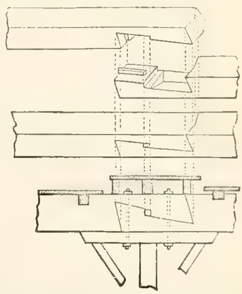
The scarfing of girders and beams have a great variety of forms given them, and are sometimes bolted through, at others strapped round with strong hoops of iron, Figs. 2449 to 2454. Where bolts are dispensed with, it is perfectly clear that the joint cannot have half the strength of an entire piece. Where the stress is longitudinal, two irons put on each side will prevent the scarf that is merely indented from pulling asunder; but such a provision will not maintain the constant horizontal position of the timber.

When a scarf is forced to its bearings by the introduction of keys or wedges driven tight, they sometimes receive an additional strain, and it is often found advisable to omit them, and to bring the joints

2451.

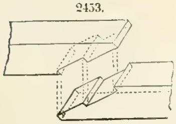


2452.

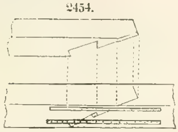


Scarfing.

2453.



2454.



to a bearing by some other means before the bolts are inserted. When keys are made use of, they should be of very hard wood, having a curled grain, which resists the insertion of the fibres opposed to it.

To prevent lateral movement cogging is adopted, in addition to the ordinary method, and a small tenon or cog is left upon a portion of the scarf, which enters into a notch prepared in the piece which is to cover it, as shown in Figs. 2448 to 2452. Beams intended to resist cross-strains require to be lengthened more frequently than any others, and, from the nature of the strain, a different form of scarf must be made use of from that which is required for a strain in the direction of its length. When timber is subjected to both strains, the cross-strain is that which demands the greatest attention. Where a floor is supported, the scarfing requires to be further secured by iron bolts, made to pass through a longitudinal piece laid to cover the under side of the joint.

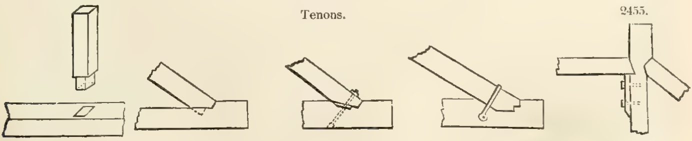
Bearing-posts, when used to support the floors of a magazine or warehouse, are generally formed exactly square. Some timber will support, while that of another quality will suspend, the most; therefore, in the selection of story-posts, we must pay attention to these peculiarities. Iron, however, is generally used for these purposes, in consequence of its horizontal sectional area occupying less space than timber of the same strength.

When a tie-beam is mortised through to receive a king or queen post, and it is necessary to provide for the means of holding it up, the tenon should not be pinned through, as it is not advisable to depend entirely on the pins for the support: the tenon should be cut like a half dovetail, or in a sloping direction on one side, and left straight on the other: the mortise-hole should be so cut that the lower end can just pass. When it is in its place, a wooden key or wedge is driven tightly on the straight side, which forces the tenon against one side of the mortise-hole, and prevents it effectually from being drawn out: oak or iron may be added, or an iron strap may be applied.

Tenons may be wedged at the end; but to do this they must be made long enough to pass entirely

Tenons.

2455.



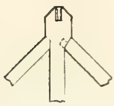
through the mortise: two saw-cuts are then made across it, and the wedges are driven home. The tenon sometimes splits, but not sufficiently to injure its strength. When in machinery it is not practicable to cut the mortise through, the fox-tail wedging is adopted: the tenon is made to fit the mortise

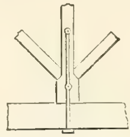
exactly, the wedges are loosely put into the saw-cuts, as before, and the whole is driven to its place When the wedges touch the bottom of the mortise, they cause it to spread, and thus hold the tenon firmly in its place.

Dovetailing in some degree resembles mortising and tenoning, and is more adapted to uniting together the angles of framework. The feet of the rafters require the mortise and tenon to be carefully made, and the thrust is destroyed to a certain extent to obtain greater strength. A portion of the rafter is tenoned into the tie-beam, and another small part is let into the upper part of it: both rafter and tenon are cut at right angles with the inclination of the roof. In Fig. 2455, the rafter has two bearing shoulders in its depth, one behind the other, in addition to the tenon which unites them. Struts and braces which are loaded require but little mortising to keep them from sliding out of their places: the more flat their ends can be cut, the more efficient will they be. The shrinking of timbers sometimes occasions them to become loose, particularly where there is not much stress upon them.

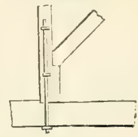
King-posts, queens, and principal rafters, which are subject to great strains, should have iron straps or ties when they unite with the tie-beam, as in Figs. 2456 and 2457; and an iron strap should embrace

2456.





2457.



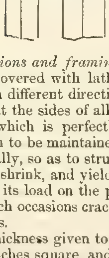
the head of the kings and queens, and unite with the principal rafters, the feet of which, in large buildings, sometimes have their abutment in a cast-iron shoe, which prevents the splitting off the end of the tie-beam.

The ends of king or queen posts may have a screw-bolt passed into them, which allows the nut to be turned at pleasure; and thus the framing may be tightened again when shrinking of the timbers renders it necessary. This, in many instances, is preferable to the iron strap, and keys or screws put in the ordinary way.

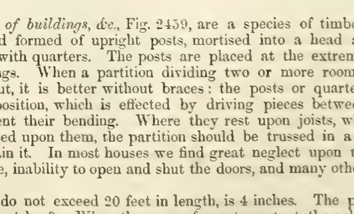
Whatever form we adopt for the butting-joint, we must be careful that all parts bear alike; for, in the general compression, the greater surfaces will be less affected and the smaller undergo the greatest change. When all have come to their bearing, they should exhibit an equally close joint; and as large timbers are moved with some difficulty, the joint cannot be often put to the test of trying whether it fits nicely: it must, therefore, be set out with great precision, and worked, with regard to its lines, with exactness. A very small portion of a tie-beam left at the end is sufficient to withstand the horizontal thrust of a principal rafter, and blocks may be used at the ends where the rafters abut to give additional strength.

Scarfing a timber in a perpendicular direction.—When the top surface is divided into nine squares, if four are cut down, the other five serve as tenons to enter into as many vacant spaces left in the piece of timber placed upon it, as seen in Fig. 2458; or two may be cut away, as in the same figure, to receive a tenon left on the upper piece.

2458.



2459.



Partitions and framing for the outside of buildings, &c., Fig. 2459, are a species of timber walls, usually covered with lath and plaster, and formed of upright posts, mortised into a head and sill, braced in different directions, and filled in with quarters. The posts are placed at the extremities, as well as at the sides of all doors and openings. When a partition dividing two or more rooms has a bearing which is perfectly solid throughout, it is better without braces: the posts or quarters have only then to be maintained in an upright position, which is effected by driving pieces between them horizontally, so as to strut them, and prevent their bending. Where they rest upon joists, which are liable to shrink, and yield to a weight placed upon them, the partition should be trussed in a manner to throw its load on the parts able to sustain it. In most houses we find great neglect upon this subject, which occasions cracking in the cornice, inability to open and shut the doors, and many other inconveniences.

The thickness given to partitions which do not exceed 20 feet in length, is 4 inches. The posts are then 4 inches square, and the other timbers 4 by 3. When they are of greater extent, they should be increased in thickness. When it is required to make a doorway in the middle, the truss may be formed

by the braces, the inclination of which should be at an angle of about 40° with the horizon. When the doors are at the sides, the truss may be formed over the heads. The posts should all be strapped to the truss, and the braces halved into the upright posts.

The weight of a square of quartered partition may be estimated at from 12 cwt. to 18 cwt., and every precaution should be taken to discharge its weight from the floor on which it is placed, to the walls, which are its best points of support. In ancient timber houses, mills, &c., the fronts or external sides are formed of upright posts, placed at a distance equal to their scantling: these are mortised and tenoned into a top and bottom plate, which serves also to carry the floors. The posts at the angles are of a larger scantling; and into these, which form openings for doors and windows, are framed horizontal pieces, which serve for heads and sills. Braces are then introduced, crossing each other, like a St. Andrew's cross. Above the lintholes, and beneath the sills, short quarters or punchions fill in the space, and the whole are mortised, tenoned, and pinned together. The framing should be placed on brickwork, or a wall of masonry, so as to be kept quite clear of the ground.

Floors.—When the bearings are equal, if joists of the same width, but of different depths or thicknesses, are used, their strength is increased in proportion to the squares of their vertical thickness: when the joists are but 6 inches deep, they are in strength to those of 8 inches in depth, as 36 to 64—the square of 6 being 36, and that of 8, 64. The quantity of timber in the one case to that of the other is as 4 to 3—so that one-third more timber gives a strength double that of the other.

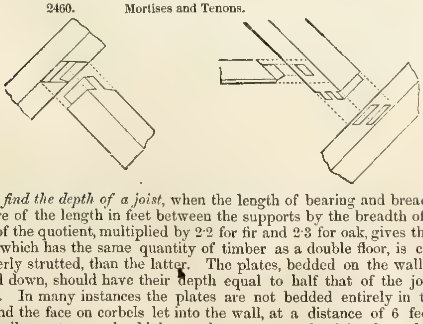
Where square oak joists are used, and the bearing 12 feet, their scantlings should be 6 inches, and laid at a similar distance apart. Such a floor contains the same quantity of timber as if entirely formed of 3-inch plank: the strength of timber being as the square of its vertical thickness, it results that the strength in these two instances is as 2 to 1: the floor composed of 3-inch plank is only half the strength of the other; but had the whole been formed 6 inches thick, instead of with joists 6 inches apart, it would have been 4 times as strong—the square of 3 being 9, and the square of 6, 36.

Naked floors are divided into *single-joisted*, *double*, and *framed floors:* and it must be remarked that unsawn timbers are considerably stronger than planks or scantlings cut out of a round tree. When a tree is cut longitudinally, and formed into two pieces, these will support less than they would do when united in the original tree, arising from the circular concentric rings which compose the tree being cut through, which renders the timber more compressible on one side than on the other; and as the texture is less close where it has been sawn, it is also more susceptible of change from humidity on alternation of temperature.

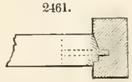
Joists whose width is less than half their vertical thickness, are subject to twist and bend if not strutted; and for this reason squared timber was usually employed by the builders in the middle ages; and we have numerous examples four or five hundred years old, where the timber selected has the pith in the centre, and the concentric rings nearly entire, being in a sound and perfect condition. Experience also teaches us that timber, whether sawn or unsawn, used for a floor of 16 feet bearing, composed of 12 joists, 8 inches square, placed at a distance of a foot apart, is much stronger than another of 24 joists, 8 by 4, placed edgeways, at a distance of 6 inches apart, although there is the same quantity of timber in both cases.

Single-joisted floors consist of one series of joists, which ought to be let down or halved on to wall-plates of a sufficient strength and scantling to form a tie, as well as a support to the floors. Each joist should be spiked or pinned to the timbers on which it lies. Wherever fireplaces occur, and the joists cannot get a bearing on the wall, they are let into a trimmer or piece of timber framed into the two nearest joists that have a bearing: into this the other joists are mortised. As the trimming joists support a greater weight, they must be made stronger than the others, and should have an eighth of an inch additional thickness given to them for every joist they carry. When the bearing exceeds 8 or 9 feet the joists should be strutted, or they will have an inclination to turn sideways: the joists in use, being generally thin and deep, require strutting on all occasions, and a rod of iron is often passed through them, which, being screwed up after the strutting-pieces are placed, gives the entire floor great solidity and firmness. The weight of a square of single-joisted floor varies from 10 cwt. to 1 ton, and the joists should never extend to a greater bearing than 20 feet in ordinary cases.

2460. Mortises and Tenons.



2461.



To find the depth of a joist, when the length of bearing and breadth in inches is given: divide the square of the length in feet between the supports by the breadth of the joist in inches, and the cube root of the quotient, multiplied by 2·2 for fir and 2·3 for oak, gives the depth in inches. A single-joisted floor which has the same quantity of timber as a double floor, is considerably stronger, particularly if properly strutted, than the latter. The plates, bedded on the walls, upon which the joists are to be tailed down, should have their depth equal to half that of the joists, and their width half as much more. In many instances the plates are not bedded entirely in the wall, but have one-half resting beyond the face on corbels let into the wall, at a distance of 6 feet apart. To form the entaille or dovetail, great care should be used, to prevent the joist from drawing out of its place when once pinned down.

Double floors are formed of *joists, binders,* and *ceiling-joists.* The binders rest upon the plates bedded on the walls, and serve the purpose of supports to the joists which are bridged on them, as well as to the ceiling-joists, which are pulleys mortised into their sides. When the depth of a binding-joist is required, the length and breadth being given, divide the square of the length in feet by the breadth in inches, and the cube root of the quotient, multiplied by 3·42 for fir, and 3·53 for oak, will give the depth in inches. When the length and depth are given, and the breadth is required, divide the square of the length in feet by the cube of the depth in inches, and multiply the quotient by 40 for fir, and 44 for oak, which will give the breadth. The above rules suppose the binders to be placed at a distance of 6 feet from each other.

Binding-joists (Fig. 2461) must be framed into the girders, and care must be taken that the bearing parts fit the mortise made for them very accurately: the tenon should be one-sixth of the depth, and placed at one-third of the depth, measured from the lower side. When binding-joists only are employed to carry the ceiling, their scantlings may be found in the same manner as those of ceiling-joists, which are small timbers, and only of a sufficient thickness to nail the laths to. When their length and bearing are given, their depth may be found by dividing the length in feet by the cube root of the breadth in inches, and multiplying the quotient by 0·64 for fir, or 0·67 for oak, which will give their depth in inches. Ceiling-joists are usually notched to the under sides of the binding-joists, and nailed to them: this is better than mortising, which weakens the binder, and gives more labor.

KALEIDOSCOPE. This instrument, the invention of Dr. Brewster, in its most common form consists of a tin tube, containing two reflecting surfaces, inclined to each other at any angle which is an aliquot part of 360°. The reflecting surfaces may be two plates of glass, plain or quicksilvered, or two metallic surfaces, from which the light suffers total reflection. The inclination of the reflector that is in general most pleasing is 18°, 20°, 22½°, or the twentieth, eighteenth, and sixteenth part of a circle; but the planes may be set at any required angle, either by a metallic, a paper, or cloth joint, or any other simple contrivance. When the two planes are put together, with their straightest and smoothest edge in contact, they will have the form of a book opened at one side. When the instrument is thus constructed, it may be covered up either with paper or leather, or placed in a cylindrical or any other tube, so that the triangular aperture may be left completely open, and also a small aperture at the opposite extremity of the tube. If the eye be placed at the aperture, it will perceive a brilliant circle of light, divided into as many sectors as the number of times that the angle of the reflectors is contained in 360°. If this angle be 18°, the number of sectors will be 20; and whatever be the form of the aperture, the luminous space seen through the instrument will be a figure produced by the arrangement of twenty of these apertures round the joint as a centre, in consequence of the successive reflections between the polished surfaces. Hence it follows that if any object, however ugly or irregular in itself, be placed before the aperture, the part of it that can be seen through the aperture will be seen also in every sector, and every image of the object will coalesce into a form mathematically symmetrical, and highly pleasing to the eye.

The eye-glass placed immediately against the end of the mirrors, as well as another glass similarly situated at the other end, is of common transparent glass. The tube is continued a little beyond this second glass, and at its termination is closed by a ground glass, which can be put on and off. In the vacant space thus formed, beads, pieces of colored glass, and other small bright objects are put. The changes produced in their position by turning the tube give rise to the different figures.

KEDGE. A small anchor used to keep a ship steady and clear from her bower anchor while she rides in a harbor or river. They are generally furnished with an iron stock, which is easily displaced for the convenience of stowing.

KEEL. The principal piece of timber in a ship, which is usually first laid on the blocks in building. It supports and unites the whole fabric—since the stem and stern posts, which are elevated on its ends, are, in some measure, a continuation of the keel, and serve to connect and enclose the extremities of the sides by transoms, as the keel forms and unites the bottom by timbers.

False-keel is a strong, thick piece of timber bolted to the bottom of the keel, which is very useful in preserving its lower side. In large ships of war the false keel is composed of two pieces, called the upper and lower false keels.

Keel is also a name given to a low, flat-bottomed vessel, used in the river Tyne to bring the coals down from Newcastle for loading the colliers: hence a collier is said to carry so many keels.

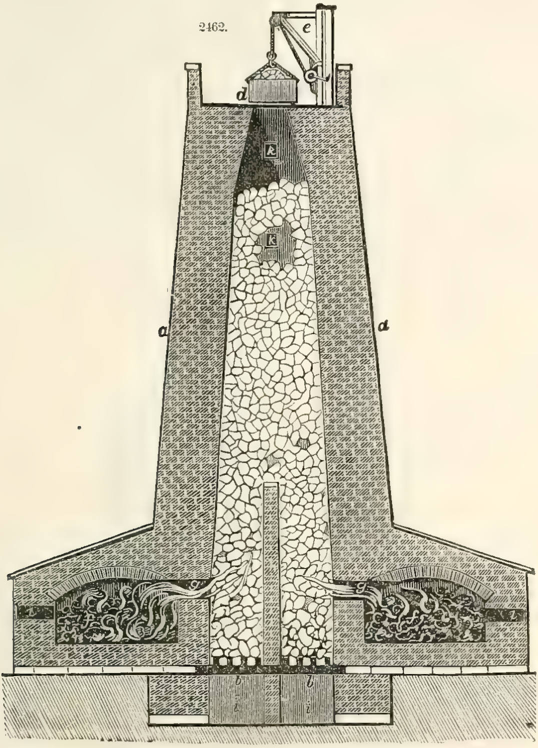
KEELSON. A piece of timber forming the interior of the keel, being laid upon the middle of the floor-timbers immediately over the keel, and serving to bind and unite the former to the latter by means of long bolts driven from without, and clinched on the upper side of the keelson.

KILN. A structure or machine designed for drying substances by the application of heat. Their forms are as various as the substances or manufactures for which they are designed; for, although it may be said that a certain kiln will answer several purposes, yet for one single purpose we often find a variety of kilns employed. The requisite qualities in a good kiln are cheapness and durability of construction, effectiveness in producing the required result with the utmost economy of fuel, a perfect command of the temperature, and facility of working. Ovens must be regarded as of the same class of apparatus as kilns: indeed, the terms kiln and oven are often indiscriminately applied to the same structure, as may be noticed under several articles in this work. Under the head of LIME the usual form of lime-kilns is described; and under COAL and IRON, several forms of coke-ovens. In this place we shall notice a combination of both, which was the subject of a patent granted to Mr. Charles Heathorn about seven years ago, since which time it has been in successful operation.

Heathorn's patent combination of a lime-kiln with a coke-oven.—The object of this invention, as expressed in the specification of the patent, is the preparation of quick-lime and coke in the same kiln at one operation. The economy of this process must be evident from the circumstance, that the inflamma-

ble part of the coal which is separated to form it into coke, is the only fuel employed to burn the lime, and as the coke is in many places as valuable as the coal from which it is prepared, the cost, if any, of making lime, must be reduced to the most trifling amount. Fig. 2462 presents a vertical section of the lime-shaft and coke-ovens: *a a* are the side walls, 4 feet thick, of a rectangular tower, the internal space being filled with limestone from the top to the iron bars *b b* at bottom, whereon the whole column rests. The limestone is raised in a box *d*, or other proper receptacle, to the top of the building, by means of a jib and crane *e*, or other tackle, which is fixed at the back of the tower, together with a platform projecting beyond the walls for affording security and convenience for "landing" the limestone when raised as represented, the jib is swung round, and the lime-box tilted, by which the whole contents are thrown down the shaft. The coke-ovens, of which there may be two, or a greater or lesser

2462.

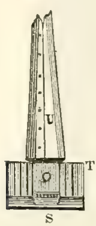


number, according to the magnitude of the works, are constructed and arranged in connection with the lime-shaft in the same manner as the two represented in the diagram at *f f*. These ovens are supplied with coal through iron doors in the front wall, (not seen in the section;) the doors have a long and narrow horizontal opening in the upper part of them to admit sufficient atmospheric air to cause the combustion of the bituminous or inflammable part of the coal; the flames proceeding from thence pass into the lime-shaft through a series of lateral flues, (two of which are brought into view at *g g*,) and the draught is prevented from deranging the process in the opposite oven by the interposition of the partition wall *h*, which directs the course of the heat and flames throughout the whole mass of the lime, the lowermost and principal portion of which attains a white heat, the upper a red heat, and the intervening portions the intermediate gradations of temperature. When the kiln is completely charged with lime, the openings in front and beneath the iron bars at *i i* are closed and barricaded by bricks and an iron-cased door, which is internally filled with sand to effectually exclude the air, and prevent the loss of heat by radiation. Therefore, when the kiln is at work, no atmospheric air is admitted but through the narrow apertures before mentioned in the coke-oven doors. When the calcination of the lime is com-

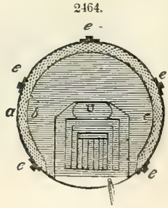
pleted, the barricades at $i\,i$ are removed, the iron bars at $b\,b$ are drawn out, by which the lime falls down and is taken out by barrows. It sometimes happens, however, that the lime does not readily fall, having caked or arched itself over the area that encloses it, in which case a hooked iron rod is employed to bring it down. To facilitate this operation in every part of the shaft where it may be necessary, a series of five or six apertures, closed by iron doors, is made at convenient distances from the top to near the bottom of the shaft: two of these are brought into view at $k\,k$. Two similar apertures are shown in section in the coke ovens at $b\,b$, which are for the convenience of stoking and clearing out the lateral flues $g\,g$ from any matter that might obstruct the free passage of the heated air. When the coals have been reduced to coke, the oven doors in front (not shown) are opened, and the coke taken out by a peel iron, the long handle of which is supported upon a swinging jib that acts as a movable fulcrum to the lever or handle of the peel, and facilitates the labor of taking out the contents of the oven. The operation of this kiln is continuous, the lime being taken from the bottom whenever it is sufficiently burned, and fresh additions of raw limestone being constantly made at the top.

Kilns for drying corn.—If air and moisture be carefully excluded from grain, it may be kept uninjured for an indefinite length of time. This is proved by an extraordinary experiment made with some Indian corn found in the graves of the ancient Peruvians, buried more than 300 years ago. Some of this corn being sown, it vegetated and came to maturity. We believe a similar fact is recorded respecting some grain found in the ruins of Herculaneum. But to preserve corn, even for a short period, it should be perfectly dry when housed, and carefully protected from dampness. But it not unfrequently happens, during a wet harvest season, that the corn is necessarily carried from the field in a damp state; and as few farmers have the means of properly and speedily drying it, large quantities are irrecoverably spoiled after all the labor and cost of production. The method of drying on the perforated floor of a kiln (which is usually resorted to *where it can be obtained*) is a very tedious, defective, and expensive mode, and is attended with great labor, owing to the grain requiring to be continually turned over and spread by a workman, whose utmost care is insufficient to cause every part to receive an equal degree of heat. It therefore becomes a matter of considerable importance to devise a simple, efficacious, and economical method of drying grain under these circumstances; and we think Mr. Jones's apparatus for this purpose, shown in the following figures, is well adapted to the end proposed. Fig. 2463 is a vertical section of the apparatus, which is formed of two iron cylinders $a\,b$, placed one within the other,

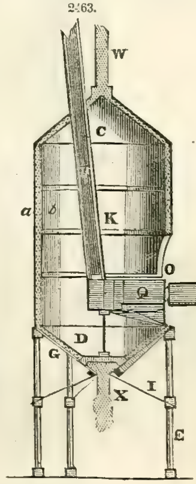
2465.



2464.



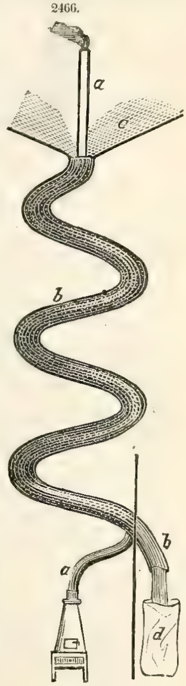
2463.



each being closed at the upper and lower end by two concentric cones, C D. The annular space between the cylinders, as also between the cones, is an inch and a quarter in width, for the reception of the grain, to be dried by its passing through the machine: both the internal and external bodies are perforated throughout with about 2300 holes to the square foot. The kiln is supported on five cast-iron columns, or legs, three of which are shown in the section as at E: these are attached to a strong iron ring which surrounds the base of the cylinder. From the heads of these columns descend, along the sides of the cone, five long bolts, as at G, which are passed through the same number of legs in the cast-iron ring surrounding the neck of the lower cone. From this ring proceed five stays, as at I, which are fastened to the middle of the columns by a nut on each side. The body is sustained, both externally and internally, by iron hoops, as at K, and the distance between the cylinders is preserved by a number of short stays. In the front of the kiln a passage is cut out, as at O, in which is fixed the fire-place, through which are passages for the heated air to pass into the cylinder. These passages, as well as the flues, which proceed circuitously from the fire to the chimney, are best shown in the horizontal

section, Fig. 2464. And in the vertical section of the detached fireplace, Fig. 2465, Q is the fire-hole, S the ash-hole, T the fire-bars, and U the chimney, which passes up nearly in the middle of the kiln. The wheat is admitted into the kiln from above through a hopper, and through the tube W, and, falling upon the apex of the cone, is distributed equally on all sides between the cylinders, the little asperities in which not only slightly retard the descent of the grain, but likewise impart to the particles a constant, slow, rolling motion, whereby every individual grain is exposed to the same degree of temperature; the grain from thence converges into the lower cone, and ultimately escapes through the spout at bottom into sacks, or on to the ground, as may be required. The passage of the grain through the machine may be either accelerated or retarded, according to its peculiar condition, by enlarging or contracting the aperture through which it is discharged. The moisture is carried off by evaporation through the perforations of the plates, with great rapidity. The kilns may, of course, be made of any dimensions. One of 6 feet internal diameter, and 12 feet in length, between the apexes of the upper and lower cones, has been said to be capable of perfectly drying more than 100 quarters of wheat in 24 hours.

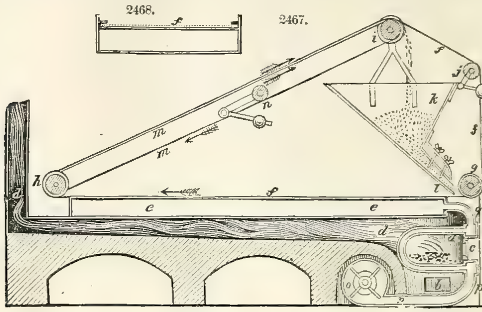
2466.



In Fig. 2466 is shown a contrivance for drying grain which has been noticed in several French papers, and announced as having been successfully adopted in one of the departments. The apparatus consists of a long spiral tube *a a* like a distiller's worm, reaching from the basement to the upper floor and through the roof of the granary, which forms a passage for the heated air from a close stove below. Externally round this tube is placed another tube *b b*, winding, like the interior one, in a spiral direction, and at about an inch and a half from it. This external tube receives the corn from above, through a hopper *c*, and it is punched throughout with numerous small holes, through which the vapor escapes, as it is formed by the damp corn coming in contact with the inclosed heated chimney. The corn, in consequence, becomes thoroughly dried before being discharged at the bottom, and that without the intervention of any manual labor.

Hebert's patent kiln was devised for drying washed grain; but as this kiln is equally applicable to the drying of malt, seeds, and all other matters of a similar kind and form, and by a mode that is as novel as it is efficacious, we give a description of it in this place. In the following engravings, Fig. 2467 exhibits a longitudinal section of the apparatus, and Fig. 2468 a transverse section of a long air-trough, shown at *e* in Fig. 2467. At *a* is shown one of a series of five or six common iron gas-tubes, placed side by side, and curved in the form represented to constitute a fireplace; the space between the tubes serving for the admission of air for combustion, which enters through the ash-pit door *b* at the side, provided with an air regulator: the fireplace is inclosed in front, at *c*, by a common door and frame. The heated air, and other products of combustion from the fuel, pass along the flue *d* to the funnel or chimney. The bottom and two sides of the flue *d* are of brick, but the top is of iron, being formed of the bottom of a long, shallow iron box, or air-trough, *e;* this box has no cover but one of extremely open-wove canvas, which forms a part of an endless cloth or band *f f f*, that is continually made to travel lengthwise over the whole area of the said trough—the edges of the cloth gliding between grooves and over tie-rods, (shown in the cross section, Fig. 2468, where the dotted line *f* indicates the endless cloth,) that prevent the cloth from sagging. This cloth is made to travel by the revolution of three rollers or drums *g h i*, to either of which the moving power may be applied. The cloth is kept distended by a self-acting tightening roller, which is screwed against the hopper *k;* this hopper receives the grain to be dried, and is provided with a shoe at *l*, adapted to deliver a thin and uniform stratum of grain upon the endless cloth, while the same is made to pass under it, and over the trough. Another endless band *m m*, of a similar fabric to the other, passes round the drums *h i* only, and is likewise provided with a self-acting tightening roller, fixable to any convenient object. The lower ends of the six tubes *a* of the fireplace before mentioned have an open communication with a rotative blower *o*, by means of a broad channel *p p;* and the upper ends of the tubes *a* also open into another broad channel *q*, which conducts the air into the long air-trough *e* The operation of this machine is as follows: A slow rotation, derived from any first mover, is to be given to either of the drums *g h i*, which will cause the endless cloth *f* to glide gradually over the top of the air-trough *e;* at the same time the blower *o* has been put into action (by connection with the first mover) at a high velocity, so as to produce a rapid current of air, which derives an increase of temperature on passing under the heated metallic bottom of the ash-pit; hence proceeding through the tubes *a*, it acquires considerable heat, which is subsequently moderated by an extensive diffusion in the air-trough *e*, before it passes through the meshes of the endless cloth *f* above, carrying with it the moisture from the grain deposited thereon. The course taken by the endless cloth is shown by arrows in the figure: upon its arriving at the drum *h*, the other endless cloth *m m* comes in contact with the grain on the cloth *f*, and, upon both the cloths passing round the said drum *h*, the corn becomes inclosed between the two cloths, and is thus carried up an inclined plane over the drum *i*, where the cloths separate, and discharge the grain back again into the hopper *k*, to undergo a repetition of the operation, should it not be perfectly dry. But when the grain is thoroughly dried, instead of allow-

ing it to fall back into the hopper, a shoot, or the band of a creeper, (not shown in the drawing,) is brought under the roller i, which conducts it to the required place. A very little experience in the working of this apparatus enables a person so to regulate its operations as to complete the drying of



damp grain by a single passage through it; such as varying the velocity of the air-forcer, the quantity of fuel in the stove, the supply of air through the ash-pit, the speed of the endless cloth, &c., the means of doing which are so well understood by mechanics as to render a description of them unnecessary in this place.

KITE. This well-known juvenile plaything has been applied to several objects of utility. The most important of these is the invention of Captain Dansey, for effecting a communication between a stranded ship and the shore, or, under other circumstances, where badness of weather renders the ordinary means impracticable. The following is an abbreviated description of the invention, extracted from the forty-first volume of the *Transactions of the Society of Arts*, where the subject is given more in detail, with engraved illustrations:—A sail of light canvas or holland is cut to the shape, and adapted for the application of the principles of the common flying kite, and is launched from the vessel or other point to windward of the space over which a communication is required; and as soon as it appears to be at a sufficient distance, a very simple and efficacious mechanical apparatus is used to destroy its poise and cause its immediate descent, the kite remaining, however, still attached to the line, and moored by a small anchor with which it is equipped. The kite, during its flight, is attached to the line by two cords placed in the usual manner, which preserves its poise in the air; and to cause it to descend, a messenger is employed, made of wood, with a small sail rigged to it. The line being passed through a cylindrical hole in this messenger, the wind takes it rapidly up to the kite, where, striking against a part of the apparatus, it releases the upper cord, and by that means the head of the kite becomes reversed, and it descends with rapidity. In the experiments made by Captain Dansey, with the view of gaining communication with a lee-shore, under the supposition of no assistance being there at hand, a grapnel, consisting of four spear-shaped iron spikes, was fixed to the head of the kite, so as to moor it in its fall; and in this emergency, the attempt of some person to get on shore along the line would be the means resorted to. In those cases where a communication has been gained, and the maintenance of a correspondence has been the object, the person to windward has attached a weight to the messenger—in some cases as much as three pounds—which, having been carried up, has of course descended with the kite; the person to leeward has then furled the sail of the messenger, and loaded it with as much weight as the kite could lift; then replacing the apparatus, and exposing the surface of the kite to the direct action of the wind, it has rapidly risen, the messenger running down the line to windward during its ascent. The kite with which Captain Dansey performed the greater part of his experiments extended 1100 yards of line, five-eighths of an inch in circumference, and would have extended more had it been at hand. It also extended 360 yards of line 1¾ inches in circumference, and weighing 60 lbs. The holland weighed 3½ lbs.; the spars, one of which was armed at the head with iron spikes, for the purpose of mooring it, 6¾ lbs.; and the tail was five times its length, composed of 8 lbs. of rope and 14 lbs. of elm plank. A complete model of the apparatus was deposited with the society, who presented Captain Dansey with their gold Vulcan medal for his invention and communication.

KNEADING is the process of making the stiff paste of flour and water for being afterwards baked into bread. It is usually effected by a sort of pommelling action of the hands and arms, and sometimes of the feet of the bakers. A variety of machines have been at different times proposed for superseding the barbarous process we have just mentioned; they have, however, been but very partially adopted, the bakers in general preferring to continue their "good old-fashioned" dirty practice. It is said that at Geneva all the bakers of that city are compelled by law to send their dough to be kneaded at a public mill constructed for that purpose. At Genoa, also, mechanism is employed for kneading: the apparatus employed at this place has been published in several of the journals, from which it appears to be so rude and ill-contrived as not to need a description in this place.

1. The *petrisseur*, or mechanical bread-maker, invented by Cavallier and Co. of Paris, consists in a strong wooden trough, nearly square, with its two longest sides inclined, so as to reduce the area of the trough in the direction of its width, and adapt it to the dimensions of a cast-iron roller, the axis of which

passes through the ends of the trough; the bottom of the trough is semi-cylindrical, leaving a smal space between it and the roller, which space is adjustable by levers. All along the top of the outside of the roller is fixed a knife-edge, which, with the roller, divides the trough into two compartments. Upon the axis of the roller is a toothed wheel, which takes into a pinion; this pinion is turned by a winch, and communicates thereby a slower motion to the roller; and the roller, by its rotation, forces the materials or dough through the narrow space before mentioned left between it and the bottom of the trough—the knife-edge on the top of the roller preventing the dough from passing by it. Being thus all forced into one of the compartments, the motion of the roller is reversed by turning the winch the contrary way, which then forces the dough back again through the narrow space under the roller into the first compartment; in this manner the working of the dough, alternately from one compartment to the other, is continued until completed.

2. Another plan was to make the trough containing the dough revolve with a number of heavy balls within it. The trough in this case is made in the form of a parallelopipedon—the ends being square and each of the sides a parallelogram, whose length and breadth are to each other as five to one. One side of the trough constitutes a lid, which is removed to introduce the flour and water, and the trough is divided into as many cells as there are balls introduced. The patentee states, that by the rotation of the trough the balls and dough are elevated together, and by their falling down the dough will be subjected to beating, similar to the operations of the baker's hands.

3. Instead of employing a revolving cylinder, it is fixed, an agitator is made to revolve, having a series of rings angularly attached to an axis, extending the whole length of the trough.

4. Mr. Clayton, a baker of Nottingham, had a patent in 1830 for a machine somewhat similar to the last mentioned, inasmuch as a set of revolving agitators are employed to produce the kneading action. The agitators are longitudinal bars, fixed to arms, which radiate from the axis, and they are forced through the dough in their revolution; but the cylinder in which they revolve, and which contains the materials, is made to revolve at the same time in a contrary direction—the motion of the latter being imparted by a short hollow axis, while the axis of the former is solid and passed through the hollow one. The solid axis, which is turned by a winch, has on it a bevelled pinion, which, by means of an intermediate bevelled wheel, actuates another bevelled pinion fixed on the hollow axis, and therefore causes it to revolve in the opposite direction. These two simultaneous and contrary motions constitute the novelty claimed by the patentee, who *states*, that dough-making machines similar to his own have all failed for want of such an arrangement. This statement, coming from a baker, commands attention; but we cannot concur in its truth, since we know that the following plan of a kneading-machine works well without opposite simultaneous motions, and without any agitators or beaters, which absorb a great deal of power without producing an adequate effect.

5. *Hebert's patent kneading-machine.*—In this a cylinder of from 4 to 5 feet in diameter, and only about 18 inches wide inside, is made to revolve upon an axis, which is fixed by a pin during the revolution of the cylinder. The flour is admitted by a door in the periphery, which closes air and water tight; and the water or liquor passes through a longitudinal perforation in the axis, and thence through small holes among the flour, in quantities which are regulated externally by a cock. By the rotation of the cylinder the dough is made to be continually ascending on one side of it, whence it falls over upon the portion below. When the mixture becomes pretty intimate and uniform, its adhesive property causes it to stick to the sides of the cylinder, and the dough would then be carried round without much advancing the process, were it not for another simple contrivance. This is a knife-edge, or scraper, 18 inches long, which is fixed along the top of the cylinder in the inside, so as barely to touch its surface: the knife is fixed to two flat arms extending from the axis, and these arms have sharp edges so as to scrape the sides of the cylinder; thus the cylinder is kept constantly clean from the sticking of the dough, which, as soon as it ascends to the top of the cylinder, (if it does not tear away of itself,) is shaved off by the knife, and falls down with great force upon the bottom; and as this effect is constant during the motion of the cylinder, it must be evident that the process of kneading is soon completed by it. When that is done, the door of the cylinder is opened, and the contents discharged into a recipient beneath; at which time the scraper is caused, by a winch on the axis, to make one revolution of the now fixed cylinder, which clears off any adhering dough, and projects it through the doorway. As the dough in this machine may be said to knead itself—there being no arms, beaters, or agitators whatever—it is calculated that the power saved by it is very considerable; while, from the simplicity of its construction, the cost is moderate.

The patentee is at present engaged in combining with this kneading machine an apparatus for preparing carbonated water, highly charged with the gas, with which he proposes to mix up the flour to form dough, for the purpose of making the bread spongy or vesicular, without having recourse to the fermentative process; the result of which process, under the most favorable circumstances, he considers to be detrimental to the health of those that eat the bread, (owing to the deposition of fermentable matter in the stomach,) while it is destructive of a portion of the nutriment of the flour.

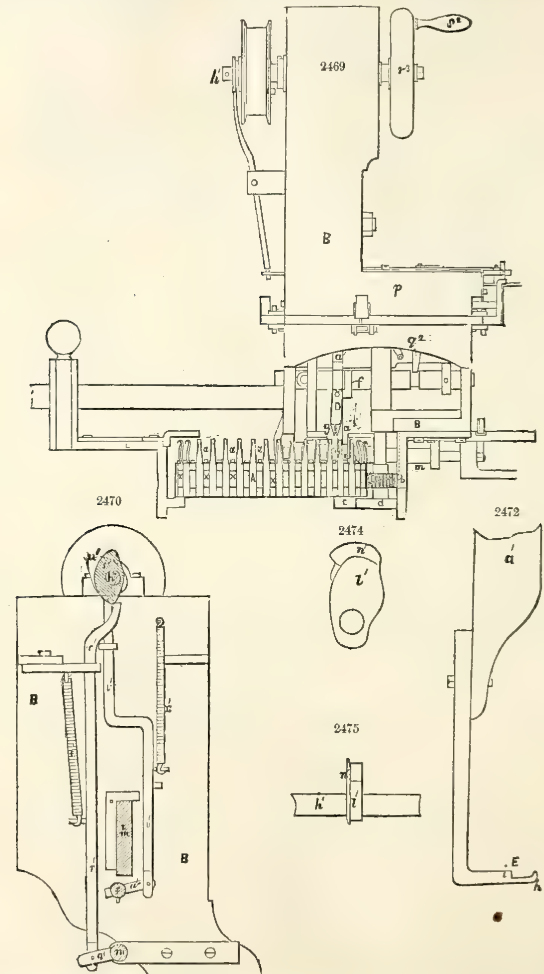
KNITTING MACHINE, *Improved.* From the specification of the inventor, J. R. Ellis, of Boston, Massachusetts, patented June 17, 1851. Fig. 2469,* denotes a front elevation of the said improved knitting machine. Fig. 2477 is a vertical and transverse section of it, the same being taken in such manner as to exhibit the yarn guide or director, the stitch hook, and the contrivance for forcing the work down towards the roots of the needles, after the formation of each new loop. Such other figures as may be necessary to a proper representation of the various parts of my improvements, will be hereafter referred to and described.

The machine as improved, is not what is usually termed a stocking loom, but is more properly named a knitting machine, for the reason it forms each stitch of the work in regular succession, and not a number of stitches at once, as does the stocking loom. It is a machine in character like others in use, al-

* The letters in the cut are by mistake made capitals instead of small letters.

though it differs from the same in sundry important particulars which constitute my invention, and which I shall hereafter describe.

In the drawings above mentioned, A denotes the endless chain belt of knitting-needles, which is so made that the needles *a a a*, &c., instead of being arranged or made to stand horizontally, and at right angles to the vertical surface of the belt, are made to stand vertically or in the plane of the belt, as seen at *a a a a*, figures 2469 and 2477.

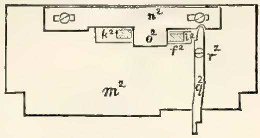


The driving pinion *b*, instead of being arranged within the belt as it has been in other machines of this character, is disposed on the exterior surface of it, and works against, or with the projecting points of the belt. That part of the inner surface of the belt, which is immediately adjacent to the pinion, is supported by, and works round a stationary vertical post or guide *c*, (see fig. 2471, which is a vertical section of the belt and its support) that extends upwards from a horizontal arm *d*, which projects from the

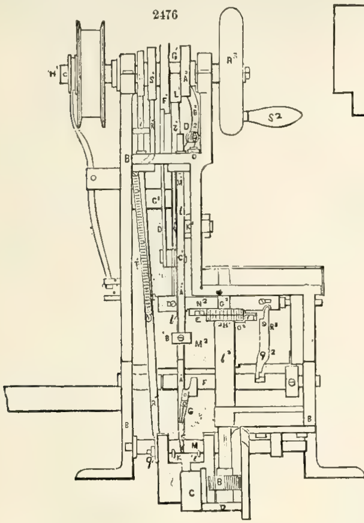
main frame B. The opposite end of the endless belt is supported by a straining contrivance L, which is similar to such as are in common use in such machines. The work or knitting hands within is the endless belt, instead of without it, or on the outside of it.

The yarn guide or director is seen at D. It consists of a curved arm, made to extend from a horizontal rocker shaft f, and to have a small conical and split tube g, on its outer end, through which tube the yarn is carried from the bobbin placed in any convenient position.

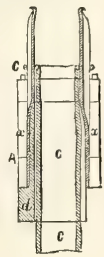
2480



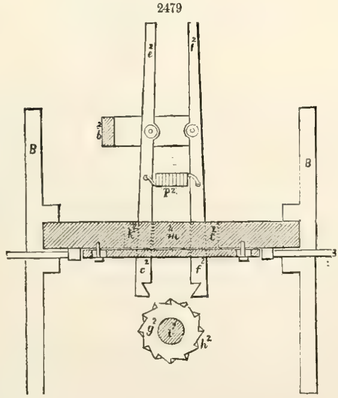
2476



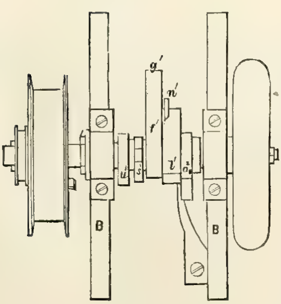
2471



2479



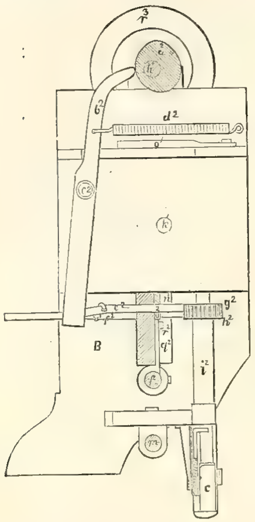
2473



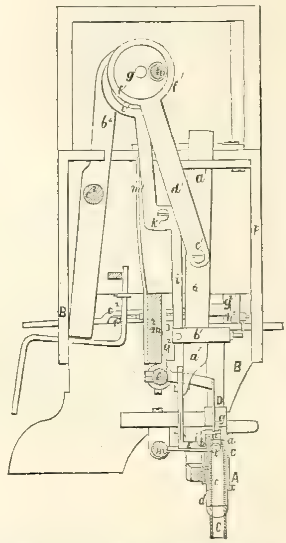
The stitch hook is seen at E. It is arranged in rear of the chain belt of needles, and is formed as represented in side view on an enlarged scale, fig. 2472, that is to say, it is made not only with a hooked end, as seen at h, but with a shoulder i, a short distance in rear of said hooked end, the shoulder performing the important office of piercing or casting the loop (taken up by the hook) over the hooked point of the needle, the same having been effected in other machines of this kind, by what is usually termed the "bent finger." By my improvement I am enabled to dispense with such bent finger, and the machinery for operating it. In order that the stitch hook may not only take up the loop, but cast it over the end of the needle and the yarn laid on the needle by the yarn director, and this to form or make a new stitch, the hook should have the following movements imparted to it. First, it should be made to

pass into the groove of the needle, and under the stitch on the needle. Next, it should be made to rise upwards so as to carry the stitch up to the hooked end of the needle. Next, it should be moved laterally far enough to be opposite the space between the needle (first operated upon) and the next needle. Next, it should be moved forwards between the two needles and so as to cause the shoulder i, to press or force, or cast the stitch over the hooked end of the needle. The stitch hook should next be drawn backwards, and depressed so as to disengage it from the stitch. The movements of the stitch hook may be produced by various kinds of combinations of mechanism. No such machinery forms any part of my invention, and I lay claim to none in particular, but employ such as may be suitable: that adopted by me is as follows, viz:

2478



2477



The stitch hook E, is fastened to the lower end of a bar a', which works or slides freely up and down through a piece of metal b', and is jointed by a joint screw c', to a connecting rod d', on whose upper end is a strap f', passing around an eccentric g', fixed on the main driving shaft h', of the machine. The upward and downward movements of the stitch hook are effected by such eccentric during its entire revolution. In order to produce its forward and back movements, a lever i', working on a fulcrum k', is jointed at its lower end to the rear end of the piece of metal b'. The upper end or arm of the said lever rests against a cam l', fixed on the driving shaft (see fig. 2473,) which denotes a top view of the said shaft, and the cams applied to it. See also figures 2474 and 2475, the former of which is a side view of the said cam, and the wing cam to be hereinafter described, while the latter is a top view of the same, made so as to show the form of the wing cam. During the revolution of the cam l', the lever i' will be moved forwards and backwards by the action of the said cam and a spring m', made to bear against the rear side of the said lever. The small wing cam n', placed on the side of, or to project above the cam l', serves to press the upper end of the lever i' laterally, in order to produce the lateral motion of the stitch hook. A spring o', (see fig. 2473,) presses the end of the lever i', against such wing cam.

Both the stitch hook and the yarn guide, are arranged between the arms of the presser, which presser consists of two arms, k, l, extended at right angles from a horizontal rocker shaft m, and long enough to play between the needles. These arms should be made to operate so as to press the work down to the roots of the needles, after the formation of each stitch; they should next be raised upwards far enough to allow of the movement of the chain belt, which having taken place, they should be depressed so as to hold the work down until the stitch hook has fairly hooked under or taken up the stitch on the needle, against which it may be acting.

The presser should next be elevated with the stitch hook, so as to allow the work to rise. While the stitch hook is casting the stitch or loop over the hook of the needle, the presser should be stationary, but as soon as this has been effected, and the hook has withdrawn itself from the stitch, the presser should be depressed so as to force the work down to the roots of the needles. Such movements may be attained by any suitable machinery applied to the rocker shaft of the presser, such mechanism constituting no part of my invention;—but that which I employ may be thus described:—Fig. 2476 is a front elevation of the machine as it appears when its front plate p', and the endless chain A, are removed from the re-

mainder of the mechanism. Fig. 2470 is a vertical cross section of the machine; the same being taken looking towards the left through the cam, which operates the presser.

From the shaft *m* of the presser, an arm q' extends towards the front, and is joined at its outer end to an upright and bent bar r', whose upper end is forced upwards against the cam s', by means of a spring t', one end of which is attached to the bar r', and the other to the frame or box B, as seen in figs. 2476 and 2470. The cam s' is fixed on the driving shaft, and during its revolution, it, in conjunction with the spring t', produces the rocker motions of the shaft *m*, such as will cause the presser to operate in the manner required.

Directly after each movement of the chain belt, the yarn guide or director D, should be moved forward beyond the back needles, so as to lay the yarn on that needle on which the new stitch is to be made. After the stitch has been formed, the yarn guide should be retrograded and carried back of the needles, in order that the chain belt may perform its next movement without obstruction. The mechanism for operating the yarn guide or director D, consists of a cam u', fixed on a driving shaft, a slide rod or bar v', (whose lower end is jointed or hinged to the outer end of an arm w', extended from the shaft *f*,) and a spring x', which forces the bar v' up against the cam—the said cam being shown in fig. 2470 by dotted lines.

The machinery for moving the chain belt forms no part of my invention, except so far as the arrangement of the gear or pinion B and the joints *x x x*, &c., of the chain belt is concerned. On the main driving shaft, there is another cam a^2, which operates against the upper end of a lever b^2, which turns upon a fulcrum c^2. See fig. 2478, which is a transverse section of the machine, taken through such cam, and looking towards the right, serves to show the machinery actuated by it. A spring d^2, is used to draw the upper end of the lever against the cam. The lower end of the lever is bent at right angles, or horizontally, and has two impelling pawls $e^2 f^2$, jointed to it, and made to extend forwards, and respectively to act in concert with two ratchet wheels $g^2 h^2$, fixed upon the upright shaft i^2, of the pinion *b* which works the chain belt. These ratchet wheels and pawls are seen in fig. 2477 and 2479, the latter figure being a horizontal section of the machine, taken just above the pawls, and so as to exhibit them. The teeth of one of the ratchet wheels are arranged in a direction opposite to those of the other, in order that when its pawl is in action with it, a motion of the shaft i^2, may be produced in a direction the reverse of that effected by the movements of the other pawl and its wheel. By the movement of either pawl an intermittent rotary motion of the shaft i^2 will take place.

The two pawls pass respectively through slots $k^2 l^2$, made in a vertical stationary plate m^2; (see fig. 2480,) which is a front view of the plate m^2, and the shifting contrivance attached to it. Such shifting contrivance is a slide n^2, which is capable of being moved longitudinally, and has a projection o^2 extending down between the two pawls. When the slide is moved in one direction, it bears against one of the pawls, and throws it out of action upon its ratchet wheel, and at the same time, in consequence of the two pawls being connected by a spring p^2, it draws the other pawl against the other ratchet wheel, thereby creating a reverse motion of the shaft i^2. The object of the *two* pawls is to enable the movement of the endless belt A to be reversed, so as to cause the knitting to be produced in an opposite direction; one pawl, however, is sufficient to produce the movement necessary to knit in one direction.

The shaft *f*, which carries the yarn director D, is made to slide longitudinally in its bearings, and is connected into the slide n^2, by a lever q^2, which turns upon a fulcrum r^2, and has its ends inserted in notches made in the slide n^2, and the shaft *f*, and this so that the movement of the slide in one direction may create a sliding movement of the shaft, sufficient to move the yarn guide into the proper position to commence the knitting in the reverse direction.

The shifting contrivance may be operated by the attendant, or by any other proper means. Some parts of other mechanism which I append or attach to the above described machine, and for purposes not necessary to mention, may be seen in the drawings. As such mechanism forms no part of my invention, I make no further reference to it or description of it.

On the driving shaft there may be a fly wheel r^2, from which a crank s^2 may extend, and for the purpose of enabling a person to put the shaft in motion—or the said shaft may be revolved by a pulley applied to it, and made to receive an endless belt from any suitable driving drum.

By having the endless chain of needles made and operated in the above described manner, the chain extends *around the work*, instead of the work *encompassing the chain*, as it does in other well-known knitting machines. My improved arrangement and disposition of the work exposes all the joints of the links of the chain so that a workman or attendant can readily remove one or more of the needles, with much greater convenience than can be done on the said well-known machines, as in the latter he would be obliged to wholly or partially *remove the work from the needles* in order to accomplish the addition or subtraction of one or more of the needles, such addition or subtraction being for the purpose of enabling him to "*widen*" or "*narrow*" the work. My improvement affords great advantages in knitting a heel, as the same can be effected in a much more perfect manner, without that strain upon the work and needles that is incident to the old and well-known machines.

KNIVES, (*including Forks.*) Knives are well-known instruments, made for cutting a great variety of substances, and adapted by differences in form to various uses; but the two principal sorts may be classed under the terms of pocket-knives and table-knives, with their accompaniments, forks.

In the making of pocket-knife blades, one workman and a boy are generally employed; the boy attends to the heats, (that is, to the rods of steel in the fire,) which he successively hands to the forger, and takes back the rod from which the last blade was formed. One heat is required to fashion the blade, and a second to form the tang, by which it is fastened into the handle. The skill of the forger is displayed in forming it so perfectly by his hammer, as to require but very little to be filed or ground off in the subsequent operations. The springs for the back of the knife, and the scales which form the rough metal under-handle, and to which the other pieces are riveted, are made by a distinct class of workmen. In the forging of table-knife blades, and other blades of a similar or greater size, the forger has an assistant, who, with a large hammer, strikes alternately with him; and the hammering of all

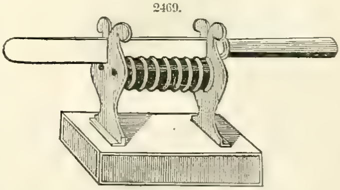
blades is continued after the steel has ceased to be soft, in order to condense the metal and render it very smooth and firm. Table-knife blades are usually made with iron backs, which are welded to the steel by a subsequent forging, to that of forming the cutting edge; the thick piece that joins the handle, called the shoulder or bolster, as well as the tang that goes through the handle, is forged out of the iron immediately after the welding of the steel blade: dies and swages being employed to perfect and accelerate the shaping of these parts. When the forging is completed, the blades undergo the processes of hardening and tempering, explained in article TEMPERING. The blades are then ground upon a *wet* stone, about 4 feet in diameter, and 9 inches wide, which roughs out the work; they are subsequently finished or *whitened*, as it is termed, upon a finer *dry* stone; and the shoulders or bolsters are ground upon a narrow stone, about 3 feet in diameter, which completes the grinding. The next process is that of glazing the blades, which is effected upon a wooden wheel, made up of solid segments, well fitted and secured together, and with the ends of the fibres of the wood presented to the periphery of the circle; over this is extended a piece of leather, which is charged with emery or other powders, adapted to the finish or nature of the work required.

The cheaper kind of forks are made by casting them from malleable pig-metal, sometimes denominated "run-steel;" and some of these, which are well annealed and worked under the hammer, turn out very serviceable and good. Those made of wrought-metal, were formerly either forged, and the prongs drawn out by the hammer, and welded together, or they were forged into one solid piece, and the spaces between them formed by cutting away the metal. These processes, however, were tedious and expensive, and a great improvement in their manufacture has been introduced. The tang, shoulder, and a thick, flat piece, called the blade, are forged, and the blade is then submitted to the action of a pair of dies, contained in a powerful fly or stamping-press; the dies being so formed as to force or cut out the superfluous portion of the metal and raise the curved swelled portions at the junction of the prongs, termed the bosom. The forks after this operation are filed up, ground, glazed, and burnished, when they are ready for hafting, which is a distinct business.

The instruments required for hafting knives and forks are few and simple. The principal are, a small polishing-wheel and treddle, mounted upon a stand, a bench vice, and a kind of hand vice to fix in the bench vice, termed a snap-dragon; it has a pair of long projecting jaws, adapted to hold a piece of metal or other substance, with the flat side uppermost, in order to be filed or otherwise worked; a few files, drills, drill-box, and breast-plate, burnishers and buffs, emery, rotten-stone, &c. The substances used for covering the handles are almost infinite; the chief are bone, horn, ivory, tortoise-shell, and wood of every kind. The several pieces of the handle being filed to the shape intended, holes are drilled through them for the pins by which they are afterwards riveted together. The pinning is at first loosely done, until the blades, springs, and all the parts are well adjusted and fit closely; they are then firmly riveted together. The handles are afterwards scraped and then polished, by means of buffing, on the wheel.

KNIFE-SHARPENERS. This term has been given to a variety of convenient modern instruments, especially adapted to the sharpening of knives at table, but particularly carvers, and are intended as substitutes for the common steel. For these instruments several patents have been obtained, and a considerable manufacture of them has been established.

2469.



Filton's patent sharpener, represented in Fig. 2469, consists of two horizontal rollers, placed parallel to each other, which revolve freely upon their axes, (represented by the two black dots;) at uniform distances, there are fixed upon each roller narrow cylinders or rings of hard steel, the edges of which are cut into fine teeth, and thus form circular files; the edges of the files in the opposite rollers overlap each other a little, so that when a knife is drawn longitudinally between them, the edge of the knife is acted upon on both of its sides at once. The rollers turn round with the slightest impulse; consequently, they wear uniformly, and will last a considerable time. A good edge is given to a knife by just drawing it from heel to point two or three times between the rollers; and thus obviates the necessity of imitating the skill exercised by a butcher upon his steel.

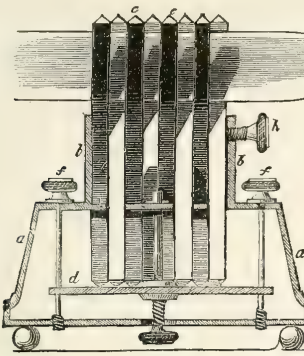
Westby's knife-sharpener, which was patented in 1828, is an ingenious instrument; an immense quantity of them have been sold, and it is said, have been the means of greatly enriching the proprietor of the patent. Fig. 2470 exhibits an end elevation of the instrument, and Fig. 2471 a side elevation of the bars, with a section of the boxes a and b, to show the interior. The same letters in each figure have reference to similar parts; a is a small oblong box, surmounted by a smaller box b; in the top of the latter there is a slit made throughout its length, and of sufficient width to receive the square steel bars $c\,c$. The box a has two similar slits. The surfaces of the bars are draw-filed; they pass through the slit in b, and alternately through both slits in a, so as to cross each other, as shown in Fig. 2470. The lower ends of these bars are supported upon a plate of metal d, which can be elevated, so as to bring a different portion of the bars into operation, by means of the screw underneath; $f\,f$ are two screws passing through the holes in d, to preserve its parallel motion, and likewise to support the bottom of the box; h is a tightening screw to steady the bars $c\,c$.

The mode of operating with this instrument is merely to place the edge of the knife upon the bars, so as to bisect the angle formed by them, and then draw the knife backward and forward. As the surfaces of the bars wear away, different sides can be presented, or they can be shifted from end to end, so as to present fresh surfaces to the knife.

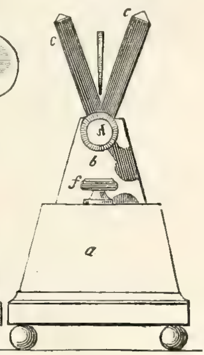
Church's patent knife-sharpener consists of two very flat truncated cones, fixed with their smaller

surfaces together, and with several rectangular projections in the one, fitting into similar cavities in the other. The conical surfaces of both pieces are serrated with a series of very fine teeth extending angularly towards their centres; these are placed upon the shank of the fork, between the shoulder and the handle, with which they correspond in diameter so nearly as to constitute an ornamental finish to the small end of the handle. In the position and size of these consist the principal merit of the sharpener. When used for sharpening scythes, or other large cutting instruments, the conical pieces are made larger, and fitted on an axis between two prongs of a forked apparatus, with an appropriate handle.

2471.



2470.



Westby's second patent.—The extraordinary success attendant upon Mr. Westby's contrivance for sharpening table-knives induced him to figure a second time as a patentee, "for certain improved apparatus to be used for the purpose of whetting or sharpening the edges of the blades of *penknives, razors, and other cutting instruments.*" The first improvement mentioned in the specification consists in the application to a hone, or oil-stone, of a guide to keep the edge of the razor, or other cutting instrument, at the same angle with respect to the surface of the hone, during the operation of whetting. This is effected in two ways: first, by placing over the hone a plate of metal extending its whole length, and adjustable, at any required distance parallel to its surface, by set-screws; now, in the operation of sharpening, the back of the instrument is kept resting upon the guide-plate, while the edge is applied to the hone. The second method consists in the application of two hones placed in an erect position, with a space between them for the razor, which is to be fixed by screws into a small horizontal frame, made to slide upon a circular rod, so that the edge can be applied alternately to the hones; these can be elevated and depressed at pleasure, so that their surfaces may be uniformly worn while in use. The patentee also mentions in his specification a method of attaching to his hone a leather strap which is made double, and kept stretched by adjusting screws attached to the frame of the hone, or else to the end of a rod extending lengthwise between the two folds of leather. This last contrivance does not appear to us to be scientifically adapted to the object in view, as the pressure of the edge of the instrument upon a strap of leather only supported at its extremities, must produce a tendency in the leather to wrap round the acute angle of the edge of the instrument, and render it obtuse.

LABURNUM WOOD is in use among turners · pulleys and blocks are made of it. Being a hard and compact wood, it is capable of endurance when exposed to the weather, and for various purposes is extremely valuable. When perfectly dry, a cubic foot weighs 52 lbs. 11 oz.

LAC. A resinous substance, the product of an insect found on several different kinds of trees in the East Indies. These insects pierce the small branches of the trees on which they feed, and the juice that exudes from the wounds is formed by them into a kind of cells for their eggs. Lac is imported into this country adhering to the branches in small transparent grains, or in semi-transparent flat cakes. The first, encrusting the branches, is called stick-lac; the second are the grains picked off the branches, and called seed-lac; the third is that which has undergone a simple purification, as we shall presently notice. There is a fourth, called lump-lac, made by melting the seed-lac, and forming it into lumps. To purify the lac for use the natives of India put it into long canvas bags, which they heat over a charcoal fire until the resin melts; a portion of the lac then exudes through the bags, which are subsequently twisted, or wrung by means of cross sticks at the ends of the bags, the surface of the latter being scraped at the same time to accelerate the process. The chief consumption of lac in this country is in the manufacture of sealing-wax and varnishes. It has been a great desideratum among artists to render shell-lac colorless, as, with the exception of its dark-brown hue, it possesses all the properties essential to a good spirit varnish in a higher degree than any other known resin. The process given by Dr. Hare leaves nothing to desire, excepting on the score of economy. Were the oxymuriate of potash to be manufactured in the large way, the two processes, that of making the salt and of bleaching the resin, might be advantageously combined. "Dissolve in an iron kettle one part of pearlash in

about eight parts of water; add one part of seed or shell lac, and heat the whole to ebullition; when the lac is dissolved, cool the solution, and impregnate it with chlorine till the lac is all precipitated. The precipitate is white, but its color is deepened by washing and consolidation; dissolved in alcohol, lac bleached by the process above mentioned yields a varnish which is as free from color as any copal varnish."

The following is Mr. Field's process: Six ounces of shell-lac, coarsely powdered, are to be dissolved by gentle heat in a pint of spirits of wine; to this is to be added a bleaching liquor, made by dissolving purified carbonate of potash, and then impregnating it with chlorine gas till the silica precipitates and the solution becomes slightly colored. Of this bleaching liquor add one or two ounces to the spirituous solution of lac, and stir the whole well together; effervescence takes place, and when this ceases, add more to the bleaching liquor, and thus proceed till the color of the mixture has become pale. A second bleaching liquor is now to be added, made by diluting muriatic acid with thrice its bulk of water, and dropping into it pulverized red lead, till the last added portions do not become white. Of this acid bleaching liquor, small quantities at a time are to be added to the half-bleached lac solution, allowing the effervescence, which takes place on each addition, to cease before a fresh portion is poured in. This is to be continued until the lac, now white, separates from the liquor. The supernatant fluid is now to be poured away, and the lac is to be well washed in repeated waters, and finally wrung as dry as possible in a cloth. The lac obtained in the foregoing process is to be dissolved in a pint of alcohol, more or less, according to the required strength of the varnish; and after standing for some time in a gentle heat, the clear liquor, which is the varnish, is to be poured off from the sediment.

Mr. Luning's process is as follows:—Dissolve five ounces of shell-lac in a quart of rectified spirits of wine; boil for a few minutes with ten ounces of well-burnt and recently heated animal charcoal, when a small quantity of the solution should be drawn off and filtered: if not colorless, a little more charcoal must be added. When all color is removed, press the liquor through silk, as linen absorbs more varnish, and afterwards filter it through fine blotting-paper. In cases where the wax found combined with the lac is objectionable, filter cold; if the wax be not injurious, filter while hot. This kind of varnish should be used in a temperature of not less than 60° F.; it dries in a few minutes, and is not afterwards liable to chill or bloom; it is therefore particularly applicable to drawings and prints which have been sized, and may be advantageously used upon oil paintings which have been painted a sufficient time, as it bears out color with the purest effect. This quality prevents it from obscuring gilding, and renders it a valuable leather varnish to the bookbinder, to whose use it has already been applied with happy effect, as it does not yield to the warmth of the hand, and resists damps, which subject bindings to mildew. Its useful applications are very numerous, indeed, to all the purposes of the best hard spirit varnishes; it is to be used under the same conditions, and with the same management. Common seed-lac varnish is usually made by digesting eight ounces of the bright, clear grained lac in a quart of spirits of wine, in a wide-mouthed bottle, putting it in a warm place for two or three days, and occasionally shaking it. When dissolved it may be strained through flannel into another bottle for use. In India, lac is fashioned into rings, beads, and other trinkets. Its coloring matter, which is soluble in water, is employed as a dye. The resinous portion is mixed with about three times its weight of finely powdered sand, to form polishing stones. The lapidaries mix powder of corundum with it in a similar manner.

LACE. A delicate kind of net-work, composed of silk, flax, or cotton threads, twisted or plaited together. See Bobbin-work.

LACQUERING is the application of transparent or colored varnishes to metals, to prevent their becoming tarnished, or to give them a more agreeable color. The basis of them is properly the lac described in the preceding article; but other varnishes made by solutions of other resins, and colored yellow, also obtain the name of lacquer. Strictly speaking, lacquer is a solution of lac in alcohol, to which is added any coloring matter that may be required to produce the desired tint; but the recipes that have been published in various scientific journals contain apparently a great many useless articles.

Lacquer for Brass.

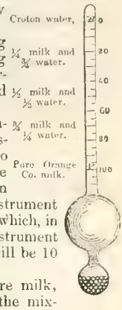
¾ oz. of gum guttæ,	¾ oz. of terra merita,
2 oz. of gum sandarac,	2 oz. of oriental saffron,
2 oz. of gum elemi,	3 oz. of pounded glass,
1 oz. of dragon's blood, of the best quality,	and
1 oz. of seed-lac,	20 oz. of pure alcohol.

Before, however, the reader ventures to meddle with so formidable a list of ingredients as the foregoing, we would recommend him to make trial of the following more simple compound:—Take 8 oz. of spirits of wine, and 1 oz. of annatto, well bruised; mix these in a bottle by themselves; then take 1 oz. of gamboge, and mix it in like manner with the same quantity of spirits. Take seed-lac varnish, (described under the previous article Lac,) what quantity you please, and color it to your mind with the above mixtures. If it be too yellow, add a little from the annatto bottle; if it be too red, add a little from the gamboge bottle; if the color be too deep, add a little spirits of wine. In this manner you may color brass of any desired tint: the articles to be lacquered may be gently heated over a charcoal fire, and then be either dipped into the lacquer, or the lacquer may be evenly spread over them with a brush.

LACTOMETER. An instrument for the purpose of ascertaining the different qualities of milk from its specific gravity compared with water. On this subject Dr. Ure observes, that it is not possible to infer the quality of milk from the indications merely of a specific gravity instrument, because both cream and water affect the specific gravity of milk alike. "We must first use as a lactometer a graduated glass tube, in which we note the thickness of the stratum of cream afforded, after a proper interval, from a determinate column of new milk; we then apply to the skimmed milk a hydrometric

instrument, from which we learn the relative proportions of curd and whey. Thus the combination of the two instruments furnishes a tolerably exact lactometer."

2472.



Frye's lactometer.—Fig. 2472, for testing the quality of milk; made under the direction of the Board of Agriculture of the American Institute, in the city of New York, who have strongly recommended it to public patronage.

This instrument was invented for the purpose of ascertaining the density, and fixing the standard weight, of pure unadulterated milk, as it is produced in the best grazing districts in the country, and with a view of detecting the frauds practised by adulterating milk with water, so often complained of by the consumer, in large towns and cities throughout the Union.

Directions for using the instrument.—Fill the tin tube, which accompanies the instrument, with the milk to be tested at a temperature of about 60 degrees, and suspend the lactometer in the milk, and if the milk is proof, the instrument will sink to the degree marked 100 on the scale, or p, showing that the milk is at par; but if the milk has been adulterated with water, or has been taken from cows that have been fed on slops from breweries, and kept confined in stables in warm weather, the instrument will, in all such cases, sink below par, and show the per centage of adulteration, which, in some instances, will be 25 per cent. below par; but if the milk is superior, the instrument will rise above p, and show the per centage above par, which, in some instances, will be 10 per cent. Each division on the scale is 5 per cent.

Any person can test the correctness of the lactometer by mixing water with pure milk, and note the per centage of water which they use, and suspend the instrument in the mixture, and it will give the proportion of water added.

To farmers the instrument has proved to be very valuable, as a ready means of testing the relative quality of their cows, by inspecting their milk, and also showing the effects produced by a change of the animals' food, as its quality will change the density of the milk.

LADDER. A portable frame, containing steps for the feet. There are various kinds, most of which are too familiar to the readers of this work to need description. Ladders are very advantageously employed in the raising of weights, by the addition of a pulley-wheel at the top, or suspended over them; passing over this pulley is a rope, to one end of which is attached the article to be raised.

Ladders are the universal means of ascent and descent in mines, the distance between the levels being generally 60 feet; a single ladder in former times reached from one to the other, but the most usual length at present is from 4 to 5 fathoms. In the perpendicular shafts the inclination is commonly such that the ladder may nearly traverse the breadth of the shaft; from 18 to 21 inches in the fathom is the inclination which experience has determined to be the best calculated to facilitate the progress of the miner, being that which enables him to stand upright on the ladder with the leg clear from the stave above, so that the effort is divided between the upper and lower extremities. The distance between the staves is generally 12 inches; in some old ladders they were 14 inches apart, but 10 inches is found the best for facilitating the climbing, by which one-fourth of the labor is estimated to be saved. The staves are of wood, though iron is in some instances preferred; in others it becomes slippery and rough from the corrosive action of water impregnated with copper, &c. Each ladder usually terminates on a *sollar* or platform, which leads to that below, which is generally placed parallel to that above.

LAMPS. The whole series of improvements made in lamps up to the present time, must be considered as the reward of no inconsiderable expenditure of ingenuity in the inventors themselves, and of a clear perception of the working of physical laws, enabling them not only to overcome the difficulties of the subject itself, but also to adapt the new contrivances to general use, and to the management of the unskilled. A general view of this interesting subject will place clearly before us the essential points which it has been the object of the inventors to attain, sometimes singly, sometimes several at once. They are these:

(*a*) To select such a form (section) of wick that the quantity of decomposed oil, and the simultaneous supply of air, may stand in such relation to each other, that the hydrogen and carbon may be consecutively consumed, and consequently no *smoke* produced.

(*b*) To make the distance between the burning part of the wick and the surface of the oil as unchangeable as possible, in order that as much oil may be drawn up at last as at first.

(*c*) To place the reservoir of oil in such a position that the shadow shall occasion little or no inconvenience. The use made of the lamp must, of course, here regulate its form; it is not, however, always a fault when these do not exactly correspond. Thus the shadow thrown by wall lamps is unimportant, as the lamp itself covers the shadow: in like manner, the shadow of a common study lamp cannot be considered as a fault, being used only by one person, although its prevention is always an improvement.

(*d*) To throw the light, radiating from the flame, by means of collectors and reflectors, from those parts where it is of little service, in the direction where it is most required.

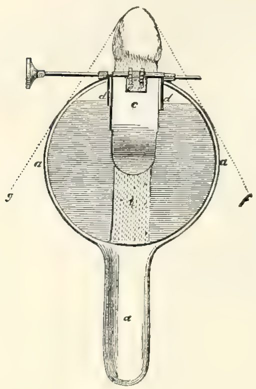
The requisitions stated under *a* have been complied with in two ways: on the one hand, by controlling the access of air, (the quantity of air;) on the other, by regulating the supply of oil, and often by both at the same time. They have reference to that part of the lamp called the burner.

The scrupulous enumeration of the manifold modifications, and, for the greater part, unimportant improvements in lamps, which have been presented to the public during the last twenty or thirty years, would be but a tedious labor; and in the following observations we shall only lay before the reader those inventions which appear to indicate important progress, or form epochs in the history of this subject.

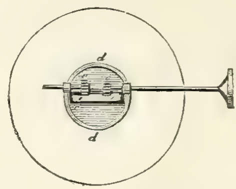
Worms' lamp.—The Worms' lamp, shown in Figs. 2473 and 2474, is well known, and characterized by the shape of the wick *t*. The fibres of the wick, instead of being collected into a round bundle, are placed in small bundles side by side, forming together a flat ribbon. The effect of this is obvious. The

edges of the flame are at no point so distant that a nucleus can form in the centre, which, from want of air, will burn incompletely and smoke. The flat socket *c* serves to hold the wick; it is soldered in the diameter of the wide ring *d*, which, with its recurved edge, rests upon that of the glass globe *a a*. An important addition to its flat form is its *movability*, and this is common to all the following kinds of lamps. The teeth of a wheel *e* and *e'*, more distinctly seen in Fig. 2474, are somewhat advanced into the space occupied by the wick, a cut being made in the socket, so that they press the wick in some measure against the back side. According as the screws are turned the wick is either raised or lowered, and a larger or smaller portion of it is engaged in the combustion. When the wick is high a large quantity of oil is decomposed; and when low a small quantity in the same space of time: the supply of oil is, therefore, easily regulated.

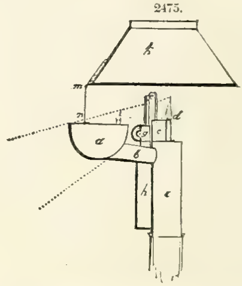
2473.



2474.



2475.



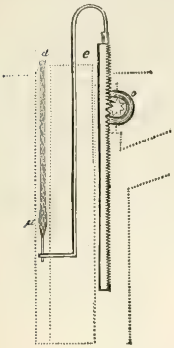
By means of the stem *a* the oil vessel can be placed upon any kind of foot. Besides the very unequal, constantly decreasing height of the surface of the oil, another objection may be raised to this arrangement, on account of the size and disadvantageous direction of the shadow, the conical space between βf and βg receiving no direct light.

Study lamp.—In the common study lamp, Fig. 2475, the oil vessel *a* is more flat, and instead of being situated below, is behind, and at the side of the flame, so that its shadow falls much beyond the immediate vicinity of the flame, and in no way interferes with the person in front of the lamp. The greater part of the light passing upwards, is collected by the shade *k*, and from every point of its inner surface is reflected downwards towards the opposite side. The inclination of the sides of the conical shade is, therefore, not unimportant, and should be at an angle of about 60°. The shade can be turned on the support *m n*. The motion communicated to the wick *d* is not from above, as in Figs. 2473 and 2474, in which arrangement the pressure interferes too much with the supply of oil, and the flame is too much cooled by the proximity of the wheels, but it is from below. The clamp *u*, Fig. 2476, which sustains the wick, is firmly connected with the toothed rod *e*. By turning the wheel *o*, this and the wick is raised up or down; the wheel works in the separate compartment *g*, as does the toothed rod in descending into *h*, whilst the clamp, the rod of wire, and the wick, by means of a rectangular appendage *c*, Fig. 2477, are all inclosed in the space allotted to the burner. This communicates with the oil vessel through the tube *b*; *i* is the inclosure round the burner. The motion of the wick, by means of a toothed rod and wheel, is, under various modifications, common to most lamps. The stopper *l*, at the aperture for filling the oil vessel, must be pierced, that the air without may not depress the oil in the burner.

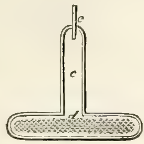
The astral lamp.—The astral lamp, of which a sketch is given in Fig. 2478, was constructed by Bordier-Marcet, with the idea of making as imperceptible as possible the sinking of the level of the oil, and at the same time the diminution of the flame by means of a very flat oil vessel, in which, therefore, a larger quantity of oil only occupies a very insignificant height. It is clear that the annular flat oil vessel will produce only a small unimportant shadow, although this will necessarily be thrown on all sides. At the same time the side nearest the flame *a a* is so inclined that it acts like a shade. The burner is not peculiar to the astral lamp, but is the well-known invention of Ami Argand, in 1789, and named after him; it is by far the most important kind of burner employed for illuminating purposes. The Argand burner, with double draught, consists of two metallic cylinders, one within the other, *c* and *d*: the ring-shaped space between them, which is closed at bottom, contains the oil and the cylindrically woven wick; the latter is clamped between two rings, which are connected with the screw.

The inner cylinder is open at top and bottom. The extraordinary advantages of this arrangement are easily understood. It has been already shown that with entire (massive) wicks, a nucleus is formed in the middle of the candle, which illumines but little, and smokes from want of air; with the hollow wick a current of air is directed exactly to that spot, so that the flame is surrounded by two concentric currents of the same kind. The current produced in the air by a freely burning hollow-wick flame, or the natural supply of air, is by no means sufficient to produce the requisite amount of light. As soon as, by

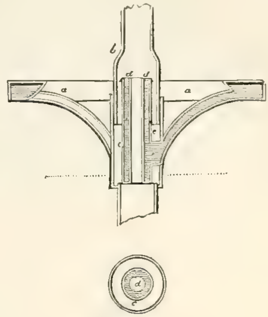
2476.



2477.



2478.

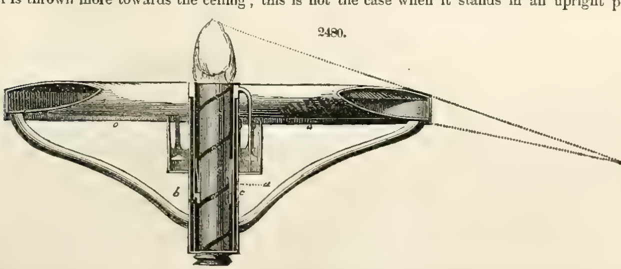


raising the wick, the size of the flame is increased, a thick smoke is the result; and when the wick is so regulated as to produce no smoke, then the flame is weak and deficient. But Argand gave a real practical use to his invention by applying the happy idea of an artificial draught. The principle is the same as that of chimneys: a rest on the outside of the burner supports a straight glass cylinder, which, including the inner and outer draught of air, exerts a powerful influence upon the velocity of both, in proportion to its height. With this arrangement, the point at which smoke begins to be evolved corresponds with a much higher intensity of flame. Another advantage, not at first anticipated, is the great steadiness caused by the chimney. When a draught of air comes in contact with an unprotected flame its force and cooling influence produce diminished combustion, and at the same time flickering and smoke; in Argand's burner, on the contrary, the supply of air to the flame is become self-dependent, whilst the heat itself is made the motive power. The cylinder protects it from any direct interruption, and that arising from the draught apertures is hardly felt at all in the interior. It must not be left unnoticed that the straight Argand cylinders, whilst assisting the draught, fall into an opposite extreme, and supply too large and injurious an amount of air. This was remedied, soon after the original invention, by Lange, and forms an important improvement; it consists in contracting the diameter of the glass chimney at a certain height above the burner at *b*, thus forming a shoulder of a few lines in width, as in Figs. 2478 and 2479. The draught, moving in the simple cylinder, in a parallel direction to the axis of the cylinder, is thus broken at the shoulder, and thrown into the flame at a certain angle. The supply of air is, therefore, lessened, but the direction given to it is preferable; and that part of the current, which, without taking part in the combustion, cooled the flame in a useless manner, and passed along the inner surface of the cylinder, is almost entirely removed. The glass chimneys are, however, applicable to all burners with flat, round, or semicircular wicks.

2479.

Sinumbra lamp.—When the astral lamp is used as a hanging lamp, the shadow of the circular oil vessel is thrown more towards the ceiling; this is not the case when it stands in an upright position.

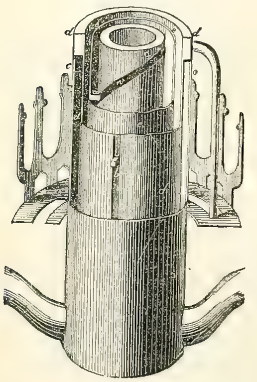
2480.



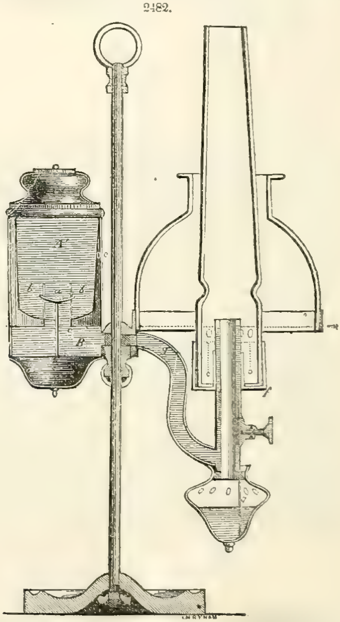
By an ingenious modification, Phillips has succeeded in his sinumbra lamp, Figs. 2480 and 2481, (*sine umbra*,) in rendering the shadow imperceptible even in the latter kind, and this is done by the peculiar

section of the circular vessel *o*. Its three surfaces meet in the form of a flat wedge, the sharp edge of which is directed towards the flame. The position of the flame, in relation to the oil vessel is such that two tangents drawn from the apex and base of the flame to the latter, meet a few inches behind it in *x*. Beyond this the vessel can cast no shadow; but even in this small space it is almost entirely destroyed by a vase-shaped ground-glass shade, which, resting upon the oil vessel, surrounds the chimney, and scatters the light in all directions around. The manner in which the wick is moved in the sinumbra burner is original, and deserves notice; there is neither screw nor toothed rod employed. The inner cylinder *f* is furnished on its outer surface with a deep, much inclined spiral groove, into which the short peg or appendage *a* of the wick-holder *e* fits. If, therefore, the latter is turned on its axis, the peg moves along the groove and forces *e* up or down. From its position in the burner, however, *e* cannot be approached by the fingers, and directly turned; this is effected by the cylinder *d*, which, throughout its whole length—that of the burner—has a slit, into which a second peg *b*, on the outer side of *e*, fits. By this arrangement *d* can at any time be freely moved up or down, but cannot be turned without taking with it the wick-holder, causing this either to be raised or depressed. In order that *d* may be moved easily, and without danger from the flame, it is firmly connected with the support for the chimney, terminating above in a thick ring, two or three lines wide, which rests upon the edge of the cylinder *c*, this being purposely made lower, and the whole is thus brought up to the full height of the burner. In this ring the supports for the chimney are fixed. If these are turned with the hand, *d* is turned at the same time, and with it the wick-holder, which is thus moved up or down. Great mobility characterizes this arrangement, and no forcing or compression of the ring holding the wick can occur.

2481.



2482.



All the lamps as yet described are subject to one common evil, that of having the oil vessel, at all events, within a few lines of the level of the burner; in a position, therefore, which throws the most objectionable shadow. A whole series of contrivances have consequently resulted from the efforts of inventors to transpose this cistern either to a considerable distance above the flame—when its shadow would fall upon the ceiling of the room—or to a position much below the flame, when it would fall at the foot of the lamp. Both resources, however, when applied, give rise to new and critical difficulties; the former requires that the supply of oil which flows *downwards* to the burner, should be accurately regulated. The most common and general application of this method is that adopted in the standing lamp, Fig. 2482. The oil cistern A is a movable metallic vessel, capable of being closed at the bottom by a valve *a*, which moves between the regulating rods *b b*. In the upright position the valve falls back and leaves the aperture open for filling the vessel; if the valve is then pulled up by its rod, the aperture is closed, and the bottle can be inverted and put in its place in the case B, (as in the figure.) It is no sooner there than an alteration occurs. The rod attached to the valve is, namely, so long that

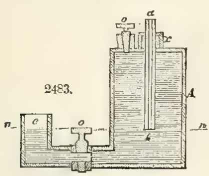
the valve is raised as soon as it touches the bottom of the case *d*. The oil, therefore, flows out for a few seconds until it has risen so high in the case as to stop the aperture of the bottle A. From this instant equilibrium is established, and as the mouth of A is on a level with the height of the burner, this becomes filled at the same moment, connection having been made by means of the tube *g*. The lamp has really two oil cisterns—an under one, which directly feeds the burner, and an upper one, the inverted bottle, for the supply of the lower as the oil is gradually consumed. As long as the level of the oil in B remains unchanged, and the mouth of A consequently closed, no air can enter A, and the whole stock of oil is kept up by the pressure of the atmosphere. When the lamp has been lighted some time, and the oil sinks below the mouth of the bottle, a few air-bubbles enter and take the place of an equal bulk of oil, which flowing out, raises the level in B until the mouth is again closed. The same operation is repeated as long as the oil is present in A.

The other parts of the lamp are easily understood: *f* is the support for the cylinder, (the peculiar form of which will be explained below,) *q* is the vessel for the toothed rod, and *e* is an aperture in the case for the easy admission of air into the interior.

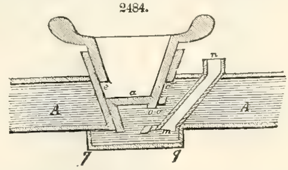
On reflection it will be immediately perceived that in all similar lamps, from the peculiar arrangement of the oil cistern, the height of the oil in the burner will not be always quite constant, but will alternately sink and immediately rise again to its former height, whilst in the lamps previously described, the suction of the wick is rendered more and more difficult by the constant sinking of the level of the oil.

The principle in question has been put into practice with better success by means of a simple vessel without case, as for instance, that represented in Fig. 2483. The mouth of the movable oil bottle corresponds here with the lower opening *b* of the tube *a b*, which passing through the air-tight collar *x*, is movable in the lid of A. The oil consumed in the burner *e* is replaced from the stock contained (above the level *n n*) in A, the place of which is then occupied by air, which enters at *b*. As soon as the consumption of oil in *e b* ceases, no more air-bubbles enter, and *vice versa*. As the level of the oil in the burner is dependent upon the position of the mouth *b*, this can be most accurately adapted to circumstances, *a b* being movable. The cocks *o* and *o′* are only used in filling the vessel.

2483.



2484.



This principle can be applied in the same manner, or in a much more compact form to lamps with circular oil vessels, by means of Caron's stop-cock, Fig. 2484. The conical plug of the cock is completely hollow, and at a certain distance from the middle it is supplied with a cross bottom *a*, dividing the space into two unequal parts. In the upper part the round lateral aperture *e* is made opposite to *o* in the lower part; *e′* and *o′* are the corresponding apertures in the case. In the position represented in the drawing, *e* is closed, whilst *o* is in free communication with the stock of oil in the circular vessel A A. This stock comprises the whole quantity, situated above the mouth *m* of the tube *m n*, corresponding with the tube *a b* of Fig. 2483. The side tube communicating with the burner also opens into *q q*. In the opposite position of the cock (by closing *o*) the space A, and, in the first instance, *q q* is shut off from communicating with the burner, whilst the same space A can then be filled, *e* being open.

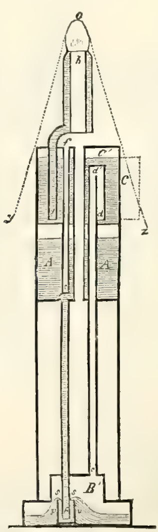
By transposing the oil cistern to the foot of the lamp, by which means all shadow is avoided, we forego the important advantage which the free flow (fall) of oil occasions, and by means of which it can easily be conducted to the burner; and, as consumption goes on, the oil must then be *raised*. The lamps made upon this principle are interesting on account of the ingenious, but at the same time very complicated elevating apparatus, which partly depends upon hydrodynamic, partly upon hydrostatic laws, and is partly also a mere mechanical arrangement.

Girard's lamp.—Girard's (hydrostatic) lamp is constructed upon precisely the same principles as the air-chamber of a fire-engine, or resembles rather Hero's fountain, Fig. 2485. In these arrangements it is well known that the pressure exerted in a vessel is transferred to any other distant cistern by means of compressed air, and is the means of forcing a liquid from its previous position, for example, in an upward direction. In Hero's fountain the primary pressure is produced by the column of water *a* fed from the vessel above it; the air inclosed between *c* and the lower bulb is thus compressed, acts upon the surface of the fluid in *c*, and forces it to a corresponding height in *d*. All these compartments are also present in Girard's lamp, but are closely packed together for the sake of saving space, as is seen by the sketch, Fig. 2486, where the unimportant parts are left out. A is the reservoir for the forcing column of oil in the tube *a b*, B the lower vessel with the inclosed air B′, which conveys the pressure received from *a b* through *c d′ d* to the vessel C, and in the first instance to the air C′ contained in it. As long, therefore, as there is pressure from *a b*, the air C′ will cause the oil in C to rise in the tube *g h* to a corresponding height, (to the burner.) This height, therefore, depends upon the uniformity of pressure in general, and ultimately upon the constant uniformity of height in the column of oil *a b*, which has a tendency every moment to shorten the play of the whole, both from above and below; from above by the sinking of the oil in A, from below by its rise in B. To avoid the former, at least for the duration of an evening's consumption, the vessel A is furnished with a tube *e f*, upon the same principle as that described in the oil cistern at Fig. 2483, so that the height of the column of oil exerting pressure

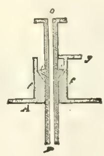
coincides with the aperture e, and all the oil above that must be considered as a store for the supply o' that column. The latter is obviated by the narrow vessel v which surrounds the aperture b, and is filled up to $s\,s$ in a few moments by the oil flowing from A, thus constituting a basis of uniform height for the column. Both contrivances are effective until the oil in A sinks below e, and has risen on the outside of v above the level $s\,s$ in B. With the requisite height of the lamps the pressure of the column would raise the oil to a greater height than is desirable. To avoid an excessive length of burner, the tube $c\,d'\,d$ may be curved like a siphon, as indeed was done by Girard, by which means the oil in $e\,f$ is caused to rise as much less as d is below the fluid level in C, therefore x less. The pressure is first exerted to overcome the column of oil x, and it is only the excess that exerts an upward influence in $g\,h$; the result is, therefore, the same as if the elevation in $g\,h$ was effected, not from the level of the oil at C, but at g, for $g\,h = e\,s\,s$.

Future endeavors to bring the principle of Girard's lamp into a form more suited to daily use will, perhaps, be successful; for the limited application which has been made of it must be ascribed to its inconvenient shape. The following points deserve particular notice; first, as is obvious enough, the working of the lamp is not independent of the changes of temperature and pressure in the atmosphere. Increasing pressure (rise of the barometer) and a lower temperature will diminish the bulk of the air inclosed in B and C, and cause an augmented flow of oil from A towards B. A fall in the barometer, and a higher temperature, will produce an opposite effect, and cause the oil to flow from the burner. The effect of temperature is the stronger of the two; but both by proper means can be rendered imperceptible, at least for the duration of an evening. Another and a greater objection arises from the position and the shape of the vessel C, upon which, as may be seen by the sketch, the supply of the burner is solely dependent, whilst the oil of A and B is only employed as a fluid pressure. C cannot well be made deeper without increasing immoderately the height of the lamp; there is, therefore, no other means of affording space for the requisite quantity of oil for an evening's consumption, than by adding to the breadth of this vessel. When this is done, and from its being placed immediately under the burner, the shadow falling between $o\,y$ and $o\,z$ will very much exceed the space occupied by the foot of the lamp. Lastly, the necessary additions and apparatus for filling the lamp deprive it of that ease and simplicity in the management which daily use justly demands.

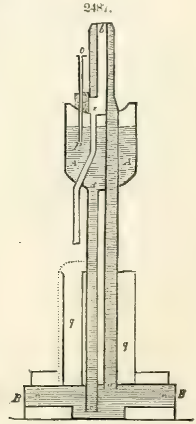
2486.



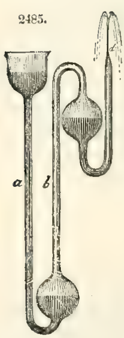
2488.



2487.



2485.



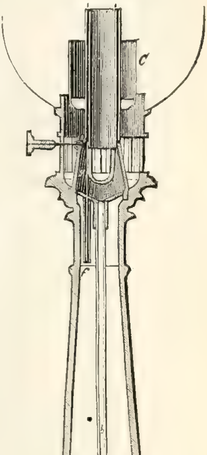
The hydrostatic lamp.—The doctrine of the equilibrium of fluid pressure has found an application in the hydrostatic lamps. Two different fluids, brought into tubes which are connected at the bottom, will balance each other at different heights, according to their respective densities. The one fluid will form a column as many times lower as its density exceeds that of the other fluid. A column of mercury requires to be only one inch in height to balance a column of sulphuric ether of 19 inches, or a column of oil of 14 inches.

After salt and water, syrup, honey, mercury, had all been tried as heavy liquids, Thilorier succeeded in 1825, at Paris, in giving a decided pre-eminence to his lamp by the use of a solution of white vitriol (sulphate of zinc) and by a suitable apparatus. When we consider that the fluid producing the pressure must not affect the oil or the sides of the vessel, (tinned iron,) that it must not become solid (crystallize) at

a temperature several degrees below 0° C., that it must be cheap, and have the proper density, we shall then understand how to appreciate the discrimination which led Thilorier to employ a solution of equal parts, white vitriol and water. Such a solution is 1·57 times denser than oil, so that a solution of zinc 10 inches high can support a column of oil 15·7 inches in height.

It is obvious that, with the diminution of the column of oil (the consumption of oil in the burner) the solution of zinc will sink to a corresponding level, and will only be enabled to force the oil to the original height, when it itself is fed by a reservoir of zinc solution. The cistern A in the section of the lamp, Fig. 2487, is solely for this purpose. In a chamber B, in the foot of the lamp, both the equally poised columns terminate, namely, the column of oil in the tube *a b*, which terminates above in the burner, and the column of zinc solution in *e d*, above which the cistern A is situated containing the zinc solution. The flow is effected in the manner described in Fig. 2483, by means of the tube *o* P, through which the external air enters bubble by bubble, as the solution in *e d* threatens to sink. The height of the column must, therefore, be reckoned from P; B is completely filled, and by both fluids at the same time, so that no air remains in it. Into the lower solution of zinc (extending to *n n* in the figure) the tube *e d* is plunged; into the oil above, on the contrary, the tube *a b* does not enter beyond the top layer of the fluid in B. From the time of lighting and during the combustion, the level *n n* naturally becomes higher and higher. At length B becomes quite filled with solution of zinc, and oil must be supplied. This is done by a separate funnel through the burner, which obliges the solution of zinc to return to its former position, an outlet being afforded for the air in A. The tube *o* P, Fig. 2488, (twice its proper size,) is intended for this purpose, having a conical appendage *h* accurately ground to fit into *f f*, and luted into the lid of A. The position represented is that for filling, and this is effected by the peg *g*, which is fixed to *o* P, and only rests on the edge of *f f*; when *h* is to be closed the tube is turned until *g* falls into a perpendicular cavity. The oil which overflows the burner in filling, and at other times, collects in the concave lid of A, and passes off by *i i* to a ring-shaped movable vessel *q*. This vessel is open and ring-shaped, to admit of the passage of *a b* and *e d* through the middle of it.

2489.



It must not be supposed, even when every thing goes on regularly, and the supply in A is not exhausted, that the level of the oil in the burner always remains the same, for the column *n a b* is constantly shortened by the rise in *n n*, and more rapidly than is the case with the zinc column *n* P during the same time. The inventor has succeeded in rendering this imperceptible for a duration of six hours, by making the diameter of B very large in proportion to that of *a b*. The difference of level does not actually exceed two to three lines, whilst the oil in the burners of astral and sinumbra lamps frequently falls one inch.

Pump lamps.—The general conclusion may be inferred from what has been said, that the different static lamps either do not attain the important advantages which their construction was intended to confer, or are accompanied with corresponding disadvantages. In contradistinction to these we have the lamps with a mechanical arrangement for raising the oil; and as a pump is generally employed for that purpose, they are called *pump lamps.*

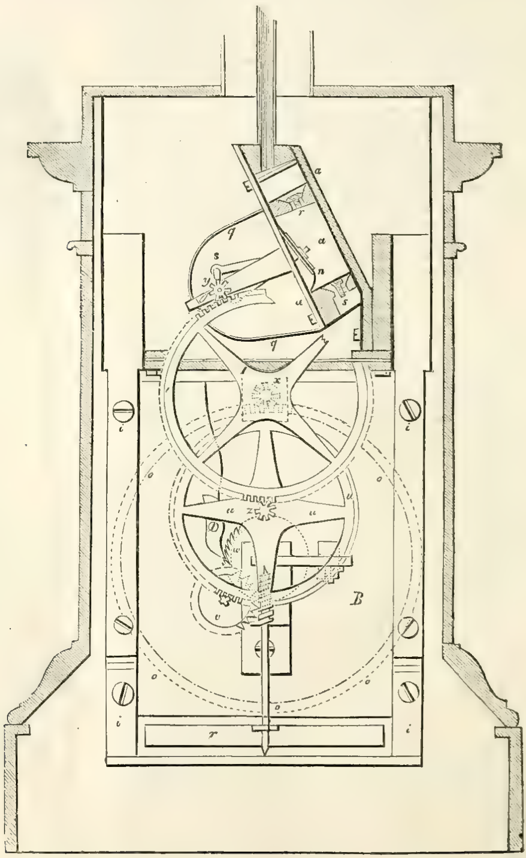
The simplest example of these is the pump lamp with a flat wick, very much used in the south of France, although not in this country: the motion of the pump is produced by the hand, but in a very imperfect manner. The piston of the pump is kept constantly raised by the tension of a spiral spring. As soon as the piston-rod, which is also the ascending tube and in firm connection with the burner, is forced down, by overcoming the power of the spring, the descending piston forces the oil in the cylinder to rise through the tube to the burner. When the stroke is ended, the elasticity of the spring brings the piston to its former position, and the cylinder becomes again filled. As candles require snuffing from time to time, so here, the pump must be used at short intervals. In lamps of this kind, with double draught, the burner is fixed, but then there is a piston-rod with a handle at the side of the ascending tube. The uniform working of such a lamp depends, therefore, upon the care which is taken to supply the oil that is consumed by repeated use of the pump. If this is only done at long intervals, the flame will vary from its utmost intensity to a very dingy light.

The numerous improvements which have here been noticed, with reference to the most successful and interesting inventions, must be considered as important advances; but they have nevertheless left one point out of view, upon which the most indispensable conditions for combining a perfect, and at all times, uniform evolution of light depend; a point which is indisputably the most difficult of all to accomplish. It has been noticed how the lowering of the oil level obstructs more and more the functions of the wick, and consequently diminishes in an equal degree the brilliancy of the flame. The lamps with a supply, upon the principle of connected tubes, are subject to this evil in its

entire extent; those with an inverted bottle or similar arrangement are also influenced by it within certain limits. In the former the brilliancy rapidly diminishes; in the latter it becomes lessened, and returns to its original state at regular intervals.

Carcel's clock-work or mechanical lamp.—Carcel, in the year 1800, was the first to carry out the idea of pumping up the oil from the foot of the lamp to the wick, by simple machinery like that of clocks, and, moreover, in such quantity as to exceed the quantity consumed during the whole period of burning. The invention of his clock-lamp is without precedent, with reference to the uninterrupted and perfect supply of oil to the wick. Whilst in the other lamps the burner contains a stationary column of oil, which either constantly decreases from above or is reinstated from time to time, the oil in Carcel's burner forms a constant ascending current, which always supplies the wick with as much as it can possibly require; and lastly, the unconsumed portion flows back to the foot over the outside of the burner.

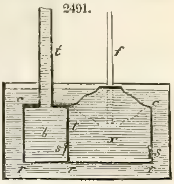
2490.



Carcel's invention left only unimportant points connected with the works and the pump to his successors, to which the skill of others has been applied. Figs. 2489 and 2490 present a section of Carcel's lamp and its various parts, with Penot's improvements. The chief parts of the lamp are arranged as follows: The case for the works B and the space A for the stock of oil, form the foot of the lamp. The stem of the column contains only the ascending tube *b*, which separates above (over the capital) into a forked appendage, (crutch,) upon which rests the burner with its two concentric tubes *e e* The burner

and the ascending tube form, therefore, a space which is connected with A by means of the pump. This latter is a so-called *priest-pump*, and is more simply represented in Fig. 2491. The space x is closed at the top by a piece of elastic cloth or leather, in the middle of which, when it is considered as a piston, the piston-rod is fixed. By its upward and downward motion, an alternate expansion and contraction of x is effected. In the first case the valve s opens, and oil enters x from $r\ r$; in the other case, through the valve s', oil passes from x, and is raised in the tube t. The motion of the cloth or leather acts in short in the manner of the cheeks and muscles in drinking and blowing. To meet the unavoidable obstructions which would result from the presence of impurities in the oil, it is all made to pass, whilst still in A and before entering the pumps, through a metallic sieve with fine holes q, which surrounds the whole of the front part, including the entrances to the valves below.

2491.



The quadrangular box of the pump contains, for preserving uniformity of action, three simple priest-pumps $c\ c\ c$, made of gold-beater's skin, which, during every moment they are in action, alter their positions relative to each other. This necessary circumstance is self-evident from the whole arrangement of the pump. Each single pump has two valves, an entrance valve (the under one in the figure) and an exit valve (the upper.) a is a separate chamber for each: the space for receiving the oil above the exit valve, on the contrary, is common to all. The three short piston-rods, if they may be so called, work upon three crooked arms B $y\ x$ on the same axis, but in different directions. One pump must, therefore, always be forcing, whilst the second is sucking, and the other midway between the two. Below, or in the direction of B, the chamber A is completely closed, with the exception of a stuffing-box, through which the crooked pin of the axle is moved. The wheel t passes under a box placed at the side, in which this stuffing-box is situated. The iron frame $i\ i$ serves to give steadiness to the works in B; the most important parts of the arrangement may be seen in Fig. 2490. Motion is obtained by the spring wound up in the case $o\ o\ o$, which is furnished with cogs. The cogs of $o\ o\ o$ first move the toothed wheel t upon the same axis by means of x. The wheel t catches the second cog y above, which has the same axis as the piston-rods, and thus the pumps are set in motion. Below, however, t moves the endless screw, on the axis of which is the fly-wheel d for regulating the works, by means of z, and the toothed wheel u and v. At the very bottom, on one side of the foot of the lamp, is a small bolt, which, when pushed forward, catches the fly-wheel, and either stops the works, when in motion, or sets them going when it is pulled back, and the whole has been wound up.

The stopping-wheel W is used for winding up the machine with a key.

The toothed rod g, with the wick-holder, works below the crutch of the ascending tube, in the case f.

Experience has shown that the whole arrangement of the works is not so tender and brittle as might at first sight have been supposed.

The overflow of oil from the burner makes it necessary to screw the wick up somewhat higher than in common lamps; and this brings with it the great advantage of the flame being more raised above the edge of the burner, where less heat is conducted from it, and it burns more perfectly, producing no carbonaceous matter on the wick and about the edge of the burner, which, in general, so materially interferes with the regular flow of oil.

Carcel's lamp would, without exaggeration, have been prized as much as Argand's had been sixteen years previously, if a less expensive and more suitable form for general use could have been given to it.

At an earlier period, and again more recently, the idea has occurred to those versed in these matters, to replace the complicated clock-work, either by the force of a falling body, (for instance, a piston in a cylinder,) or, at least, to cause the tense spring to act upon a larger piston of that kind. In both cases the oil is contained in a lamp-like vessel, resembling the cylinder of a pump, from whence it is slowly forced upwards by the piston (moved either by gravity, or a spring) to the burner.

So far, all is simple and easy; but the practical use of the lamps has always foundered on the difficulty of regulating the *acceleration* of the fall, or the *diminution of the force of the spring*, to the uniform demand of the burner. The arrangements of this kind are all wanting in simplicity, or they effect their purpose but imperfectly. Generally, the ascending tube is contracted conically at a certain spot, into which a conical plug fits. The spring in rising enlarges the aperture at the contracted spot, whilst the sinking piston lessens it, by forcing the plug either backwards or forwards, in proportion as their motion is irregular.

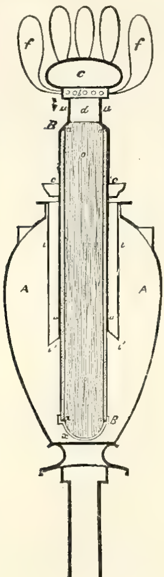
The application of a phenomenon for raising the oil in lamps, first proposed by Celarier, is worthy of notice, from its novelty and simplicity, and because it may possibly be productive of something else, not from the use actually made of it at present, which is by no means established. It is of very common occurrence, and may easily be observed. Celarier's lamp consists principally of two vessels, fixed one above the other, which are separated from each other by a partition; the upper contains oil, the lower air. In the partition, a narrow tube is placed, which opens into the air-chamber below by a valve, and somewhat higher in the oil vessel with a simple aperture. On filling the lamp, the oil in this tube rises to the same height as in the vessel; but as soon as the valve is opened, the air begins to escape by the same tube as that through which the oil is passing, in endeavoring to fill the lower vessel. The result is—with such a narrow tube—that with the bubbles of air, drops of oil, or rather little columns of oil, are carried up much above the level of the oil. Another plan, applied by Samuel Parker and Mallet, in which the oil is warmed in a ring-shaped vessel above the flame, before reaching the burner, promises theoretically to be of value, but requires to be subjected to further proof.

Lüdersdorff's lamp.—In Berlin, the prices admit of using instead of pure oil of turpentine (that is, the lighting material of Lüdersdorff) a mixture of this spirit with 4 parts of strong alcohol, of at least 90

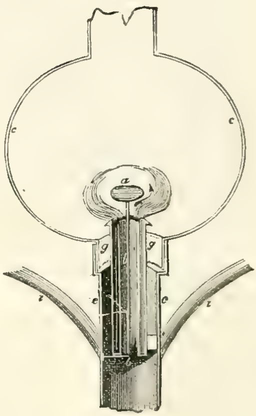
per cent. (This is the camphene in use with us.) This strength is necessary; for, with a greater amount of water the flame would be too much cooled, and the oil of turpentine be imperfectly held in solution. The carbon, originally amounting to 88 per cent., or 8 times the quantity of hydrogen, is diminished by this mixture (illuminating spirit) to 63 per cent., or three times the hydrogen, which is much less than is contained in oil or tallow. The lesser evolution of light, from the same weight of spirit, is, however, actually compensated, although at some cost, by the greater rapidity with which the light is evolved from the same quantity. Lüdersdorff's lamp, Fig. 2491½, is well adapted to show the different mode adopted in burning the volatile oils, from that employed with the fats.

A is the vase for the illuminating spirit, into which the burner B descends from above almost to the bottom. It consists first of a straight, pretty wide metal tube *a a*, fitting tightly into the real burner-tube *u u*, which surrounds a loose cotton wick *o o*, and fastens it by the semicircular piece *x*. Above A, at

2491½.



2492.



a distance of about two inches, (the wick extending thus far,) the tube becomes narrower, and ends at *d*, in the knob *c*, which is the real burner; at the base of *b*, from ten to twelve holes, ¼ line in bore, are made in a circle at equal distances from each other. When the lamp is to be used, common spirits of wine is ignited in the cup *e e*, to vaporize the illuminating spirit in the upper part of the wick. As soon as the vapor issues from the apertures *b*, it is ignited, and forms the flames *f*, which surround the knob *c*. The metallic mass is then sufficient, on account of its high temperature, to keep up vaporization with ease, (even at the distance of *c* from the wick,) and the lamp continues to burn by itself. To protect A from the action of the burner, which gradually becomes heated, the latter is surrounded, to the depth of three inches, with a wide case *i i*, which is attached to it below, (at *i i*,) so that a space filled with air surrounds it thus far. Lamps of this kind give a costly but brilliant light, free from all the inconveniences of common wicks.

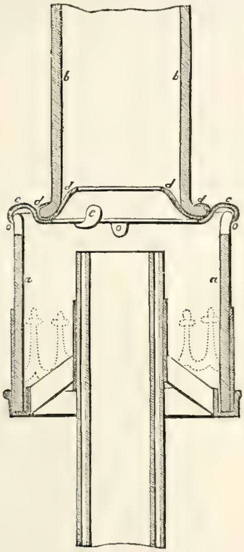
The Liverpool burner.—The original Argand burner *g*, Fig. 2492, is supplied with oil by the tube *i*. At its lower aperture a wire *b* is fastened, which rises through the axis of the burner to a few lines above its upper margin, where the projecting end is furnished with a screw. This is intended to support a round copper plate *a* (in the shape of a button) of equal diameter with the wick. It is difficult, at first, to establish the proper relation of distance between *a* and the margin of the burner, but it is easily found, experimentally, by screwing the plate backwards and forwards. As the result of this arrangement, the internal draught is forced from its original perpendicular direction, and broken against the plate *a*, whence it is propelled at a sharp angle, nearly horizontally, against the flame, which thus assumes a globular, instead of its ordinary cylindrical form, and (as is shown in the figure) is forced into contact with the external current. The form of the flame makes it necessary to have the peculiar bulging chimney *c*, and this is supported by the case *e* of the burner. Complete combustion, together with

intense brilliancy and whiteness, characterizes the flame · but there is nevertheless a certain want of uniformity, which, however, does not exist in the nature of the principle, and can be avoided by a proper regulation of the draught.

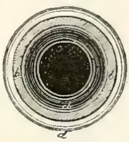
The lamps constructed by Benkler and Ruhl, in Wiesbaden, since the year 1840, depend entirely upon the same principle, causing the draught to impinge at an angle upon the flame. The apparent novelty of the invention, the surprising brilliancy and peculiarity of the flame, and partly the solid and elegant workmanship of the lamps themselves, led the public, at least for a time, to confound these advantages with the more essential one, namely, the economical consumption of the oil, and created in a short time an enormous demand for this invention. Some hasty experiments, which were published, tended very much to augment this over-estimation of its value.

Fig. 2493 is a sketch of the general plan of Benkler's burner. Fig. 2494 is the ground plan; and Fig. 2495 represents the upper distinct parts. The shoulder of the chimney is here formed at the junction of two pieces; a narrower glass *b*, above the flame, and a wider glass *a*, which is below it. Just at this junction is placed the most important part of the arrangement, which consists of a conical

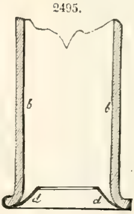
2493.



2494.



2495.



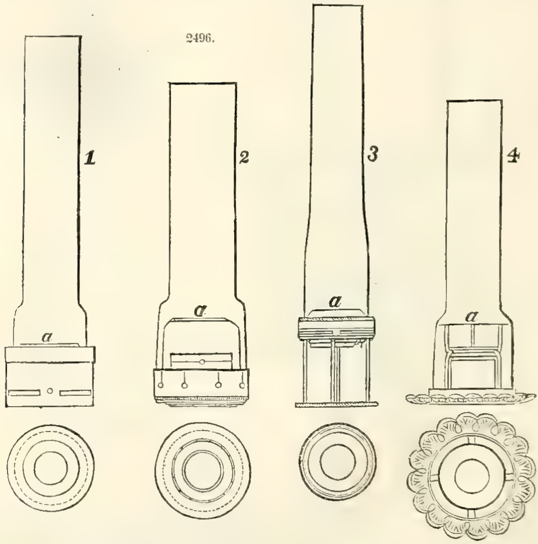
ascending brass ring *d d*, with an aperture of the same diameter as the wick. This flat, open cone is immovably fixed to the upper glass *b*, by bending up its outer edge, Fig. 2495. The connection of *b* with *a* is effected by a so-called bayonet joint. For this purpose, on the lower margin of the plate *d*, there are two tongues *e*, and these correspond with two cuts in the ring *c*, with which the margin of *a* is encircled. When, therefore, *d* is so placed upon *a* that the tongues and cuts correspond, a simple turn of *d* is sufficient to bring the tongues under the ring *c*, and thus secure the whole. The apertures *o o* are made around *a*, to increase the draught from without. The principal addition, therefore, in Benkler's lamp is a sudden contraction in the chimney at a certain distance from the flame, the aperture being of the same diameter as the wick, and this is produced by the insertion of a metallic ring, or cone.

The action of such a contrivance is easily understood. The external and internal currents of air and the flame must pass through the aperture of *d*, where a rapid contraction results. The outer current is driven against the axis of the flame at a sharp angle, and thus forces the flame itself into the inner current, so that an intimate mixture of air is effected with the products of decomposition of the oil. The flame becomes narrower, and three times as long, when, by keeping back all the air which has no part in the combustion, and by giving a proper direction to that which has, the highest and whitest brilliancy, and considerable evolution of heat, is attained. A perfectly white heat is produced; for, in consequence of the well-ordered combustion, the suspended particles of carbon are more intensely heated than in any other lamp. Notwithstanding the intensity of the heat, the chimneys—in corroboration of what was stated above—stand well. A very short portion of the flame, that which produces the least light, is naturally situated below the cone *d*; but the longer portion, the essentially luminous

part, is above, and throws a shadow from *d* downwards, which is perceptible in standing and hanging lamps, but is of no moment in the determination of the intensity of light, as it only occurs in the direction of the edges of *d*. As the cone *d* has no other object than that of producing a sudden contraction, chimneys are now made in one piece with an inward bend in the proper place.

The lamps constructed by Benkler and Ruhl are on the principle just described, and have been carried out in this country under the name of Solar Lamps. The main point in the peculiar construction of these lamps, is the manner in which the air is caused to impinge upon the flame by the adaptation of a metallic or glass cone, represented at *a* in the figures below. The introduction of air at this particular part of the flame, or at this certain angle, admits of crude cheap oil being consumed in the lamps, which would produce smoke if burnt in lamps of the ordinary construction. The combustion of this oil in the ordinary manner being attended by an evolution of smoke and smell, indicating an imperfect consumption of the constituents of the oil, gives rise to the necessity for an increased supply of oxygen or air to that particular part of the flame where these unconsumed portions are evolved, to produce the inodorous and invisible products which alone should result from perfect combustion. The oil in the solar lamp is contained in an annular vessel, similar to that described at Fig. 2478, and the lamps are constructed in precisely the same manner, with the exception only of the burner. The first form in which the new burner was introduced is represented in section at 1, Fig. 2496, and consists of a solid metallic box fixed upon the circular wick-holder of ordinary construction, so that the cone or

2496.

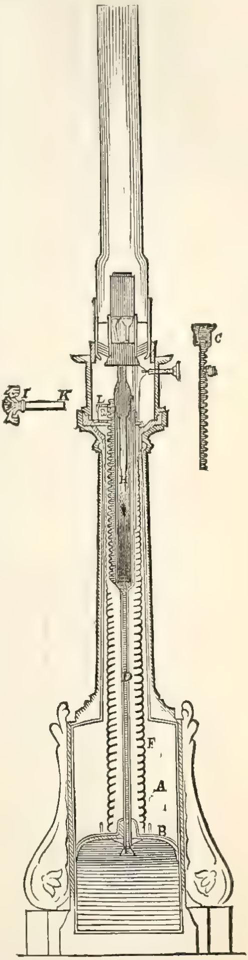


contracted aperture *a*, shall be bare ⅛th of an inch above the top of the wick-holder. This relative position is observed in all the burners. This form of cone box was found very inconvenient, by becoming exceedingly hot and throwing a considerable shadow, it was consequently soon superseded by that represented at 2, Fig. 2496, in which the metallic box is very much diminished in size, and the cone is composed of glass, with a small ring of metal round the mouth *a*. This ring of metal is essential, as it is necessary that the aperture should be always of the same diameter, and glass cones can never be made with sufficient nicety to present at all times an exactly similar mouth. The solid box was subsequently replaced by the open skeleton cone holder represented at 3, Fig. 2496, called the screw cone glass-holder, in consequence of the tall thin chimney being screwed on to the top of the holder. The last improvement is the plate cone glass-holder represented at 4, Fig. 2496, in which the metallic cone is replaced by a flat metallic ring fixed upon a skeleton support, the external edge of which fits closely to the glass chimney.

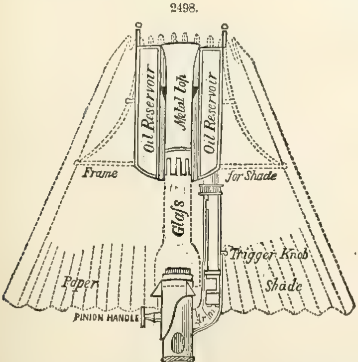
In the last form of burner, little or no external current impinges upon the flame from the outer sides of the cone or its substitute; but the flame is only forced inwards so as to come more completely into contact with the current of air passing through the interior of the burner. The solar lamp has been extensively used in consequence of the low price of the oil which it consumes; it requires, however, a good deal of care and cleanliness in trimming, the wick must be freshly cut every time the lamp is used, and the reservoir should be refilled with oil.

A form of pressure lamp, called the Elliptic lamp, in which the constant flow of oil to the wick is regulated in an ingenious manner, has been patented, and is found to answer perfectly, even when crude vegetable oils are consumed in it. Fig. 2497 represents an entire section of the lamp. The foot of the lamp forms at the same time the oil cistern: it is of a cylindrical shape, and a leather piston or valve B, is worked up and down in it by rack and pinion seen at L. F is a spiral spring of strong iron wire fixed at the top to the solid stem of the lamp, and exerting a constant pressure on the piston, so long as it is in any position above the bottom of the oil cistern. The tube D, which opens at the bottom in the shape of an inverted funnel, and ends in a disk pierced with holes, supplies the oil to the burner and passes in an air-tight manner through a stuffing-box in the piston B, and can thus be moved with ease, the piston remaining stationary. This tube D, is widened above on approaching the burner, and receives a fine silver tube several inches long, and one-thirtieth of an inch internal diameter, which is surrounded by a cap of gauze, made of copper wire tinned, to prevent corrosion. This gauze has very small meshes, that no solid particles mechanically mixed with the oil may be carried up into the silver tube, and thus impede or altogether stop the passage of the oil. The whole of the oil must pass through the silver tube before reaching the burner, and the friction thus exerted against the sides of the narrow tube is the only resistance offered to the oil, which would otherwise be forced up all at once to the burner by the pressure of the spiral spring. This, therefore, is the regulator for the supply of oil, and must be so proportioned in length and bore to the force of the spring, as to admit of a constant excess of oil flowing to the wick and over the sides of the burner, where it is caught in a receptacle and carried back into the oil vessel at the foot of the lamp. The lamp is filled with oil by slightly raising the whole interior portion from L, and pouring oil through the stem to the cistern below; the oil then rests in the first instance on the top of the piston. The whole interior portion of the lamp is then wound up by the key I K and the rack-work L, until the top of the cistern prevents the piston B from ascending higher. The tube D and the burner, &c., attached to it is then pushed down by the hand through the stuffing-box until it attains its original position. The oil which was previously above, having passed

2497.



2498.

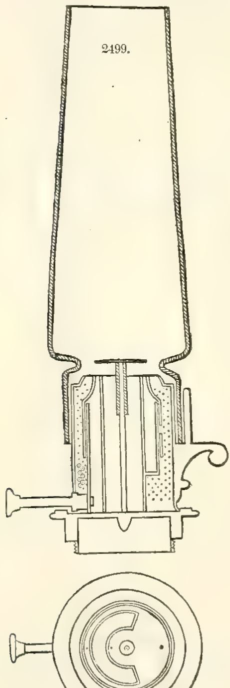


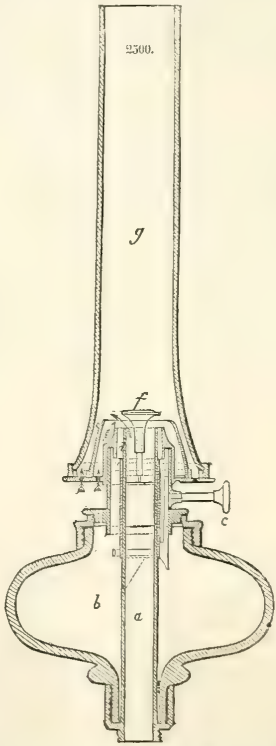
during the ascent of the piston between it and the sides of the cylinder, is now below the piston, and the spring in forcing the latter down will tend to force the oil out through the tube D to the burner. The force of the spring and the resistance offered by the silver tube are so proportioned that the supply of oil shall last eight or ten hours.

The thick consistence of crude whale oil offers such powerful resistance to the action of capillarity at the ordinary temperature of the air, that the oil cannot be burned in common lamps, unless it is previously rendered more fluid by the aid of heat. To effect this a very ingenious form of lamp has been introduced, called the Economic, or hot-oil lamp. The oil reservoir of this lamp, Fig. 2498, is composed of a double cylinder surrounding the upper part of the chimney, which is constructed of

metal and slightly curved outwards, so as to reverberate the heat upon the oil vessel, and heat the oil to a considerable extent. The hot oil then descends by the arm to the burner, as shown in the figure. The lower part of the arm, which is attached to the oil vessel, is furnished with a slide valve worked by the trigger, so that the supply of oil can be cut off by raising the trigger, and the oil vessel entirely removed from the lamp for the purpose of filling, &c. The oil is introduced by this valve, the oil cistern being inverted, and this should be refilled each time the lamp is used, care being taken that no air remains in the vessel, as this would be expanded very much by the heat, and cause the oil to overflow

The flame is regulated by raising or lowering the bell-mouthed glass chimney, which rests upon three points below and is moved by rack and pinion. The wick is not movable, as is the case in ordinary lamps, and a fresh wick, which is accurately cut by machinery expressly for this lamp, must be inserted every time the lamp is used. A paper or glass shade surrounds the whole of the upper part of the lamp, according as the light is required to be thrown downwards or uniformly diffused through the apartment. Dr. Ure has reported the illuminating power of this lamp to be superior to that of Carcel's mechanical lamp, and when consuming southern whale oil, it would appear from his statements to deserve the appellation of the "Economic" to the full extent of the word.





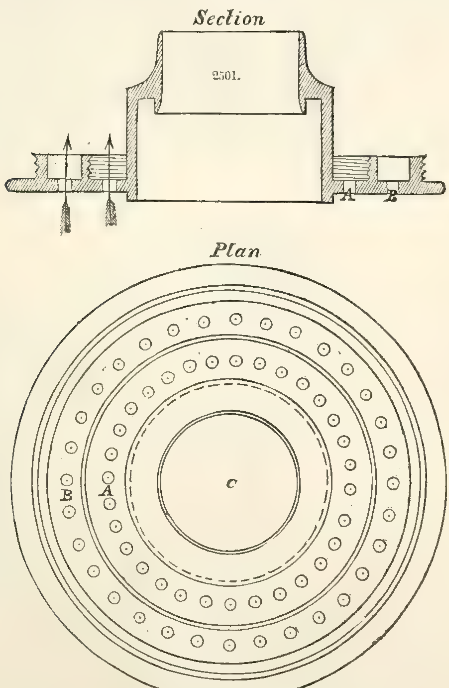
Camphene lamps.—It is only within the last few years that oil of turpentine or camphene has been successfully introduced into general use as a source of illumination; and it is by applying the principle of the solar cone in an extended manner that this highly carbonaceous substance can be completely and conveniently consumed. The pure oil is clear, colorless, and very mobile; it has a peculiar smell and a burning taste. Its specific gravity is 0·86 to 0·87. The commercial oil is frequently adulterated with resin, which raises the specific gravity, and which increases in quantity when the oil is exposed, in consequence of the absorption of oxygen from the air. When pure, the oil boils at 312°, and contains no oxygen, but consists of:

88·46	carbon.
11·54	hydrogen.
100·	

A glance at the composition of this substance, containing so large an amount of carbon, shows that

it must be a powerfully illuminating body, if proper modes can be adopted of supplying a sufficient quantity of oxygen or air for the entire consumption of the two combustible constituents, and at the same time so regulating the order of combustion that the full amount of light shall be obtained from it.

Mr. Young was the first who applied the increased draught of air produced by a cone to the flame of oil of turpentine. The burner of Young's Vesta lamp is shown in Fig. 2499. It is an ordinary Argand burner with a Liverpool button *a*, for deflecting the internal current of air, which enters by a space left open near the pinion handle and passes through *a*, against the inner side of the flame; *b* is the wick tube and *c* the space between the latter and the cone, which only rises in this case to the same level as the burner. Through *c* a current of air impinges upon the flame at that part where it is expanded by the button *d* and the internal current of air, and again the air in passing up the inner sides of the chimney is deflected inwards upon the flame by the contracted portion at *e*. *f* is the pinion-handle for raising or lowering the wick. The whole of the burner is screwed upon the glass vessel containing the oil of turpentine, and completely insulated by a ring of wood or other non-conducting material. No metallic tube passes through the spirit to supply air to the interior of the flame, as it was supposed that this would become too strongly heated and give rise to acrid and offensive fumes from the volatile spirit. Fig. 2499 shows a plan of Young's burner. This lamp, when properly managed and supplied with pure camphene, gives an excellent light, much superior to that produced by any oil lamp; but if attention is not paid to the management, or the camphene is not pure, it frequently evolves a strong smell of turpentine, producing headache and other disagreeable sensations, or large flakes of soot escape unconsumed and cover every thing in the vicinity. The evolution of smell or soot is always the result of imperfect combustion, and the lamp has been modified in different ways to avoid the possibility of unconsumed products being evolved.



The lamp which fulfils the conditions for the perfect combustion of camphene in the most successful manner, is the Gem lamp, a section of which is shown in Fig. 2500. It differs from Young's lamp, in the mode of deflecting the currents of air, and in allowing the Argand tube supplying the internal current of air to pass through the reservoir containing the oil of turpentine. In Fig. 2500, *a* is the tube supplying the internal current of air which passes through the reservoir *b* to the burner *d*, with which it is in metallic connection, and it is not found that the turpentine is heated by this tube to more than one or two degrees above the temperature which it attains in Young's lamp; the temperature of the

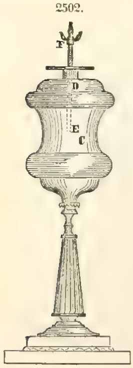
spirit in both cases being from ten to fifteen degrees above the temperature of the surrounding air and this appears to be no more than is required for the proper action of lamps of this description The button *f*, which deflects the inner current upon the flame, and forces the flame to take an outward direction and come into contact with the first outer current, has the form of an inverted cone, and the deflection of the air is consequently not so abrupt. The supply of air to the inside and outside of the cone is regulated by a series of holes drilled in the brass gallery, and the number and size of these holes are proportioned to the size of the burner, or to the quantity of air admitted through the internal channel.

Fig. 2501 shows a plan and section of the gallery. C is the space occupied by the inner current of air deflected outwards by the button, A the first series of holes admitting air to the interior of the cone, and B the series of holes through which the air passes to the exterior of the cone. The circle A has 32 holes, drilled with a drill one-twelfth of an inch in diameter; the circle B has also 32 holes, drilled with a drill one-tenth of an inch, this number and size of the holes having been found by a series of experiments most advantageous for a burner of the dimensions represented in the drawing. The cone *o*, Fig. 2501, in this lamp, rises above the level of the wick tube, so that the inner current of air and the first outer current meet the flame below the button at the point represented by the meeting of the two arrows. The outer current of air, passing through the holes in the circle B, meets the flame at a higher level, and insures the complete combustion of any products that may have been unconsumed after passing the point where the arrows meet. The height of the chimney will of course materially alter the draught, and an additional quantity of air must be admitted if the chimney is heightened. The proper quantity of air and the direction of the different currents to those parts of the flame where they are most beneficial, are the objects aimed at in the construction of this lamp, and they appear to have been attained more perfectly in the Gem lamp, than in any other spirit lamp yet invented. A Gem lamp of the larger form is reported to give a light equal to 20 wax candles: the light from one of the smaller size is equal to 13 wax candles.

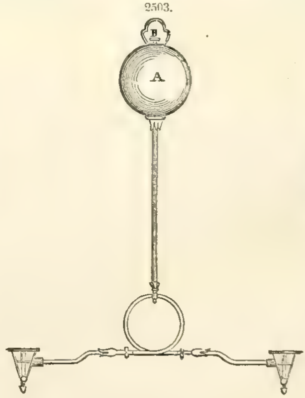
LAMPS, SPIRIT-GAS. The lamps which we here present are designed to burn the gas of the so-called "spirit-gas," which is a composition of alcohol and turpentine distilled together. No wick is burned, and only in the lamp, Fig. 2502, is a wick used, and only for capillary attraction.

C is the reservoir of the fluid. D is a brass tube extending into the fluid, and it has a cap at the top, perforated all around. F is the flame ignition points of the gas, as it comes out of the perforations. E is the wick; the wick, by capillary attraction, carries up the fluid by heating the top of the tube D until the fluid becomes gaseous, it then rushes out through the perforations, and is ignited in a state of inflammable gas, as represented at F. Great numbers of this kind of lamp are now manufactured and used in this city.

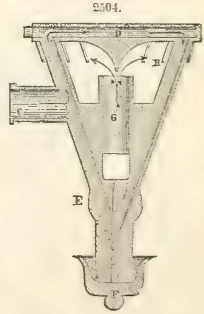
2502.



2503.



2504.

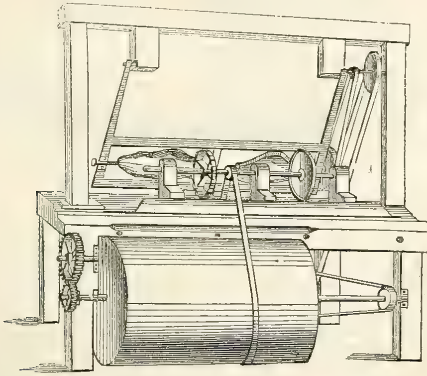


Figs. 2503 and 2504 is another kind of lamp altogether. It does not use any wick at all. Fig. 2503 is a front elevation of it, and Fig. 2504 is an enlarged section of one of the burners. A is the camphene reservoir, which can be filled at the top. B is a handle passing down the centre of the vessel and fitted to a conical valve at the bottom, where it joins the top of the central vertical tube, so that the flow from the reservoir may be cut off at pleasure. Two curved stems carry the burners, the construction of which is particularly represented in Fig. 2504. C on the right is the screwed attaching branch-pipe. The camphene enters by this branch and passes through the diaphragm, as represented by the arrow; thence upward by a sloping arm into the top horizontal passage D, which is formed on the surface of a circular disk surmounting the whole. It then descends by the opposite arm to the flattened boss E, and rises through a small conical aperture in its centre. This aperture is fitted with a conical spindle, screwed at its lower end, and in one piece with the cup F, which answers as a nut for turning the spindle to adjust the size of the opening. The course of the gaseous matter is then directed through the central chimney G, and is deflected by the inverted cone above it, and it then rushes out by a circular

ring of eight, ten, or more jets, like those of Fig. 2502. The burner is of brass, and the rest may be all cast in one piece, with the exception of the bottom cup. By unscrewing the cup a wire can be introduced to remove any obstructions in the side tubes, but no obstructions are at all likely to get in them. In lighting this lamp a few drops of alcohol is poured into the cup F and ignited, when the heat volatilizes the camphene in the passages of the burner, which can then be ignited, and the heat resulting from the ignition of the gases so produced, by acting upon the inverted cone at H, keeps up a continuous stream of gas. For suspension lamps, this one has no ordinary qualities to commend it. It no doubt requires attention, but the way in which it heats the fluid, and generates a very rarified gas, renders it capable of giving a very brilliant light.

LATHE FOR TURNING IRREGULAR FORMS—Blanchard's. Fig. 2505. This machine is represented in the figure in its most simple form, for turning shoe lasts, and is so constructed that, from one as a pattern, an exact *fac-simile* can be formed from a rough block of wood. Both the pattern and block are fixed on the same axis, and are made to revolve around their common centre, in a swinging lathe, by a pulley and bolt on one end of the axis, as shown in the figure. On a sliding-carriage is attached three posts, through which are fixed pivots, to which are suspended the axles of a *cutting* and a *friction* wheel. The cutting-wheel, which is about one foot in diameter, turns on a horizontal axle, and to its periphery is fixed a number of crooked cutters to act like a *gouge* when the wheel is put in motion. This cutting-wheel is placed opposite the rough block. The friction-wheel, which is of the same diameter as the cutting-wheel, is placed opposite the pattern, so as to press against it when in motion. These two wheels are in a line with each other, and are attached to the same carriage. On the axle of the cutting-wheel is fixed a pulley, around which passes a band which puts the cutting-wheel in motion by a large drum revolving under it. A crank or first mover communicates motion to the drum, which in its turn transfers a rapid motion to the cutting-wheel, while a band which passes from a small pulley on the drum-shaft, puts in operation a feeding screw-pulley, which moves the sliding-carriage horizontally from left to right. Another pulley on the drum-shaft gives a slow rotary motion both to the pattern and the rough block, in a direction opposite to the cutting-wheel. The friction-wheel is turned by the pattern resting against it.

2505.



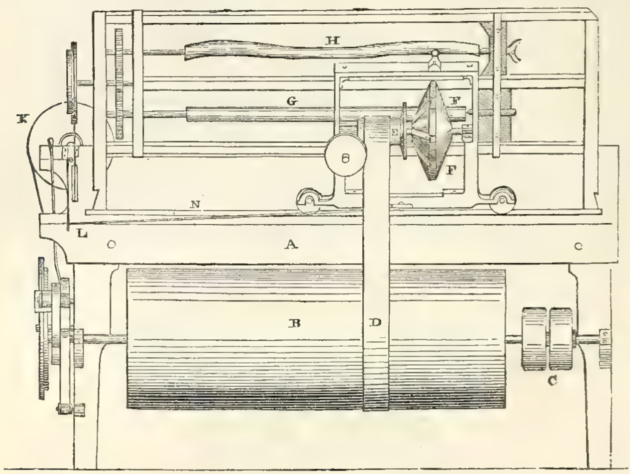
During the revolution the pattern, being irregular in its surface, causes the axis to approach and recede from the wheel. Thus, it will be seen, as it presents its whole surface to the friction-wheel, so in like manner the *block* presents its surface to the cutting-wheel, which being in rapid motion, cuts away all that part of the block which is further from the common centre than the surface of the pattern, and thus forms, from a rough block, an exact resemblance of the model.

Another application of the same principle is shown in Fig. 2506. This machine can turn out a duplicate or *fac-simile* of any pattern whatever, and it is now brought to such perfection that an oar-blade, a spoke, a last, and an axe-helve, are all turned upon it with equal facility and equal perfection.

This is a front view, as seen looking somewhat down upon the machine. A is the frame. B is a large drum. C is a driving-pulley. D is a band which, from the drum, passes over a pulley E, and drives its rotary cutter-wheel F F. This cutter-wheel is fixed on an axis in a small sliding-frame which moves from one end to the other of the lathe by a cord N winding upon a spindle lying across the machine, which cannot therefore be seen, but which is driven by the large pulley K, thus giving it a requisite slow motion. H is the pattern axe-helve, and G the rough material to be cut exactly like H. The pattern and rough material are placed in the lathe, represented by the upright frame, and sustained by spindles. On the back part of the machine there is a curious but beautiful sliding-rest, which is the subject of a patent in itself. It moves along after the cutter-wheel, and has two plane faces on which the pattern and cut helve rest. The pattern and helve roll upon the planes, while the rest has a rocking motion which accommodates itself to all the uneven turning of the patterns, &c., as they revolve. For turning long articles, this rest is a beautiful and positively necessary part of the machine. To turn a *fac-simile* of any pattern it will at once be evident to every mechanic, that if a pattern be placed in

a lathe, and the material to be turned be placed with its axis of rotation similar to that of the pattern, and if a guide pressing on the pattern directs a wheel with cutters to operate on the rough material over a surface like the pattern as guided, a perfect representation of the pattern will be produced on what was the rough material—simply by the cutters chipping away all the rough material outside of the axis of direction—in other words, all the wood on the rough material outside of the pattern. This is the principle upon which this machine is constructed. The cutter-frame slides from one end to the other of the pattern; and the small guide seen on the frame pressing on the pattern, makes the cutters chip away all the rough material outside of the pattern on G, as the cutter-frame moves from end to end of the lathe. The cutter-wheel has three motions—a rotary, a horizontal, and an eccentric motion

2506.



The pattern and rough material revolve in the lathe. This is done by three pinions on the right, moved by the pulley seen above K. The speed of the spindles in the lathe is regulated by a very excellent arrangement of a small gang of pulleys and straps, seen on the right at the end of the machine. These pulleys are operated by a lever L, and they are so arranged that a slower motion is communicated to the spindles when the thicker part of the pattern is to be turned, or such a part as an oar-blade. The cutter-frame moves along from one end to the other of the lathe upon a rail, and it is pressed out and in according to the shape of the pattern, by the upper guide; and the cutter-wheel being directed in the same manner, thus cuts the pattern on the rough material. The strap D is retained in its proper place by a grooved pulley on the cutter-frame, and the whole kept firm and snug to the work to be turned.

LATHE, SMALL ENGINE. Fig. 2507, side elevation. Fig. 2508, end elevation.

S is the bed-piece and head-stock, cast in one piece.

B, spindle which runs in gun-metal boxes.

C, cone-pulleys on live spindle.

D, upper cone-pulleys for driving feed-shaft.

D′, lower cone-pulley for driving feed-shaft. It runs loose on a stud, and has a pinion on inner end to drive the two worms.

E, worms—one right, the other left—which drive the two worm-wheels so as to feed towards the right or left, as the operator may wish. On the worm-geer shaft there is a pinion driving a geer on the shaft above, which has a chain-pinion, around which an endless chain passes, attached to the rest.

A is a hand-wheel for moving rest by hand. There is a pinion on the other end of the hand-wheel shaft geering into a rack K on the side of the bed, as shown in Fig. 2507.

F is the tool-holder.

J, top part of the rest which slides crosswise of the bed by means of the crank and screw.

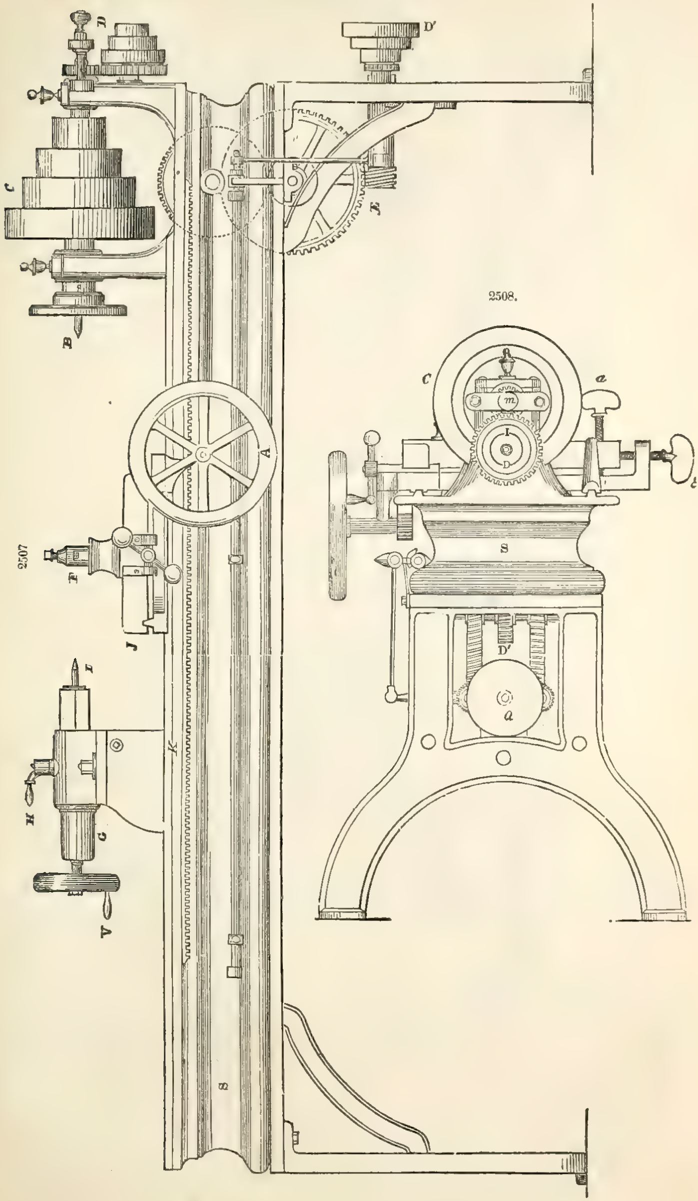
I, square spindle, which is moved by hand-wheel V, and screw inside of shell G. It is held firm in its place by the handle-nut H.

a, thumb-screw for raising rest.

m, step-screw.

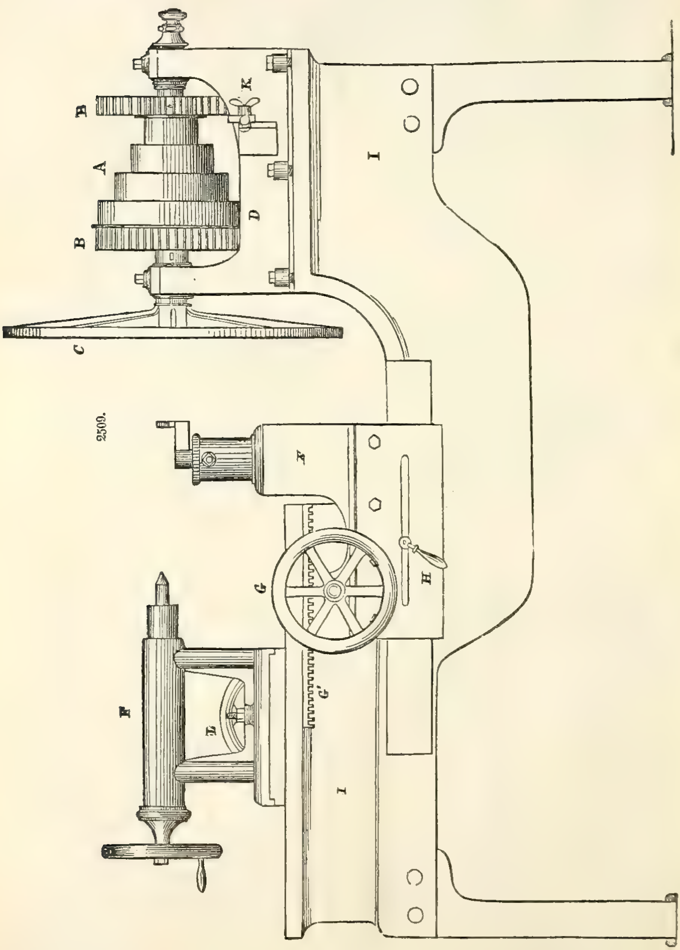
b, thumb-screw for adjusting tool in rest.

This lathe will swing 16 inches over the sills and 7 inches over the rest.



2507

2508.



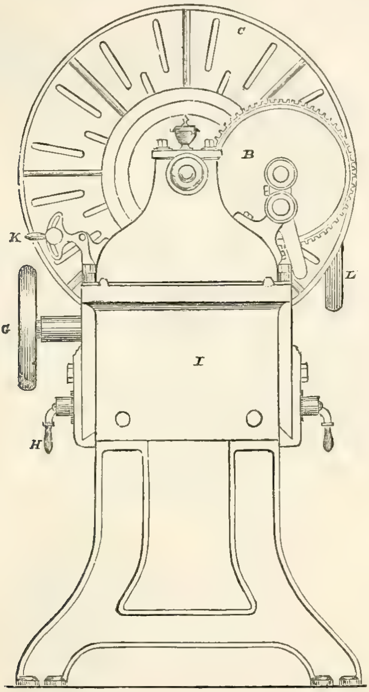
2509.

LATHE, BORING AND REAMING. Figs. 2509 and 2510. I, the main bed-piece, supported by two cast-iron standards.

D, head-stock, which carries the spindle and cone-pulleys A.

G, sliding-frame that supports rest P. This frame is traversed backward and forward by means of the hand-wheel R, which has a pinion on the other end geering into the rack G on side of the bed, (seen in Fig. 2509,) and is held down by the plates N, which hook under the slides S, and is secured by means of the nuts with handle H, one on each side.

2510.



C, face-plate on live spindle, to which the work is fastened by bolts when drilling or reaming.

F, tail-stock, with a traversing spindle, worked by the hand-wheel M, which turns a screw inside of spindle in the usual way, for pressing in the drills or reamers, &c.

L, hand-wheel on a screw for setting the tail-stock so as to make a tapering hole.

A, cone-pulleys on spindle.

U, geer on spindle.

b, pinion on spindle, playing into geer B.

B, geer on back shaft for reducing motion of spindle and increasing the power—same as is common in geered head-lathes.

K, handle for throwing the back geer-shaft out of or into geer.

This machine will bore out a hole 3 inches diameter in a wheel 3 feet diameter

LATHE, ENGINE. Figs. 2511, 2512, 2513. Will swing 50 inches in diameter over the ways, and 32 inches in diameter over the rest.

Fig. 2511 is a side elevation of the engine.

Fig. 2512 is an end elevation.

Fig. 2513 is a side elevation of the tail-stock.

P represents the bed-piece which supports the head and tail stocks and rest.

C is the head-stock in which the live spindle runs; it is made in a saddle form, and very heavy; bolted to bed-piece by six bolts.

B B′ are the geers by which the motion of the spindle is reduced and the power increased.

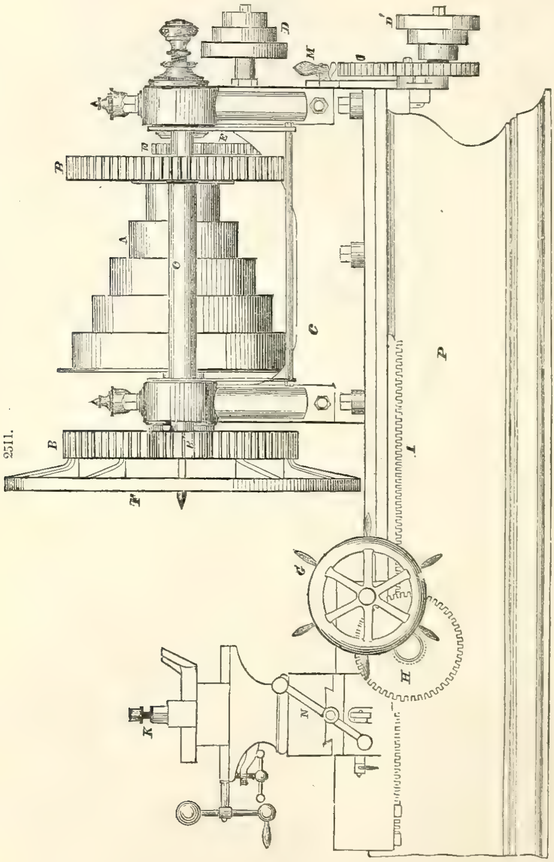
D D′ are small cone-pulleys for driving the long feed-screw, which is on the inside of the bed-piece, and not shown in the drawing.

O, geer on end of feed-screw, driven by a pinion on the hub of the lower feed-cone D′.

A, cone-pulleys on spindle of cast-iron.

F, face-plate with geer B attached to the back side.

K, tool-holder, which slides upon a swivel-post S, that can be set at any angle and fastened by the lever and screw R to the block N, which slides crosswise of the bed-piece by means of the crank and screw with a balance bolt seen in Fig. 2511, and at N′ in Fig. 2512.



2511.

G is a hand-wheel for traversing the rest by handcraft. This wheel runs on a stud, with a pinion on its hub which works into the geer H. H is placed on the end of a short shaft with a pinion *h* on the other end, geering into the rack I attached to the side of the bed.

T is the main sliding-saddle or plate for the rest; it is very heavy, and permanently fitted to the slides and hooked down by pieces J, and is well adapted to fastening on heavy work for boring, &c.

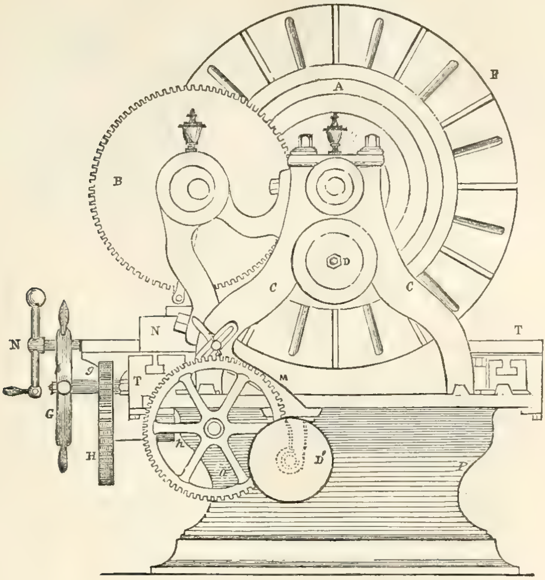
M, lever for changing the direction of the feed.

U, handle for stopping and starting feed.

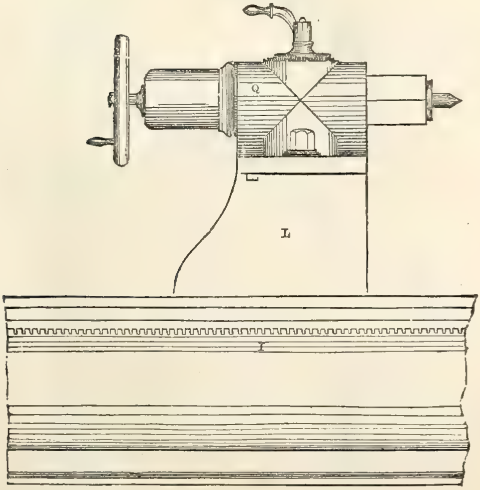
L is the lower part of tail-stock, which is notched on to the slides or ways of the bed-piece.

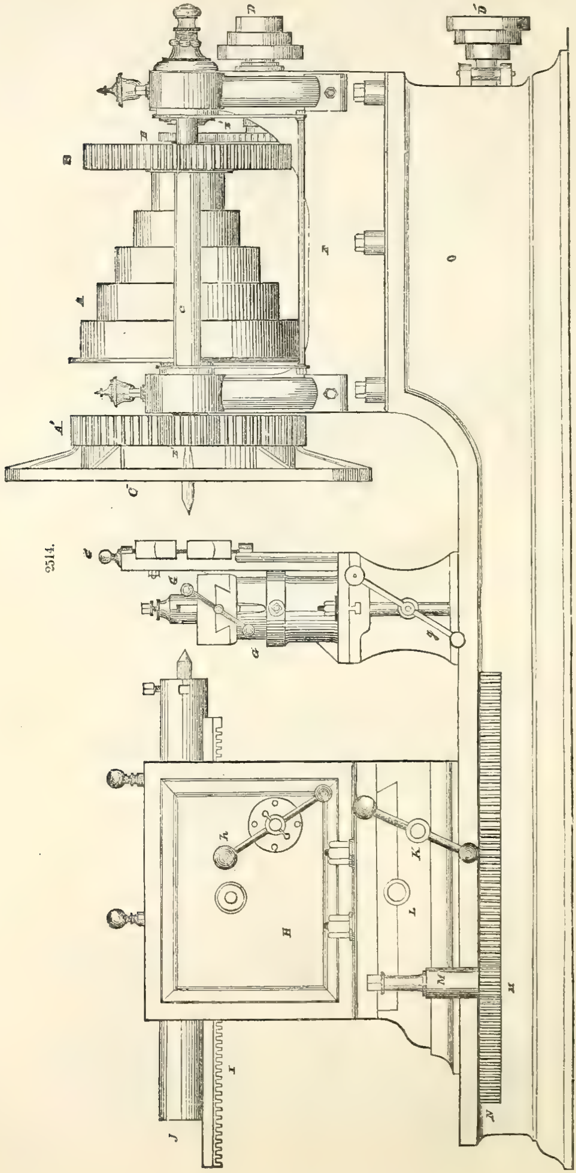
Q, upper part of the tail-stock, which is made to slide crosswise for tapering work, in the usual way

2512.



2513.





2514.

LATHE, LARGE BORING AND REAMING. A very convenient and useful tool for boring and reaming locomotive and car wheels, pulleys, geers, &c., &c. It will turn out a hole straight or tapering, and spline the same, without removing it from the chuck. It is adapted to turning or drilling out holes, or boring, by using the shell boring-tool; all self-feeding.

Fig. 2514 is a side elevation.

Fig. 2515, end elevation, looking towards the face-plate.

A, cone-pulley of cast-iron which runs on the live spindle. The spindle has strong journals, running in gun-metal boxes.

A′, geer on face-plate.

B, geer on front shaft.

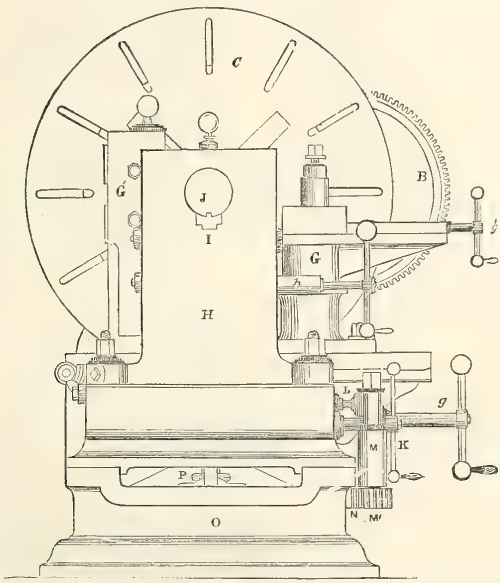
o, shaft, thrown out of and into geer by eccentrics.

C, face-plate, to which the work is fastened by means of bolts.

D, upper cone for driving the feed motion.

D′, lower cone on the splined shaft which passes through the centre of bed-piece, giving motion to the rack I, which can be connected with the spindle J, by the screw on top.

2515.



F, head-stock in which the live spindle rests.

G, swivel-post on which the tool-holder slides.

g, bed-piece on which G stands.

G′, rest, with jaws, for using flat drills and reamers, adjusted by the screw on top.

H, upper part of tail-stock, inside of which is the feeding apparatus. This piece rests upon a sliding-plate that is traversed crosswise by the screw L.

S, worm which geers into a segment on side of tail-stock for giving the proper angle when a hole is to be turned out tapering.

K, crank, with a bevel pinion on the inside end of its shaft, geering into a large bevel-wheel that has an internal screw cut through its hub for fastening down tail-stock to the bed.

M, stand cast on the side of the lower piece of tail-stock, carrying a shaft and pinion geering into a rack on side of bed-piece, for the purpose of moving tail-stock by hand.

M′, pinion, geering into rack.

N, rack on side of bed-piece.

O, bed-piece, cast with cross-pieces and made very strong.

This lathe will admit a wheel 5½ feet in diameter, and is adapted to turning off the rims of pulleys, and for surface turning generally. These engines (pp. 166 to 172) are from the Lowell Machine Shop

LATHE, FOR GUN BORING, TURNING, AND PLANING, arranged for the Ordnance Department, U. S. Navy Yard, Washington, by WM. M. ELLIS, Engineer. Figs. 2516 to 2522.

Fig. 2519. *c*, rest for supporting the muzzle of the gun while boring.

d, pulley, with belt motion above, for drawing boring-bar.

When boring, the turning mandrel is taken out and the boring-bar put in its place; the back-head is forced up by feed-screws in the same manner as slide-rest for turning.

Fig. 2518. C, planing-head and tool-holder, bolted on slide-rest of lathe in place of tool-holder for turning.

h, slide of tool-holder.

i', cogged sector working in rack on bottom of drill of tool-holder.

i, shifting crank to convey motion to sector.

E, ratchet-wheel on main mandril of lathe, to give motion to gun on the centres while planing between the trunnions.

D, eccentric connection to give motion to feed-hand.

B, bevel-geer to work planing-head and feed-hand.

A, pulleys on bevel pinion-shaft.

2516.

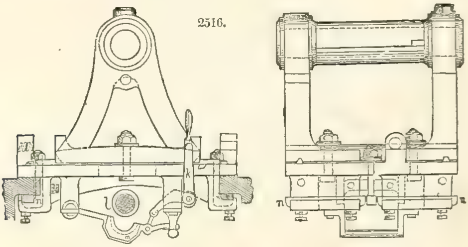


Fig. 2516. Back (sliding) head for turning or boring.

k, lever for throwing head out of geer.

l, feed-screw.

n, gibs.

Fig. 2520. *h*, lever for throwing slide-rest out of geer.

f, feed-screw.

m, half-rest for feed-screw.

n n, gibs on slide-rest.

Fig. 2521. *d*, pulley for drawing boring-bar.

e, ratchet-wheel.

f, lever on ratchet-wheel, for boring.

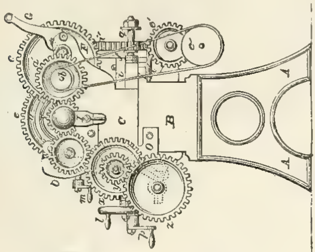
LATHE, SMALL SELF-ACTING AND SCREW-CUTTING, by Charles Walton, Leeds, Eng
Fig 2523 is a general side elevation of the lathe, and

Fig. 2524 is a plan corresponding.

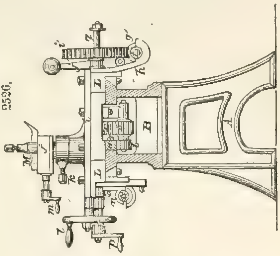
Fig. 2525 is an end elevation showing the geering.

Fig. 2526 is a transverse section taken between the fast-head and the slide-rest, showing the latter in elevation, as also the arrangement of the geering for traversing the same.

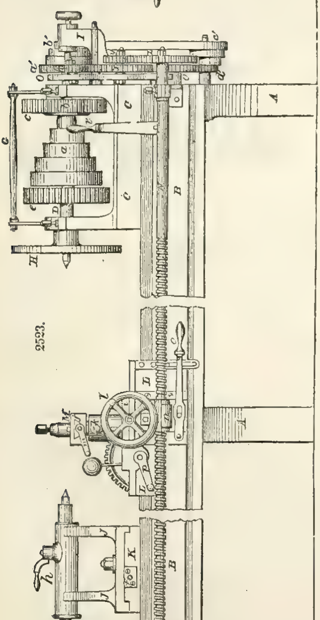
2525.



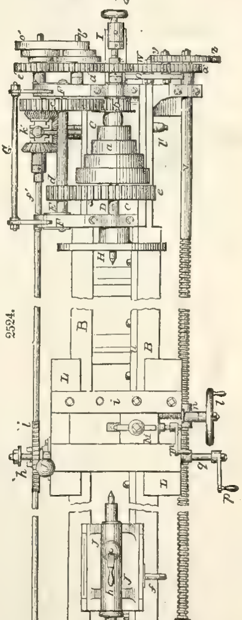
2526.



2523.



2524.



Figs. 2527, 2528, 2529, 2530, show details of the geering for working the slide-rest.

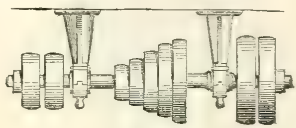
Fig. 2231 is an elevation of the top cone and driving pulleys: these consist of two sets, the smaller set being used for reversing the motion of the saddle when the lathe is employed in screw-cutting, and the larger when the tool is in action, and a slower motion consequently necessary.

Fig. 2532 is a section through the driving-cone on the lathe-spindle.
Fig. 2533 is a front view of the chuck.
Fig. 2534 is a side elevation of the same; and
Fig. 2535 a vertical section in the plane of the lathe-spindle.

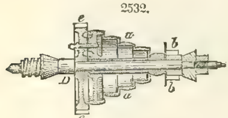
These figures exhibit in full detail the several parts of a very efficient, and, in many respects, convenient self-acting and screw-cutting lathe.

The machine is carried upon three standards marked A, and of which the general forms are shown in Figs. 2525 and 2526. These standards are planed on their upper surfaces to afford a solid rest for the bed B B, the upper surface of which is also planed. The exterior edges of the bed are bevelled in the usual way, as a means of retaining the saddle-plate L L of the slide-rest, as shown in the cross-section, Fig. 2526. The fast-head C C is fastened to the bed by means of bolts: it carries the main spindle D, upon which is the driving-cone *a*, a section of which, showing its relation to the spur-wheel *e* and pinion *b*, is the subject of Fig. 2532. The cone is as usual loose upon the spindle, and can be attached at pleasure to the wheel *e*, which is fast upon the spindle, when it is necessary to throw the back-speed shaft E out of geer. This is effected by the hand-rail G, which connects the two levers commanding the bearings of the shaft in the two standards of the fast-head, a method commonly adopted when the arrangement of the geering does not conveniently admit of the shaft being shifted longitudinally. The motion of the leading-screw N is derived from the cone-spindle through the train of wheels *v w x y z*, in screw-cutting; and in plain work the parallel motion of the tool is obtained through the train *v a′ e′ c*, and the band-pulleys *b′* and *c′*, to the traverse-spindle *f′ f′*, which, by means of the worm *g*, Figs. 2526 and 2530, and worm-wheel *i′* communicates through the intervening spur-pinions *r* and *s* with the pinion *t*, Fig. 2527, geering with the toothed-rack *u*, Figs. 2526 and 2529 attached to the under side of the saddle-plate L of the slide-rest. The geering for reversing the motion of the saddle consists of three meter-wheels and the clutch-box *k′*, arranged upon the traverse-rod *f′ f′* The clutch *k′* communicates by means of a spanner fixed upon a horizontal shaft, passing through the

2531.



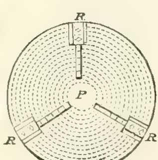
2532.



2535.

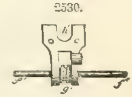
2534.

2533.



2527.

2530.



2529.

2528.

bed of the lathe, with the reversing-lever *l′* in front. By this means the shaft communicating with the train of wheels from the cone-spindle may be geered either directly with the traverse-rod *f′ f′*, or through the intervention of the meter-wheels at pleasure. A weighted lever *j′*, shown in Fig. 2526, serves the purpose of throwing the worm-wheel *i′* in or out of geer with the worm upon the traverse-rod, thereby connecting or disconnecting the lathe with the saddle of the slide-rest as may be required. The slide-rest can be relieved from connection with the leading-screw N by means of the handle *o* attached in front of the saddle: by pressing this handle down, it acts upon a stud in the plate, carrying the screw-box *n*, which is thereby opened, and the saddle relieved.

The movable head-stock J J is provided with a screw *f* for shifting it out of the line of the axis of the main spindle, thereby adapting the lathe to conical turning.

Action of the lathe.—The arrangement of the geering in the views given of the lathe in the plates, is that adapted to screw-cutting. The cone *a*, which is loose on the spindle, is fast to the pinion *b* of 13 teeth; this pinion geers with the wheel *c* of 52 teeth upon the back-speed spindle E, which also carries the pinion *d* of 13 teeth, geering with the wheel *e* of 52 teeth, fast upon the cone-spindle D. According to this arrangement, the ratio of the speed of the driving-cone to that of the main spindle is as 16 to 1.

The connection between the cone-spindle and the leading-screw N is accomplished by means of the wheel *v* of 40 teeth, fast upon the driving-cone spindle; this wheel is working into the wheel *w* of 60 teeth, upon a shifting-stud attached by means of a radial slot-bar to the bracket O, bolted upon the fast-head; this latter wheel again is in geer with the wheel *x* of 90 teeth, also upon a shifting-stud, and carrying a wheel *y* of 45 teeth, in geer with the wheel *z* of 90 teeth, fast upon the leading-screw shaft N. This train can, of course, be varied at pleasure to suit the particular pitch of screw to be cut, the positions of the radial slot-bars, carrying the studs of the carrier-wheels, being at the same time shifted to allow the wheels to come into geer.

To adapt the lathe for plain sliding, the back-speed shaft is put out of geer with the cone-spindle, by means of its hand-rail G: the wheel *e* upon the cone-spindle then geers with the wheel *a′*, working

loose upon a stud attached to the head-stock, and carrying the cone-pulley b'. This last is connected by a band with the loose cone-pulley c', working likewise upon a stud fixed to the standard A, and carrying a wheel d', which geers into the wheel e', fast upon the end of the traverse rod $f'f'$, on which are the three meter-wheels and clutch-box k', also the sliding-worm which works into the cone-wheel i' upon the shaft q. This shaft revolves in bearings attached to the saddle, and carries the pinion r, Fig. 2527, working into the wheel s, keyed upon the same spindle which carries the pinion t, also fast. This latter geers with the rack u bolted to the under surface of the saddle. By this arrangement motion is transferred from the cone to the traverse-rod $f'f'$, and thence to the slide-rest through the geering attached to the saddle.

Literal references.—A A A the standards upon which the lathe is supported.

B B the bed or shears having the upper ledges upon which the shifting head-stock and saddle rest, planed.

C C the fast-head, which is firmly bolted upon the bed.

D the main spindle, which is highly finished and case-hardened. It revolves in conical collars of hardened steel, and is further secured against end-long shift by a set-screw bearing against its outer end through the bracket I.

E the back-speed shaft revolving in bearings inserted in the projecting lugs F F, cast on the standards of the fast-head.

G hand-rail for throwing the back-speed shaft in and out of geer with the cone-spindle.

H the face-plate which is screwed upon the end of the main spindle.

I bracket bolted to the outer standard of the fast-head; see D.

J J the movable head-stock. It is planed and fitted upon a saddle K, both the upper and under surfaces of which are planed; on the upper to allow the head-stock to slide upon it transversely, and on the under to allow of its being travelled on the bed of the lathe.

L L the saddle-plate of the slide-rest. It is planed and fitted with bevelled pieces to retain it upon the bed of the lathe, as shown in Fig. 2526.

M the tool-holder of the slide-rest.

N the leading-screw, carried in bearings at its two extremities, attached in front of the lathe.

O the bracket for carrying the train of carrier-wheels by which the motion of the main spindle is transmitted from the leading-screw.

P, Figs. 2533, 2534, and 2535, the front plate of the universal chuck. And

Q the back plate of the same, showing the spiral groove for expanding and contracting the clutches or jaws.

R R R the clutches or jaws of the chuck. These are fixed upon separate soles through which one of the tails passes, while the other passes over the inner end of the sole; these tails slide between radial slots in the front plate P, and enter the spiral grooves formed in the face of the back plate Q. When the back plate is turned upon its axis, which coincides with the axis of the main spindle, the front plate being meantime held fast, the clutches or jaws will be guided simultaneously, further from, or nearer to the centre, and thereby be made to clutch the work in the usual way.*

a the driving-cone of the lathe; it is loose upon the main spindle, and fast to

b the first pinion of 13 teeth; it is fast to the driving-cone a.

c wheel of 52 teeth on the back-speed shaft E; and

d a pinion of 13 teeth on the same shaft.

e first wheel of 52 teeth on the main spindle of the lathe.

f screw for moving loose head-stock transversely for conical turning.

g hand-wheel for working the spindle of the loose head-stock; and

h a handle for tightening the pinching-screw of the same.

i adjustable check by which the slide-rest M is retained upon the saddle-plate L.

j rest-plate for the tool-carrier; and

k a screw for fixing the tool-holder upon the slide-rest.

l a hand-wheel and handle upon the end of the transverse-screw of the side-rest. This screw works in plain collars attached to the saddle-plate, and in a nut attached to the sliding-sole of the rest, so that the screw being turned it carries the slide from or towards the axis of the lathe.

m a crank-handle upon the upper slide-screw, for putting the tool in and out of cut.

n the screw-box for the leading-screw. The under part is screwed internally to the same pitch as the leading-screw, and is carried upon a sliding-sole, into which is inserted a stud passing through a slot in

o the handle for connecting and disconnecting the screw-box of the leading-screw. It acts as a lever of the second kind, the stud of the sliding-sole of the nut passing through a slot in it, between the fulcrum and the part acted on by the hand.

p the crank-handle for working the saddle-plate by hand; it is placed upon

q the transverse-shaft upon which is the screw-wheel i', working into the sliding-worm g', carried along the rod $f'f'$ by a fork h' attached to the saddle-plate.

r a spur-pinion keyed upon the transverse-shaft q, and working into

s a small spur-wheel keyed upon a short spindle, attached by bearings on the bottom of the saddle plate, and which geers with the pinion r on the transverse-shaft q.

t a spur-pinion keyed on the same spindle as s, and which geers with

u an inverted rack fast to the bed of the lathe.

* This arrangement has an advantage over the mode of working the clutches by separate screws, in their being simultaneously expanded and contracted in respect of the centre; but it frequently happens that it is necessary to chuck articles which are not cylindrical, and in which it is more convenient to have the clutches movable, independently of one another. As a familiar example may be instanced half-lap coupling ends of shafts, which are semi-cylindrical, and must be made up by packing to the cylindrical form before they could be caught in a chuck of this kind.

v the first pinion in the trains of the head-geering of the lathe.

w a carrier-wheel which geers with the pinion v; it is loose upon a stud in the stud-plate O.

x a second carrier-wheel upon another stud in the stud-plate O, geering with the former.

y a third carrier-wheel on the same stud as the wheel x, and made fast to the latter.

z a wheel keyed upon the end of the leading-screw, and geering with the pinion y.

It is through this train that the leading-screw derives its motion from the main spindle of the lathe.

a' a wheel of the back-train geering with the pinion v, on the end of the main spindle; it is keyed upon a pap of

b the upper cone of the back-train, carried upon a stud in the standards of the fast-head. It is loose upon the stud, and has the eye prolonged into a pap upon which the wheel a' is keyed.

c' the lower of the two cones of the back-train. It is also loose upon its stud, and is connected by a band with the upper speed-cone b'.

d' a spur-pinion keyed upon the eye of the speed-cone c', which is prolonged for that purpose, and which geers with

e' a spur-wheel on the end of the worm-shaft $f'f'$, geering with the pinion d'.

$f'f'$ the traverse-rod or worm-shaft; a grooved rod passing at the back of the lathe, and having its bearings at the two extremities. It is also supported between by the fork which slides the worm g' along upon it, the projecting sides of which are formed into a species of double gallows, as shown in Figs. 2526 and 2530.

g' worm or endless screw upon the traverse-spindle, geering with the worm-wheel i'. It has a fixed key in the eye which slides in a groove in the rod $f'f'$.

i' worm-wheel on the end of the transverse-shaft q, worked by the worm g'.

j' a weighted lever for disconnecting the worm-wheel i'.

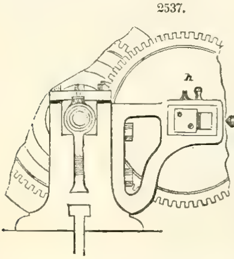
k' reversing-geer upon the worm-shaft $f'f'$, consisting of the three meter-wheels and clutch-box, arranged in the usual manner, and worked by

l' the lever of the reversing-geer k'; it acts by a spanner upon the clutch-box lever, bringing the clutch into geer with either of the wheels upon the worm-shaft at pleasure.

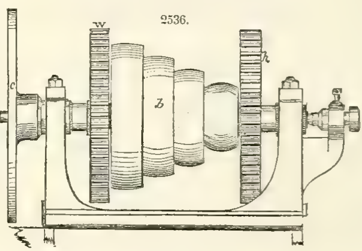
LATHE, BACK-GEER TURNING. This is a good specimen of a back-speed lathe.

Fig. 2536 is a side elevation of the fast-head; Fig. 2537 an end elevation of the same taken from the back, and Fig. 2538 is a plan of the fast-head. The same letters are used on each.

2537.

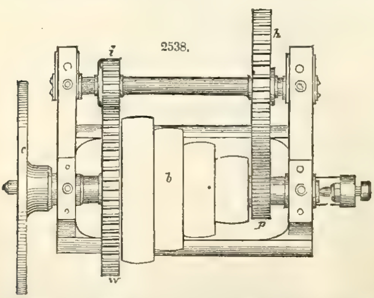


2536.

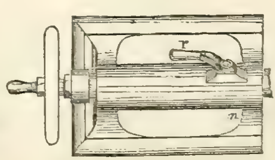


b, the driving cone-pulleys, loose on the spindle of the lathe and fast with the pinion p, Fig. 2538. h, a spur-wheel, fast on the back shaft, and i a pinion also fastened on the same. w, a wheel fast on the lathe-spindle, geering with the pinion i. c, is the chuck or face-plate; this admits of being taken off the lathe-spindle when not required. The spindle is kept forward by a back-centre pinching-screw.

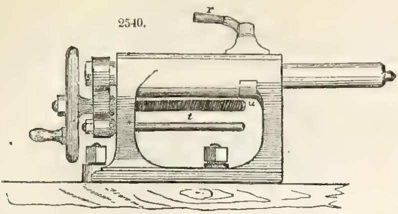
2538.

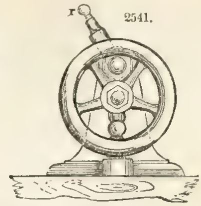


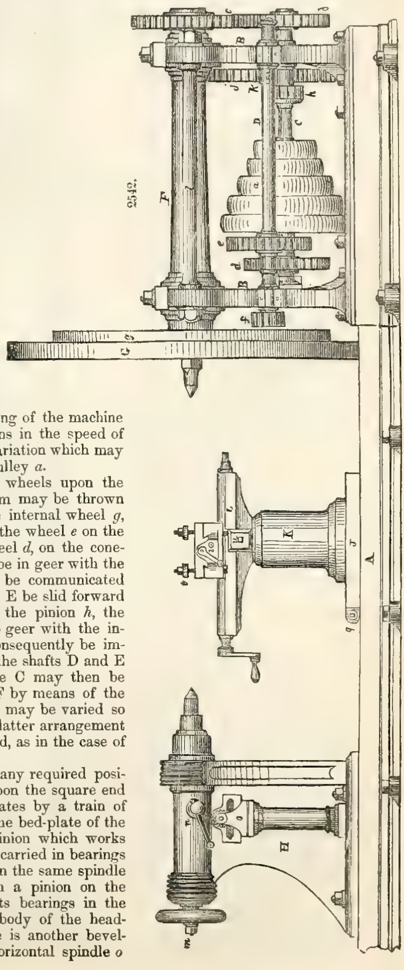
2539.



Figs. 2541 and 2540, are end and side elevations of the shifting-head of which Fig. 2539 is a plan. is a screw for shifting the spindle. A hand-wheel is placed on the outer end of it, which revolves in







a gland embracing the ends of the shifting-spindle and a guide-rod under the screw, Fig. 2540; by this means it is made to move horizontally, and to carry the shifting-spindle of the head along with it. *u* is an eye-bolt, tightened up by the traveller *r* on the spindle, to take the strain off the screw. When quicker speeds are wanted, the shaft carrying the wheels *h* and *i* is moved back by taking out a pin seen under *h* in Fig. 2537, and the cone is made fast to the wheel *w* by a latch in the usual way.

LATHE, BORING AND TURNING, by Mr. Kinmonds.

Fig. 2542 is a side elevation of the machine.

Fig. 2543 is a general plan corresponding.

Fig. 2544 is an end view from the left.

Fig. 2545 is a section taken in front of the shifting head-stock.

The fixed head-stock B B is provided with four bearings, cast in each of the two standards, for the purpose of receiving the cone-spindle C, the second motion shafts D and E, and the main spindle F, upon which the face-plate G is fixed. The geering of the machine is calculated to produce a series of variations in the speed of the main spindle F, independently of any variation which may be effected by means of the driving cone-pulley *a*.

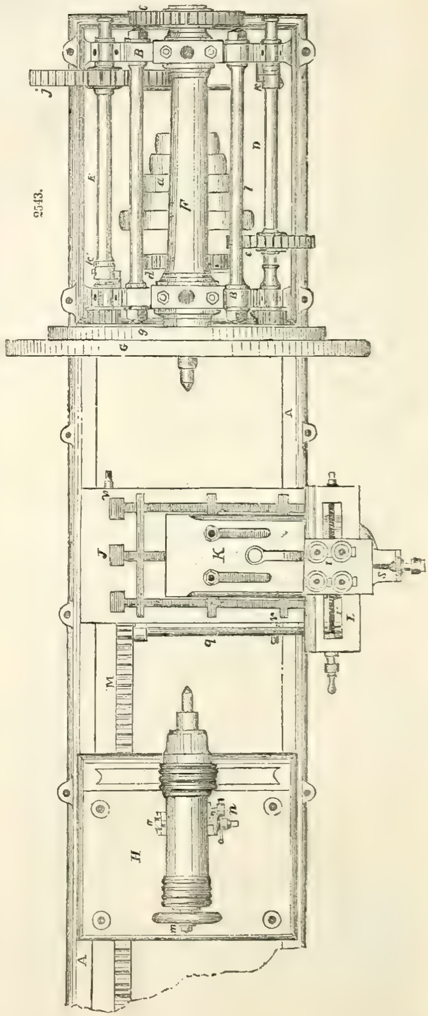
To effect this the arrangement of the wheels upon the shafts D and E is such that either of them may be thrown into geer with the cone-spindle C, and the internal wheel *g*, on the back of the face-plate G. Thus, if the wheel *e* on the shaft D be brought into geer with the wheel *d*, on the cone-spindle, the pinion *f* will at the same time be in geer with the internal wheel *g*, and a quick motion will be communicated to the face-plate; but if the opposite shaft E be slid forward longitudinally till the wheel *j* geers with the pinion *h*, the pinion *f′* on that shaft will be thrown into geer with the internal wheel, and a slower motion will consequently be imparted to the face-plate. Again, let both the shafts D and E be thrown out of action; the cone-spindle C may then be directly connected with the main spindle F by means of the wheels *b* and *c*, the relative sizes of which may be varied so as to produce any required velocity; this latter arrangement is only employed for obtaining a high speed, as in the case of polishing.

The loose head-stock H is adjustable to any required position by means of a crank-handle fitting upon the square end of the spindle marked *o*, which communicates by a train of toothed geer with the rack M, fixed upon the bed-plate of the machine, as shown in Fig. 2546. The pinion which works into the rack is keyed upon the spindle *p*, carried in bearings attached to the sole of the head-stock. On the same spindle is a small bevel-wheel, which geers with a pinion on the lower end of a vertical spindle, having its bearings in the interior of a hollow column, cast in the body of the head-stock. On the upper end of this spindle is another bevel-wheel, which geers with a pinion on the horizontal spindle *o*

thereby completing the connection with the fixed rack M. This arrangement is fully exhibited in dotted lines in Fig. 2546.

The same rack M serves also for moving the side-rest K in a longitudinal direction, by means of a pinion keyed upon the shaft *q*, shown in Fig. 2543. This shaft is carried in bearings attached to the edge of the sole-plate of the slide J, and terminates in a *square*, to which a lever may be applied to give motion to the shaft. The sole-plate of the slide is provided with dovetail grooves in its under surface, to receive the correspondingly formed heads of two bolts, for the purpose of attaching and fixing to the saddle-plate J the sole of the bracket K, which carries the slide-rest L. To afford the utmost possible facility for adjustment, the bolt holes in the sole of the bracket K are slots of considerable length, and the fixing bolts hold the two plates firmly together, metal to metal, their surfaces of contact being planed true.

2543.



By this arrangement the slide may be made fast in any position upon the saddle-plate, which in turn is retained upon the bed-plate of the machine by wedge-pieces worked by means of two horizontal eccentric spindles *v v*, shown in Fig. 2543.

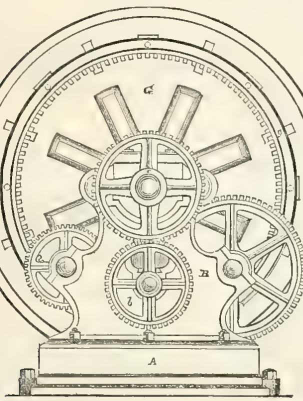
The longitudinal and transverse motions of the tool-holder, for the purposes of traversing the work, and placing the tool in and out of cut, are obtained by means of the screws *r* and *s*, which work at right angles to each other, in the usual manner; the tool is made fast on the tool-holder by means of the two clamps *t t*. In adjusting the slide primarily to the work the sole K is released from the saddle-plate J by relaxing the connecting bolts; the bracket K is then shifted to the required distance from the longitudinal axis of the machine, and also, to a certain extent, in the line of that axis by sliding the bolts in the dovetail grooves of the saddle-plate, should that operation be more convenient than moving the latter on the bed-frame of the machine. For transverse adjustment to a limited extent, the screw *s* can be used; for longitudinal adjustment, the tool-carrier may be set in a similar manner by the screw *r*.

Action of the machine.—Supposing it is required to *face* a heavy piece of work by this machine, it is clamped to the face-plate by means of bolts which pass through radial slots formed in the latter. The wheel *c*, upon the end of the main spindle F, is then removed, and the shaft E is slid longitudinally in its bearings until the wheel *j* and the pinion *f′*, both keyed upon it, geer respectively with the pinion *h*, upon the cone-spindle, and the internal wheel *g*, which is fast upon the back of the face-plate. By this arrangement the slowest motion of the face-plate is obtained. If a quicker motion be required, as when the action of the tool is near the axis of the machine, the shaft E is thrown out of geer, (as shown in the views, Figs. 2542 and 2543,) and the shaft D is moved endways until the wheel *e* and pinion *f* upon it geer respectively with the wheel *d* upon the cone-spindle, and the internal wheel *g* upon the back of the face-plate. The speed is thus increased in the ratio of the number of teeth in the wheel *d* and pinion *h*; that is, as 51 to 15. A still higher speed,

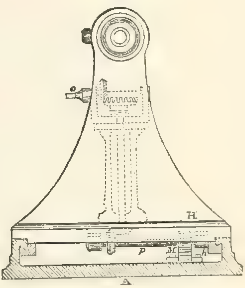
and indeed the highest, is obtained by arranging the geering of the machine as it is represented in the engravings. The shafts D and E, it will be observed, are both out of geer, (being retained in that position by the catches $k\,k'$,) and the wheel b upon the cone-spindle C is in geer with the wheel c, upon the end of the main spindle F, so that the speed of the cone is transmitted to the face-plate through the single pair of wheels b and c, which are to each other in the ratio of 51 to 66.

These three speeds, which are independent of the five speeds obtained by the cone, may be thus compared:—The numbers of teeth in the wheel j and pinion f, upon the back-shaft E, are respectively 78 and 13, and the numbers in the pinion h, upon the cone-spindle, and in the internal wheel g upon the back of the face-plates, are 15 and 119; consequently when the shaft E is in geer, the ratio of the speed between the cone-spindle and the face-plate is as $78 \times 119 : 13 \times 15$, or as 47·6 to 1, being the slowest motion of which the machine is capable. Again, the numbers of teeth in the wheel e and the pinion f, upon the shaft D, are respectively 51 and 13; and the numbers in the wheels d upon the cone-spindle, and the internal wheel g, being 51 and 119, therefore when the shaft D is in geer, the ratio of the speed of the cone-spindle to that of the face-plate is as 119 : 13, or as 9·15 to 1. And when both of these shafts are out of geer, and the wheel b upon the cone-spindle is working into the wheel c upon the main spindle, the numbers of teeth being respectively 51 and 66, the ratio of the speed is 1 to 1·3 nearly.

2545.



2546.



The action of the machine in ordinary parallel turning is the same as in any common lathe. The mode of obtaining a self-acting longitudinal motion of the tool-carrier is by a stellar-plate fixed upon the end of the screw r, and which is worked by an arm bolted to the face-plate or to the object which is being turned, so as to come in contact with the plate, and cause it to advance one tooth at each revolution.

Application of this lathe to the boring of cylinders.—When the machine is to be used as a boring-mill, the slide-rest and shifting head-stock are removed, and a boring-bar is substituted; one end being supported by a standard fixed upon the bed-plate.

Literal References.

A A, the bed-plate of the machine.
B B, the fixed head-stock, bolted to the bed-plate.
C, the driving cone-spindle.
D E, the second motion shafts.
F, the main spindle carrying the face-plate G.
a, the driving cone-pulley with five speeds.
b, a wheel of 51 teeth working into
c, a wheel of 66 teeth on the main spindle.
d, a wheel of 51 teeth working into
e, an equal sized wheel on the second motion shaft D.
$f\,f'$, pinions of 13 teeth on the shafts D and E, working into
g, the internal wheel of 119 teeth attached to the face-plate.
h, a pinion of 15 teeth working into
j, a wheel of 78 teeth upon the second motion shaft E.
$k\,k'$, catches for retaining the shafts D and E when put in or out of geer.
$l\,l$, stay-rods for strengthening the fixed head-stock.
H, the shifting head-stock.
m, a screw-spindle with hand-wheel for adjusting the centre in the shifting head-stock.
n, a pinching-screw for fixing the centre when adjusted.
o, a spindle for moving the shifting head-stock longitudinally.
p, a transverse shaft forming part of the mechanism by which the shifting head-stock is moved.
$h'\,h'$, hooked bolts for fixing the shifting head stock.
J, the saddle-plate, forming a support for
K, a bracket for carrying the slide-rest.
L, the longitudinal carriage of the slide-rest.

M, the toothed rack, fixed to the bed-plate for the purpose of moving the slide-rest and shifting head-stock.

q, a shaft carrying a pinion which works into the rack M, for moving the slide-rest longitudinally.

r, longitudinal screw of the slide-rest.

s, transverse screw of do.

$t\ t$, clamps for fixing the tool upon the slide-rest.

u, screw for fixing the slide-rest.

$v\ v$, screws for fixing the saddle-plate.

LATHE, BORING MILL AND LARGE TURNING LATHE. This is an indispensable tool in works where engines of a large class are constructed. The plates exhibit a side elevation and plan, with the parts marked by the same letters of reference.

A, the boring-bar, having a recess in it to receive the feeding-screw; see Fig. 2547.

C C and D D, brackets for carrying bar.

B, bed-plate for fixing the work by T-headed bolts, passing through the longitudinal slots cast in it.

E, Fig. 2547, boring-block, fitting accurately on the bar; it is moved along it by the feed-screw working into the nut v, inserted into the boring-block.

H, main spindle carrying the driving cone-pulleys.

G, the face-plate for fixing the work to be turned.

S, Fig. 2548, a cylinder undergoing the process of boring.

t, bars for fixing the cylinder to the bed-plate.

y, a coupling bolted to the face-plate for the purpose of driving the boring-bar.

a, pinion fast to driving cone-pulleys and to the boss on the spindle H.

b, wheel fast on the shaft o, and geering with the pinion a.

e, pinion driving the wheel d, but which may be slid along the shaft on a sunk feather towards g, so as to be clear of d when required.

g, wheel fast on the shaft o.

h, wheel which geers with the wheel g, when required.

c, wheel on the shaft p, which geers with that marked b, on the shaft o.

k, internal wheel fast on the back of the face-plate G.

i, pinion fast on the shaft p, and geering with the internal wheel k, to communicate motion to the face-plate.

$s\ s$, planed rails for the brackets C and D, or other supports that may be used to carry lathe-heads.

w, x, boring-rings; the internal ring w is usually bored to fit E, and allowed to remain on the boring-block, the larger ones being keyed on it. The ring x, suited to bore the cylinder $s\ s$, has 24 slots in its circumference; 12 of these receive the cutters, which are adjusted and fixed by small wedges; sometimes they are bedded on paper. The other slots are fitted with pieces of hard wood driven tightly into them to form a general guiding surface.

l, wheel loose on the boring-bar, and having external and internal teeth. The internal teeth geer with those of a pinion on the end of the feed-screw; see Fig. 2549.

m, wheel fast on the boring-bar, and having the same number of teeth as the wheel l, (64.)

n, q, wheels fast on the small shaft u, and geering with m and l. The wheel q has one tooth less than n, (35 and 36,) so that one turn of the wheels n and q advances the wheel l one tooth on the bar, and (the internal wheel having the same number of teeth as the external) produces a motion of one tooth of the screw-pinion. The screw being $\frac{1}{2}$ inch pitch, and the piston 16 teeth, the feed motion of the boring-block will be $\frac{5\cdot}{16} = \cdot03125$ inch for each turn of the wheels n and q, or $\frac{\cdot03125 \times 64}{35} = .0571$ inch during one turn of the boring-bar.

The following table exhibits the various speeds of which the boring-bar is susceptible.

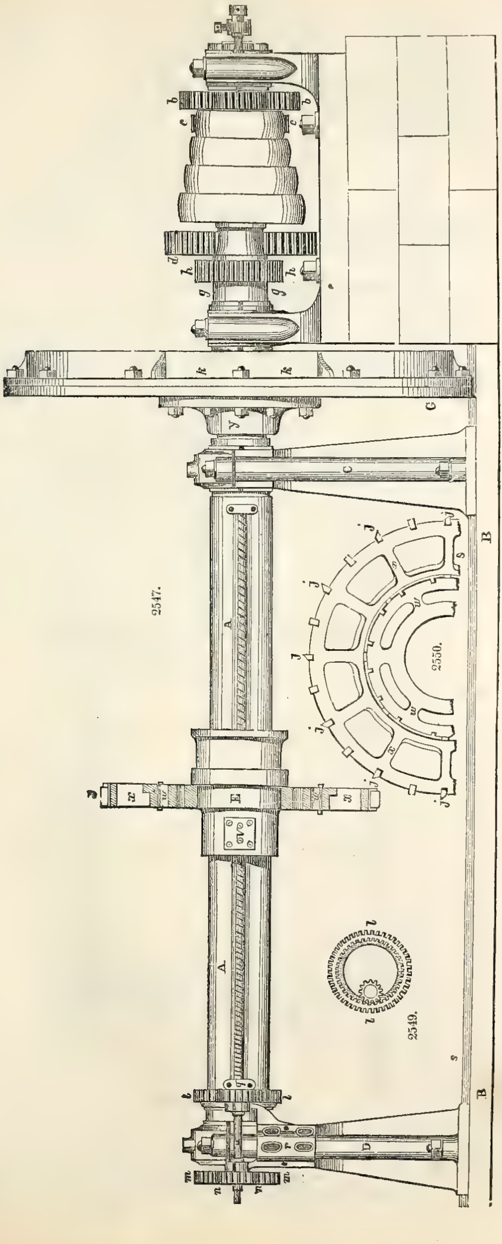
	Turns per minute.			Turns per minute.
1	·333	$\times 3 \doteq 1$	13	4·839
2	·416		14	6·049
3	·520		15	7·561
4	·650	$\sqrt{\cdot650 \times 3} = 1\cdot4$	16	9·451
5	·812	$\sqrt{\cdot812 \times 3} = 1\cdot56$	17	11·814
6	1·015		18	14·767
7	1·269		19	18·457
8	1·586		20	23·079
9	1·982	$1\cdot982 \times 3 = 5\cdot946$	21	28·842
10	2·478		22	36·053
11	3·077		23	45·066
12	3·871		24	56·333

The speeds increase as 1 to $1\frac{1}{4}$, so that any speed within the range may be procured to within $\frac{1}{8}$ of that required; that is, the boring speed being 7 feet per minute, the greatest deviation will be $\frac{84}{8} = 10\frac{1}{2}$ inches per minute.

The cone-pulleys of the machine are driven by a similar set of cone-pulleys on an intermediate shaft. This shaft is again driven from the main shaft by pulleys of the following relative diameters:

3 feet.	$22\frac{1}{2}$ in.
$22\frac{1}{2}$ in.	3 feet.

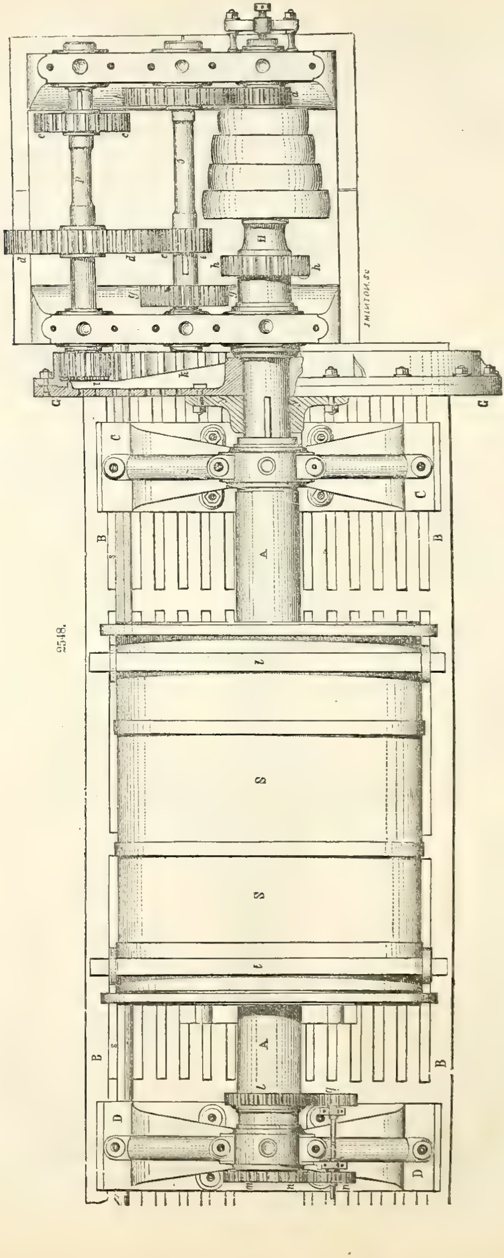
The diameters of these pulleys are to each other as the first to the fifth speed of the bar, so that the smaller is to the larger pulley as $\sqrt{\cdot333} : \sqrt{\cdot812} = 1 : 1\cdot56$. The increase of speed from the largest



2547.

2550.

2549.



2548.

to the smallest pulley on the spindle H is as the first to the fourth speed, and the diameters of the pulleys are $\sqrt{\cdot 333} : \sqrt{\cdot 650} = 19 : 26\frac{1}{2}$.

The first eight speeds are obtained with the wheels d and e, the second eight with the wheels b and c, and the third eight by geering g and h, disengaging e and c, and taking the pinion i out of geer with the large internal wheel on the face-plate by shifting the shaft p towards the shaft o.

Numbers of Teeth in Wheels.

Driving Wheels.	No. of Teeth.	Feed Wheels.	No. of Teeth.
a	24	l, external	64
b	52	l, internal	64
c	40	m	64
e	14	n	36
d	64	q	35
g	34	Pinion on traverse screw,	16
h	40		
i	15		
k	144		

The speeds produced by the wheels $e\,d$ and $b\,c$ are to each other as the first to the ninth speed of the chuck; therefore, $64 \times 52 \div 14 \times 40 = 5\cdot 94$ nearly.

The boring speed being about 7 feet per minute, the slowest speed, viz., $\frac{1}{3}$ of a revolution per minute, would cut a cylinder of 80 inches diameter $\frac{84 \times 3}{3\cdot 1416} = 80$. All the cylinder boring speeds are in the first eight of the table, the others are for turning and polishing heavy articles, such as large cylinder covers.

Another modification of the boring-lathe is seen in the vertical boring-mill of J. P. Morris & Co., of Philadelphia.

A modification of the reaming and boring-lathe may be seen in the vertical boring-mill built in the Washington Navy Yard, under the direction of Wm. M. Ellis. This is essentially the same as the boring-mill of J. P. Morris & Co., of Philadelphia.

f, brace to support counterbalance geering g.

h, cone supporting counterbalance.

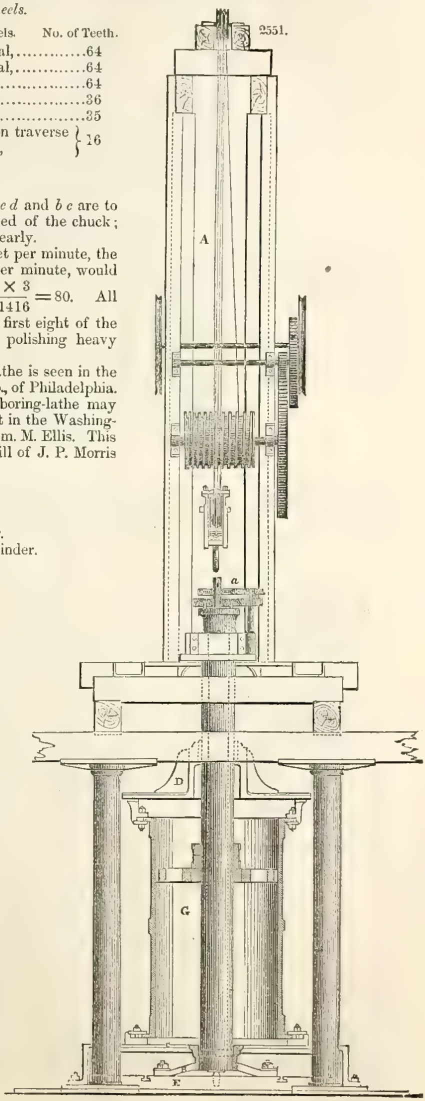
i, hexagon mandrel counterbalance.

Fig. 2554. G, cast-iron frame to support upper end of boring-shaft.

Fig. 2555 shows the stand or bed indicated by letter C, Fig. 2551, on which the cylinder rests which is to be bored out.

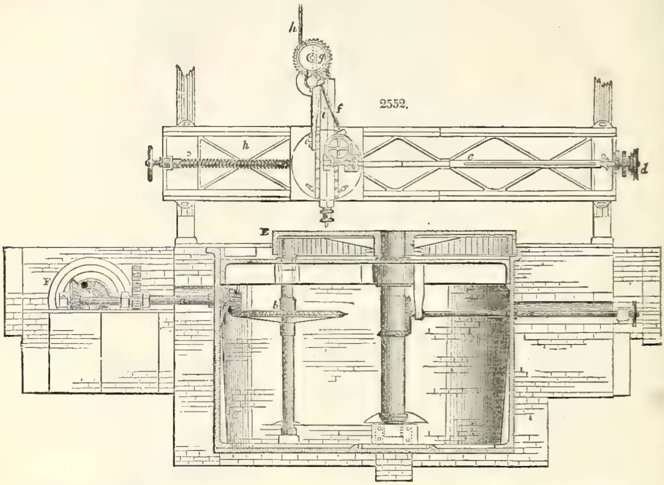
Fig. 2556 shows a guide, indicated by D, Fig. 2551, which is placed upon top of cylinder, and serves as guide for boring-bar. The boring-bar is then connected to the revolving-plate, as shown

2551.



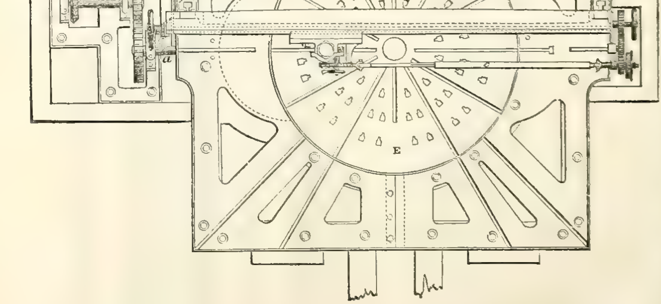
in B and E, Fig. 2551, and turns with it. The boring-head which holds the cutters is shown at G, and is connected with two screws nearly the whole length of boring-bar, set in grooves and moving with the bar and shown by dotted lines, which screws regulate the descent or feed, as it is termed, of the boring-head

2552.



On the upper end of the boring-bar shown at *a*, Fig. 2552, is placed the geer by which the proper motion is given to the feeding-screws. On the end of each feeding-screw is placed a small pinion, which geers into the inner teeth of a wheel which is loose on the top of boring-bar, and of course does not turn

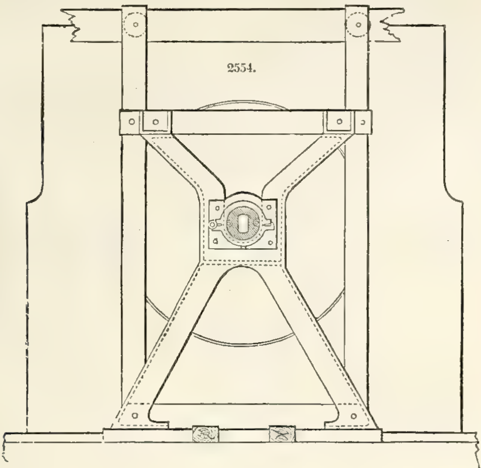
2553.



with it. This wheel has teeth on the inner and outer sides of its periphery; the outer teeth geer into one of a set of two wheels which turn together, and are placed on a fixed pivot, independent of the boring-bar. The upper wheel of this set geers into the upper wheel *a*, which is keyed to the boring-

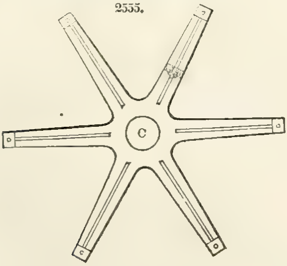
bar, and of course turns with it. The amount of feed, or the advance of the feeding-screw, is due to the difference of the velocities which are given to the wheels *a* and *m*. This difference of the velocities of these two wheels may be varied by varying the diameter of the wheels *a* and *m*.

2554.

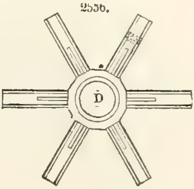


The geering shown above the top of the boring-bar is for hoisting up the boring-bar, when the machine is to be used for planing a flat, or turning a cylindrical or conical surface. The machine, as arranged for this purpose, is shown in Fig. 2552.

2555.

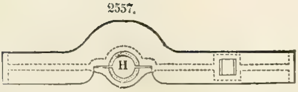


2556.



2558.

2557.



The cutting-tool is attached to the bar *i*, in which a rack is cut, into the teeth of which a pinion geers, which pinion is moved by a perpetual screw on the bar; by this arrangement the vertical motion is given to the tool. The method of producing the lateral motion of the tool by the screw *h* is shown by the figure, and does not need explanation.

Fig. 2557, H, cross-bar and bearing for upper end of shaft of chuck-plate.

LAP AND LEAD OF THE SLIDE-VALVE. The slide-valve is that part of a steam-engine which causes the motion of the piston to be reciprocating. It is made to slide upon a smooth surface, called the cylinder face, in which there are three openings to as many pipes or passages: two for the admission of steam to the cylinder, above and below the piston, alternately; while the use of the third is to convey away the waste steam. The first two are, therefore, termed the induction or steam ports, and the remaining one the eduction or exhaustion port.

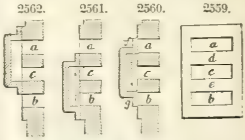
The slide is inclosed in a steam-tight case, called the slide-jacket; and motion is communicated to it by means of a rod working through a stuffing-box.

The steam from the boiler first enters the jacket, and thence passes into the cylinder, through either steam port, according to the position of the slide, which is so contrived that steam cannot pass from the jacket to the cylinder through both steam ports at the same time, or through the eduction port at any time.

CASE 1.—*When a Slide has neither Lead nor Lap.*—Fig. 2559 represents the cylinder face for a "Murray slide" without lap; *a* and *b* being the induction ports, and *c* the eduction.

Figs. 2560, 2561, and 2562, are similar sections of the nosle, showing the slide in its central and two extreme positions. It occupies the mid-position, Fig. 2560, when the piston is at either extremity of its stroke; the extreme position, Fig. 2561, when the piston is at half-stroke in its descent; and that shown in Fig. 2562, when the piston is at half-stroke in its ascent.

2562. 2561. 2560. 2559.



When a slide has no lap, the width of its facing, at *f* and *g*, Fig. 2560, equals that of the steam ports; the lap being any additional width whereby those ports are overlapped.

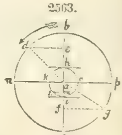
That the waste steam may have unobstructed egress, the exhaustion port *c* must be made of no less width than the steam ports; and, for the same reason, the bars *d* and *e* should correspond with the slide face at *f* and *g*. The three ports, together with the bars between and beyond them, are therefore drawn of equal width; the total length of the slide being equal to the distance between the steam sides of the steam ports.

The distance through which the slide moves, in passing from one extreme position to the other, is called its *travel;* which, in this case, equals *twice the port.*

When the motion of a slide is produced by means of an eccentric, keyed to the crank-shaft and revolving with it, the relative positions of the piston and slide depend upon the relative positions of the crank and eccentric.

Demonstration.

2563.



Let *a b*, Fig. 2563, represent the crank; then *b* being the crank-pin, and *a* the centre of motion, the larger circle represents the orbit of the crank, and its diameter *b c* the stroke of the piston. Supposing the cylinder to be an upright one, having the crank-shaft immediately above or below it, the connection between the piston-rod and crank being merely a connecting-rod, without the intervention of a beam, it is evident that when the position of the crank is *a b*, the piston will be at the top of the cylinder, and at the bottom when its position is *a c*. The relative positions of the crank and piston, at any point of the stroke between the two extremes, depend upon the length of the connecting-rod: for the present, however, let us suppose the connecting-rod to be of infinite length, and therefore always acting upon the crank in parallel lines, so that when the crank is at *d*, *e* will be the apparent position of the piston, and *f* the same when the crank is at *g*; the piston being represented by the sine of the arc described by the crank from either of the points *b* and *c*, in the direction of the arrow.

The diameter *h i*, of the inner circle of the figure, represents the travel of the slide, and its radius the eccentricity of the eccentric; or, regarding the eccentric as a crank, the radius may be said to represent that crank, as *a b* represents the main crank. The travel of a slide, without lap, being equal to twice the port, the two steam ports are represented by the spaces *a h* and *a i*, but transposed, *a i* being the passage to the top of the cylinder, and *a h* that to the bottom.

Supposing the piston to be at *b*, (the top of the cylinder,) the position of the slide will be that shown in Fig. 2560, the direction of its motion being downward, so that the port *a*, Fig. 2560, or *a i* in Fig. 2563, may be gradually opened for the admission of steam above the piston, until the piston has arrived at half-stroke, when it will be fully open, as shown in Fig. 2561. The direction of the slide's motion is then reversed, so that when the piston has completed its descent, the port *b*, Figs. 2559 to 2562, or *a h* in the diagram, will begin to open for the admission of steam beneath it, and exhaustion will commence from above it through the port *a*, or *a i*, and exhaustion port *c*, the slide being again brought into its central position, Fig. 2560.

Now the slide being at half-stroke, when the piston is at either extremity of its stroke, if we make *a b* the position of the crank, *a k* will be that of the eccentric; and the axis of the crank being likewise that of the eccentric, they must necessarily revolve in equal times, and always at the same distance apart; therefore, when the crank has reached the point *d* (supposing it to move in the direction of the arrow) the eccentric will have advanced to *l*, and *e d* and *l m* represent the positions of the piston and slide respectively; showing, that when the piston has descended to *e*, the steam port *a i*, Fig. 2563, or *a*, Figs. 2559 to 2562, will be open to the extent *a m*. Again, when the crank is at *n*, and the piston consequently at half-stroke, *a i* will be the position of the eccentric, the port *a i* being fully open, and the slide occupying the extreme position shown in Fig. 2561. The direction of the slide's motion is now reversed, and the port is again gradually covered by the slide face until the positions of the crank and eccentric are *a c* and *a o*, when the piston will have completed its descent, and the port *a i* will be completely closed, the slide being again brought into its central position, Fig. 2560. The opposite steam

port $a\,h$ now begins to open for the admission of steam, and the direction of the piston's motion is reversed; the port continues to open until the crank and eccentric reach the points p and h, when the piston will again be at half-stroke, and the slide in its extreme position, Fig. 2562. Meanwhile, exhaustion from above the piston has been taking place, to the same extent, through the port $a\,i$. Finally, the piston having completed its ascent, the slide again occupies its original position, Fig. 2560, and, its course being downward, steam is again admitted into the cylinder, through the port a; the piston then begins to descend, and, at the same instant, exhaustion ceases from above, and commences from below it, through the port b.

It is sometimes urged against the use of the eccentric, as a means of actuating the slide, that the steam ports are opened and closed too slowly; but it must be remembered that the piston does not move at a uniform velocity, as the crank does; for example, while the crank describes the arc $b\,d$, the piston descends only from b to e, the versed sine of that arc; and its velocity is gradually increased as it approaches the middle of its stroke, where it is greatest, being equal to that of the crank. Again, as the piston approaches the end of its stroke, its velocity is diminished in the same ratio as that in which it had previously increased, until the completion of its stroke, where it remains stationary during the small space of time in which the direction of its motion is reversed.

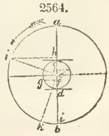
Now, it must be obvious that less steam is required to impel the piston at a slow rate than at a rapid one; and a glance at Fig. 2363 shows that the steam admitted into the cylinder, when the slide is actuated by an eccentric, is at all times proportioned to the velocity of the piston, the port being least open when the piston is near the end of its stroke, and fully open when it is at half-stroke.

When an eccentric, instead of being set, as in the preceding case, so that the steam port shall only begin to open when the piston commences its stroke, is so placed that the port shall be open to some extent prior to the commencement of the stroke, the width of that opening is termed

THE LEAD.—The non-use of lead is disadvantageous, chiefly because at the commencement of every stroke, the steam has to contend with the whole force of that which had impelled the piston during its previous stroke. But besides obviating that disadvantage, the lead is of essential service in locomotive engines, "where it is found necessary to let the steam on to the opposite side of the piston before the end of its stroke, in order to bring it up gradually to a stop, and diminish the violent jerk that is caused by its motion being changed so very rapidly as five times in a second. The steam let into the end of a cylinder before the piston arrives at it, acts as a spring cushion to assist in changing its motion; and if it were not applied, the piston could not be kept tight upon the piston-rod."

CASE 2.—*When a slide has lead without lap.*—Let $a\,b$, Fig. 2564, represent the stroke of the piston; $c\,d$ the travel of the slide; and $e\,f$ the *lead;* then, supposing the piston to be at the top of the cylinder, $e\,a$ is the position of the crank, and $e\,g$ that of the eccentric. Following the course of the crank, in the direction of the arrow, we find the port $e\,d$ fully open, not, as in the former case, when the piston is at half-stroke, but when it has descended to the point h,—the arc $a\,i$, described by the crank, being equal to the arc $g\,d$, described by the eccentric. Again, we find the port reclosed when the piston has descended to i', at which point exhaustion commences from above the piston through $e\,d$, and steam enters below it through $e\,c$, for the return stroke, at the commencement of which the port $e\,c$ is open to the extent $e\,l$ (equal to $e\,f$) for the admission of steam, while $e\,d$ is open to the same extent for exhaustion.

2564.



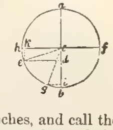
It is to be remarked, that the amount of *lead* is necessarily very limited in practice, its tendency being to arrest the progress of the piston before the completion of its stroke. The greatest possible amount of lead equals half the travel of the slide. The eccentric would in that case be set diametrically opposite to its first position, which would have the effect of reversing the direction of the piston's motion.

In the case of a slide having lead without lap, the distance of a piston from the end of its stroke, when the lead produces its effect, is proportional to the lead as the versed sine of an arc is to its sine, supposing the radii of the crank and eccentric to be equal.

Demonstration.

Let $a\,b$, Fig. 2565, represent both the travel of the slide and the piston's stroke; then $c\,a$ and $c\,b$ represent the steam ports. And let $c\,d$ represent the lead; then $c\,a$ and $c\,e$ represent the crank and eccentric, the piston being at the top of the cylinder. Now, steam will enter the cylinder, below the piston, when the eccentric is at f, and the crank at g; for the arcs $a\,e\,g$, and $e\,b\,f$ are equal. Again, the arc $g\,b$ is equal to $h\,e$; therefore, $i\,g$ is equal to $k\,e$, and $i\,b$ to $k\,h$. Now, $k\,e$ is the sine of the arc $h\,e$, and $k\,h$ (equal to $i\,b$) is its versed sine: hence

2565.



Rule I.—To find the distance of the piston from the end of its stroke, when the lead produces its effect:—Divide the lead by the width of the steam port, both in inches, and call the quotient sine; multiply its corresponding versed sine, found in the table, by half the stroke, and the product will be the distance of the piston from the end of its stroke, when steam is admitted for the return stroke, and exhaustion commences. Or,

Rule II.—To find the lead, the distance of the piston from the end of its stroke being given:—Divide the distance in inches by half the stroke in inches, and call the quotient versed sine; multiply its corresponding sine by the width of steam port, and the product will be the lead.

Example 1.—The stroke of a piston is 48 inches; width of steam port $2\frac{1}{2}$ inches; and lead $\frac{1}{2}$ inch: required the distance of the piston from the end of its stroke, when exhaustion commences.

Here, $\cdot 5 \div 2\cdot 5 = \cdot 2 =$ sine; and versed sine of sine $\cdot 2 = \cdot 0202$.

Then, $\cdot 0202 \times 24 = \cdot 4848$ inches.

Example 2.—The stroke of a piston is 48 inches; width of steam port 2·5 inches; and distance of piston from the end of its stroke, when exhaustion commences, ·4848 inches: required the lead.

Here, $\cdot 4848 \div 24 = \cdot 0202 =$ versed sine;

and sine of versed sine $\cdot 0202 = \cdot 2$.

Then, $\cdot 2 \times 2\cdot 5 = \cdot 5 =$ lead.

When the lead of a slide is equal to the width of steam port multiplied by any number in the first column of the following table, the distance of the piston from the end of its stroke, when steam is admitted on the exhaust-side, will be equal to half the stroke multiplied by the corresponding number of the second column. Or, if the distance of the piston from the end of its stroke, when steam is admitted on the exhaust-side, be equal to half the stroke multiplied by any number in the second column, the width of steam port multiplied by the corresponding number of the first column equals the lead.

When the lead is equal to the width of steam port multiplied by	The distance of the piston from the end of its stroke, when steam is admitted on the exhaust-side, equals half the stroke multiplied by

THE LAP.—A slide is said to have *lap* when the width of its face is greater than that of the steam ports, the ports being thereby overlapped, as in Fig. 2569.

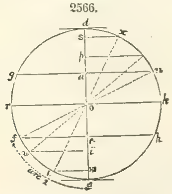
It is to be remarked that slides should have some degree of lap on both the steam and exhaustion sides of the passage, because, although in theory an aperture may be said to be completely closed when covered by a bar of similar width, yet, in the construction of a slide without lap, we cannot insure such accuracy of *fit* as to preclude the possibility of steam entering or leaving both steam ports at the sam time.

Lap on the steam side has the effect of cutting off the steam from the cylinder, by closing the port before the completion of the stroke, the remainder of the stroke being effected by the expansion of the steam already admitted.

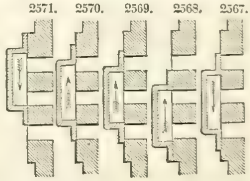
Demonstration.

CASE 3.—*When a slide has lap on the steam side, without lead.*—Let $a\,b$ and $b\,c$, Fig. 2566, represent the lap at both ends of the slide; and let $a\,d$ and $c\,e$ represent the two steam ports; then $d\,e$ will represent the travel of the slide, which, in this case, equals twice the steam port, plus twice the lap.

2566.



2571. 2570. 2569. 2568. 2567.



Supposing $d\,e$ also to represent the stroke of the piston, and that the piston is on the top stroke, then $b\,d$ and $b\,f$ are the respective positions of the crank and eccentric; for the slide, instead of occupying its central position, when the piston is at the end of its stroke, (as in Case 1,) must be set in advance of that position to the extent of the lap, that steam may enter the cylinder when the piston begins to move. See Fig. 2567.

When the eccentric has advanced from f to e, the crank will have reached the point g; the piston is therefore at a when the port $c\,e$ is fully open, the slide being then in the position Fig. 2568. Again, when the eccentric has reached the point h, the port $c\,e$ will be reclosed, Fig. 2567, and i will be the position of the piston; therefore, the distance of the piston from the end of its stroke, when the steam is cut off, is proportioned to the whole stroke, as $i\,e$ is to $d\,e$.

When the eccentric arrives at k, the slide will occupy its central position, Fig. 2569, and the piston will be at m, where exhaustion commences from above it; but steam is not admitted below it, for the return stroke, until the eccentric has reached the point n, where the port $a\,d$ begins to open, the position of the slide at that moment being that shown in Fig. 2570.

When the eccentric arrives at d, the port will be fully open, the slide being then in its extreme position, Fig. 2571; and it will be reclosed when the eccentric arrives at g, and the piston at p, where the steam is cut off, the position of the slide being again that shown in Fig. 2570. Again, when the eccen-

tric reaches the point r, exhaustion ceases from above the piston, which is then at s, and commences from below it, the slide being then in its central position, Fig. 2569, and moving downward. Finally, the crank having arrived at d, and the eccentric at f, the piston will have completed its ascent, and the slide will occupy the position, Fig. 2567, as at starting.

The steam was shown to be cut off when the piston had descended from d to i, the crank having described the arc $d\,g\,u$, and the eccentric the arc $f\,e\,h$. Now, $d\,i$ is the versed sine of $d\,g\,u$, and $e\,c$ is the versed sine of half $f\,e\,h$; and $d\,g\,u$ and $f\,e\,h$ are equal arcs. Hence

Rule III.—To find at what part of the stroke steam will be cut off with a given amount of lap:—Divide the width of steam port, by itself, plus the lap, and call the quotient versed sine. Find its corresponding arc in degrees and minutes, and call it arc the first. If arc the first be less than 45 degrees, multiply the versed sine of twice that arc by half the stroke in inches, and the product will be the distance of the piston from the *commencement* of its stroke, when the steam is cut off.

If arc the first exceed 45 degrees, multiply the versed sine of the difference between double that arc and 180 degrees by half the stroke, and the product will be the distance of the piston from the *end* of its stroke when the steam is cut off.

Rule IV.—To find the amount of lap necessary to cut off the steam at any given part of the stroke:—

If it be required to cut off the steam before half-stroke, divide the distance the piston moves before steam is cut off, by half the stroke, and call the quotient versed sine. Find the arc of that versed sine, and also the versed sine of half that arc. Divide the difference between the versed sine last found and unity, by the versed sine, and multiply the width of steam port by the quotient; the product will be the lap.

If it be required to cut off the steam at a point beyond half-stroke, divide the distance of the piston from the end of its stroke, when steam is cut off, by half the length of stroke; call the quotient versed sine; find its corresponding arc, and abstract it from 180 degrees. Find the versed sine of half the remainder, and subtract it from unity. Divide the remainder by the versed sine, and multiply the width of the steam port by the quotient; the product will be the lap.

Example 3.—The stroke of a piston is 36 inches; width of steam port $1\frac{1}{2}$ inch; and lap 6 inches: required the point of the stroke at which steam will be cut off.

$$\text{Here } 1{\cdot}5 + 6 = 7{\cdot}5\text{ ; and } 1{\cdot}5 \div 7{\cdot}5 = {\cdot}2 = \text{versed sine;}$$
$$\text{arc of versed sine } {\cdot}2 = 36^\circ\ 52', \text{ (arc the first;)}$$
$$\text{and } 36^\circ\ 52' \times {\cdot}2 = 73^\circ\ 44' = \text{are of versed sine, } {\cdot}7198.$$

Then $\cdot7198 \times 18 = 12{\cdot}95$ inches = distance of the piston from the commencement of its stroke when the steam is cut off.

Example 4.—The stroke of a piston is 36 inches; width of steam port $1\frac{1}{2}$ inch; and extent of lap $1\frac{1}{4}$ inch: required the point of the stroke at which steam is cut off.

Here $1{\cdot}5 + 1{\cdot}25 = 2{\cdot}75$; and $1{\cdot}5 \div 2{\cdot}75 = {\cdot}5454$ = versed sine of arc $62^\circ\ 58'$ (arc the first.)

Then $62^\circ\ 58' \times 2 = 125^\circ\ 56'$; and $180^\circ - 125^\circ\ 56' = 54^\circ\ 4'$ = arc of versed sine, $\cdot4131$; $\cdot4131 \times 18 = 7{\cdot}43$ inches = distance of the piston from the end of its stroke when the steam is cut off.

Example 5.—The stroke of a piston is 36 inches; width of steam port 1·5 inches; and distance of the piston from the commencement of its stroke, when the steam is cut off, 12·95 inches: required the lap.

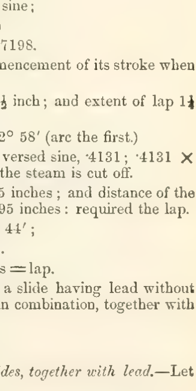
$$\text{Here } 12{\cdot}95 \div 18 = {\cdot}7198 = \text{versed sine of arc } 73^\circ\ 44'\text{;}$$
$$73^\circ\ 44' \div 2 = 36^\circ\ 52' = \text{arc of versed sine } {\cdot}2.$$
$$\text{Then } 1 - {\cdot}2 = {\cdot}8\text{ ; and } {\cdot}8 \div {\cdot}2 = 4\text{; } 1{\cdot}5 \times 4 = 6 \text{ inches} = \text{lap.}$$

The Lead and Lap.—Having separately investigated the two cases of a slide having lead without lap, and lap without lead, we now proceed to consider the effect of both in combination, together with that of lap on the exhaustion side.

Demonstration.

Case 4.—*When a slide has lap on both the steam and exhaustion sides, together with lead.*—Let $a\,b$ and $a\,c$, Fig. 2572, represent the double lap on the steam side; $a\,f$ and $a\,g$, the same on the exhaustion side; $b\,e$ and $c\,d$ the steam ports; and the line $e\,d$ both the travel of the slide and stroke of the piston. Then, supposing $c\,h$ to represent the lead of the slide, $a\,i$ will be the position of the eccentric when that of the crank is $a\,e$; the slide occupying the position shown in Fig. 2573, and the piston being at the top of its downward stroke.

2572.

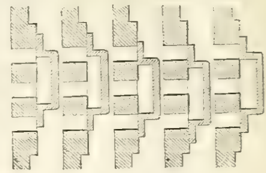


When the eccentric reaches the point k, the port $c\,d$ will be fully closed, as shown in Fig. 2574, and the piston will have descended to l, the arc $e\,m$ being equal to the arc $i\,k$. Again, when the eccentric arrives at n, the slide being then brought into the position Fig. 2575, exhaustion commences from above the piston, which has descended to o; the arc $e\,m\,p$ being equal to the arc $i\,k\,n$. When the eccentric arrives at q, the port $b\,e$ begins to open for the admission of steam beneath the piston, (see Fig. 2576,) which has then descended to r; the arc $e\,m\,s$ being equal to the arc $i\,k\,q$. When the eccentric has reached the point i', opposite to i, the port $b\,e$ will be open to the extent of the lead $b\,h'$, equal to $c\,h$, and the piston will have completed its descent.

Steam continues to enter the port $b\,e$ during the ascent of the piston, until the eccentric reaches the point k', when the port $b\,e$ will be reclosed, Fig. 2576, the direction of the slide's motion being downward, and the piston having ascended to l'. Exhaustion ceases from above the piston when the eccentric reaches the point t, the piston being then at u, and the slide again in the position Fig. 2575

When the eccentric reaches the point n', opposite to n, exhaustion commences below the piston, the slide being then in the position Fig. 2577, and the piston at o'. Finally, when the eccentric reaches the point q', and the crank the point s', opposite to s, steam begins to enter the port $c\,d$ for the return stroke, at the commencement of which the port $c\,d$ will be open to the extent of the lead $c\,h$; the crank and eccentric occupying their original positions $a\,e$ and $a\,i$.

2573. 2574. 2575. 2576. 2577.



It is here shown that four distinct circumstances result from the use of a slide having lap on both sides of the port, with lead, during a single stroke of the piston. These are—

First: The cutting off the steam, for the purpose of expansion.

Second: The cessation of exhaustion on the exhaustion side.

Third: The commencement of exhaustion on the steam side.

Fourth: The readmission of steam for the return stroke.

With regard to the first of these results, we found the steam port $c\,d$ closed, when the crank and eccentric had described the equal arcs $e\,m$ and $i\,d\,k$. Now, $c\,d$, the steam port, is the versed sine of $d\,k$; and $h\,d$, the steam port *minus the lead*, is the versed sine of $i\,d$. Hence,

Rule V.—To find the point of the stroke at which steam will be cut off:

Divide the width of the steam port, and also that width minus the lead, by half the slide's travel, and call the quotients versed sines. Find their corresponding arcs, and call them arc the first, and arc the second, respectively. Then, if the sum of those arcs be less than 90 degrees, multiply the versed sine of their sum by half the stroke, in inches, and the product will be the distance of the piston from the *commencement* of its stroke, when the steam is cut off.

If the sum of arcs the first and second exceed 90 degrees, subtract it from 180 degrees; and the versed sine of the difference, multiplied by half the stroke, equals the distance of the piston from the *end* of its stroke, when the steam is cut off.

Example 8.—The stroke of a piston is 60 inches; the width of steam port 3 inches; lap on the steam side $2\frac{1}{2}$ inches; lap on the exhaust side $\frac{1}{8}$th inch; and lead $\frac{1}{2}$ inch: required the point of the stroke at which steam will be cut off.

$$\text{Here } \frac{3}{3+2\cdot5} = \cdot5454 = \text{versed sine of } 62^\circ\ 58' \text{ (arc the first;)}$$

$$\text{and } \frac{3-\cdot5}{3+2\cdot5} = \cdot4545 = \text{versed sine of } 56^\circ\ 57' \text{ (arc the second.)}$$

Then $62^\circ\ 58' + 56^\circ\ 57' = 119^\circ\ 55'$; and $180^\circ - 119^\circ\ 55' = 60\ 5'$ = arc of versed sine, $\cdot5012$. $\cdot5012 \times 30 = 15\cdot036$ inches = distance of the piston from the *end* of its stroke when the steam is cut off.

Exhaustion was shown to cease, during the ascent of the piston, when the eccentric had reached the point t, and the crank the point x; the crank having described the arc $d\,k\,x$, equal to $i'\,e\,t$ described by the eccentric.

Now $i'\,e$ is equal to *arc the second*, (Rule V.;) and $e\,t$ is equal to 90 degrees minus $t\,t'$, or the arc of versed sine $e\,f$; and $e\,f$ is half the slide's travel minus the lap on the exhaust side. Hence,

To find the point of the stroke at which exhaustion ceases:

Divide half the slide's travel, minus the exhaustion lap, by half the travel, call the quotient versed sine, and add its corresponding arc, calling it arc the third, to arc the second. The versed sine of the difference between their sum and 180 degrees, multiplied by half the stroke, equals the distance of the piston from the end of its stroke when exhaustion ceases.

Example 9.—The several proportions being as in the preceding example.

$$\text{Here } 3 + 2\cdot5 = 5\cdot5 = \text{half the slide's travel;}$$

$$\text{and } \frac{5\cdot5 - \cdot125}{5\cdot5} = \cdot9772 = \text{versed sine of arc } 88^\circ\ 42' = \text{(arc the third.)}$$

Then $88^\circ\ 42' + 56^\circ\ 57'$ (arc the second) $= 145^\circ\ 39'$; and $180^\circ - 145^\circ\ 39' = 34^\circ\ 21'$ = arc of versed sine, $\cdot1743$. $\cdot1743 \times 30 = 5\cdot229$ inches = the distance of the piston from the end of its stroke when exhaustion ceases.

Exhaustion was shown to commence from above the piston when the crank and eccentric had described the equal arcs $e\,k'\,p$ and $i\,d\,n$.

Now $i\,d\,n$ is equal to 180 degrees minus $n\,i'$; $n\,i'$ is equal to $n'\,i$; and $n'\,d$ is equal to arc the third. Hence,

To find the distance of the piston from the end of its stroke when exhaustion commences:

Subtract arc the second from arc the third, and multiply the versed sine of their difference by half the stroke. The product will be the distance required.

Example 10.—The proportions being as in the two preceding examples.

Here $88^\circ\ 42' - 56^\circ\ 57' = 31^\circ\ 45'$ = arc of versed sine, $\cdot1496$; and $\cdot1496 \times 30 = 4\cdot488$ inches, the distance required.

Steam was found to be readmitted, for the return stroke, when the piston had reached the point r in its descent, the crank and eccentric having described the equal arcs $e\,k'\,s$ and $i\,d\,q$.

Now $i\,d\,q$ is equal to 180 degrees minus $q\,i'$; i' being diametrically opposed to i. And $q\,i'$ is equal to $i\,q'$, the difference between arcs the first and second. Hence,

To find the distance of the piston from the end of its stroke when steam is readmitted for the return stroke:

Multiply the versed sine of the difference between arcs the first and second by half the stroke, and the product will be the distance required.

Example 11.—The proportions being as before.

Here $62° 58' - 56° 57' = 6° 1' =$ arc of versed sine ·0055.

Then $\cdot 0055 \times 30 = \cdot 165$ inches $=$ the distance required.

Rule VI.—To find the proportions of the steam lap and lead; the points of the stroke where steam is cut off, and readmitted for the return stroke, being known:

When the steam is cut off before half-stroke, divide the portion of the stroke performed by the piston by half the stroke, and call the quotient versed sine. Likewise, divide the distance of the piston from the end of its stroke when steam is readmitted for the return stroke, by half the stroke, and call that quotient versed sine. Find their respective arcs, and also the versed sines of half their sum and half their difference. The width of the steam port in inches, divided by the versed sine of half their sum, equals half the travel of the slide: and half the travel, minus the width of port, equals the lap. The difference of the two versed sines last found, multiplied by half the travel of the slide, equals the lead.

When the steam is to be cut off after half-stroke, divide the distance of the piston from the end of its stroke by half the stroke; call the quotient versed sine, and subtract its corresponding arc from 180 degrees. Divide the distance the piston has to move when the steam is admitted for the return stroke, by half the stroke; call the quotient versed sine, and find its corresponding arc. Then proceed with the two arcs thus found, as in the former case.

Example 12.—The stroke of a piston is 60 inches; the width of steam port 3 inches; distance of the piston from the end of its stroke when steam is cut off 15·036 inches; and when steam is admitted for the return stroke ·165 inches: required the lap and lead.

$$\text{Here } 15{\cdot}036 \div 30 = {\cdot}5012 = \text{versed sine of arc } 60° 5';$$

$$\text{and } 180° - 60° 5' = 119° 55'.$$

$$\text{Then } {\cdot}165 \div 30 = {\cdot}0055 = \text{versed sine of } 6° 1'.$$

$$119° 55' + 6° 1' = 125° 56'; \qquad 119° 55' - 6° 1' = 113° 54'.$$

$$\frac{125° 56'}{2} = 62° 58' = \text{arc of versed sine } {\cdot}5454;$$

$$\frac{113° 54'}{2} = 56° 57' = \text{arc of versed sine } {\cdot}4545.$$

$$3 \div {\cdot}5454 = 5{\cdot}5 \text{ inches} = \text{half the slide's travel};$$

$$\text{and } 5{\cdot}5 - 3 = 2{\cdot}5 = \text{lap}.$$

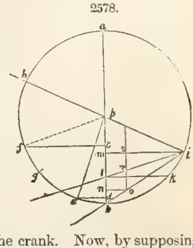
$${\cdot}5454 - {\cdot}4545 = {\cdot}0909; \text{ and } {\cdot}0909 \times 5{\cdot}5 = {\cdot}5 \text{ inches} = \text{lead}.$$

To find the lap and lead by construction.

The stroke of the piston; width of steam port; and distances of the piston from the end of its stroke when the steam is cut off, and when it is readmitted for the return stroke, being known:

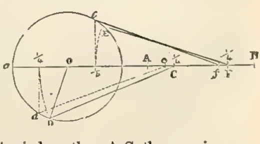
Let the circle, Fig. 2578, represent the crank's orbit, and its diameter $a\,b$ the stroke of the piston, to some known scale. Make $a\,c$ equal to the part of the stroke performed before the steam is cut off; and $b\,d$ equal to the distance of the piston from the end of its stroke when steam is readmitted for the return stroke. Draw $d\,e$ and $c\,f$ at right angles to $a\,b$, and mark the point g at the distance $b\,e$ from f. Bisect the arc $a\,g$, and from the point of bisection, h, draw the diameter $h\,i$. Make $i\,k$ equal to $b\,e$; draw $i\,m$ and $k\,l$ at right angles to $a\,b$; and draw $i\,l$ and $i\,b$ indefinitely. From the point m set off $m\,n$ equal to the width of steam port, full size; from n draw $n\,o$ parallel to $i\,m$, and meeting $i\,b$, and also $o\,p$ parallel to $a\,b$, and meeting $h\,i$; then will $s\,p$ equal the lap, and $s\,r$ the lead.

2578.



In all the foregoing cases, we have taken the versed sine of the arc described by the crank, from either extremity of the stroke, as the portion of the stroke performed by the piston; but, as has been already observed, the relative positions of the piston and crank depend upon the length of the connecting-rod, which will be seen by reference to Fig. 2579, where A B represents the stroke of the piston, C D the connecting-rod, and D O the crank. Now, by supposing $a\,d$ to be the arc described by the crank when the piston has performed one-fourth of its stroke, and from the length of that arc, calculating the amount of lap required to cut off the steam at that part of the stroke, we appear to be in error—for, from the oblique action of the connecting-rod, the piston would have descended only to the point c. But the engine being double-acting, we have to take into consideration the position of the crank when the piston has performed one-fourth of its stroke in the opposite direction from the point B; and here we find, that by supposing the crank to have described the arc $b\,e$, (equal to $a\,d$,) instead of the true arc b E, we cause the steam to be cut off when the piston has reached the point f; and the distance Bf being precisely as much more than B F as A c is less than A C, the seeming error is self-corrective.

2579.



A Table of Multipliers to find the Lap and Lead, when the Steam is to be cut off at ½ to ⅞ths of the Stroke.

The lap must be equal to the width of the steam port multiplied by col. 1.
The lead must be equal to the width of the steam port multiplied by col. 2.

Half-Stroke.		Five-Eighths of the Stroke.		Three-Fourths of the Stroke.		Seven-Eighths of the Stroke.		The distance of the Piston from the end of its stroke when steam is readmitted for the return stroke being equal to half the stroke multiplied by

Example of its application.—Stroke 36 inches; width of port 2 inches; steam to be cut off at half-stroke; distance of the piston from the end of its stroke when steam is readmitted for the return stroke, 1·5 inch.

$\frac{1{\cdot}5}{18} = 0833$. Find that number, or the one nearest to it, in the right hand, or last column, and take out the multipliers on the same line under the head Half-stroke.

Then $2 \times 1{\cdot}21 = 2{\cdot}42$ inches = the lap.

And $2 \times {\cdot}638 = 1{\cdot}276$ inches = the lead.

LEAD—A well-known metal much used in the arts. Lead unites with most of the metals, has little elasticity, and is the softest of them all. Gold and silver are dissolved by it in a slight red heat, but when the heat is much increased the lead separates, and rises to the surface of the gold, combined with all heterogeneous matters; hence lead is made use of in the art of refining the precious metals. If lead be heated so as to boil and smoke, it soon dissolves pieces of copper thrown into it; the mixture, when cold, being brittle. The union of these two metals is remarkably slight, for upon exposing the mass to a heat no greater than that in which lead melts, the lead almost entirely runs off by itself.

Among the ores of lead some have a metallic aspect; are black in substance, as well as when pulverized; others have a stony appearance, and are variously colored, with usually a vitreous or greasy lustre. The specific gravity of the latter ores is always less than 5. The whole of them, excepting the chloride, become more or less speedily black, with sulphureted hydrogen or with hydrosulphurets; and are easily reduced to the metallic state upon charcoal, with a flux of carbonate of soda, after they have been properly roasted. They diffuse a whitish or yellowish powder over the charcoal, which, according to the manner in which the flame of the blowpipe is directed upon it, becomes yellow or red; thus indicating the two characteristic colors of the oxides of lead.

The lead ores most interesting to the arts are:

1. *Galena*, sulphuret of lead. This ore has the metallic lustre of lead, with a crystalline structure derivable from the cube. When heated cautiously at the blowpipe it is decomposed, the sulphur flies off, and the lead is left alone in fusion; but if the heat be continued, the colored surface of the charcoal indicates the conversion of the lead into its oxides. Galena is a compound of lead and sulphur, in equivalent proportions, and therefore consists, in 100 parts, of 86⅗ of metal, and 13⅓ of sulphur, with which numbers the analysis of the galena of Clausthal by Westrumb exactly agrees. Its specific gravity, when pure, is 7·56. Its color is blackish gray, without any shade of red, and its powder is black—characters which distinguish it from *blende*, or sulphuret of zinc.

2. The *seleniuret of lead* resembles galena, but its tint is bluer. Its chemical characters are the only ones which can be depended on for distinguishing it. At the blowpipe it exhales a very perceptible smell of putrid radishes. Nitric acid liberates the selenium. When heated in a tube, oxide of selenium of a carmine red rises along with selenic acid, white and deliquescent. The specific gravity of this ore varies from 6·8 to 7·69.

3. *Native minium* or *red lead* has an earthy aspect, of a lively and nearly pure red color, but sometimes inclining to orange. It occurs pulverulent, and also compact, with a fracture somewhat lamellar. When heated at the blowpipe upon charcoal, it is readily reduced to metallic lead. Its specific gravity varies from 4·6 to 8·9. This ore is rare.

4. *Plomb-gomme.*—This lead ore, as singular in appearance as in composition, is of a dirty brownish or orange-yellow, and occurs under the form of globular or gum-like concretions. It has also the lustre and translucency of gum, with somewhat of a pearly aspect at times. It is harder than fluor spar. It consists of oxide of lead, 40; alumina, 37; water, 18·8; foreign matters and loss, 4·06; in 100. Hitherto it has been found only at Huelgoet, near Poullaouen, in Brittany, covering with its tears, or small concretions, the ores of white lead and galena which compose the veins of that lead mine.

5. *White lead, carbonate of lead.*—This ore, in its purest state, is colorless and transparent, like glass, with an adamantine lustre. It may be recognized by the following characters:

Its specific gravity is from 6 to 6·7; it dissolves with more or less ease, and with effervescence, in nitric acid; becomes immediately black by the action of sulphureted hydrogen, and melts on charcoal before the blowpipe into a button of lead. According to Klaproth, the carbonate of Leadhills contains 82 parts of oxide of lead, and 16 of carbonic acid, in 98 parts. This mineral is tender, scarcely scratches calc-spar, and breaks easily, with a waved conchoidal fracture. It possesses the double refracting property in a very high degree; the double image being very visible on looking through the flat faces of the prismatic crystals. Its crystalline forms are very numerous, and are referrible to the octahedron, and the pyramidal prism.

6. *Vitreous lead,* or *sulphate of lead.*—This mineral closely resembles carbonate of lead; so that the external characters are inadequate to distinguish the two. But the following are sufficient. When pure, it has the same transparency and lustre. It does not effervesce with nitric acid; it is but feebly blackened by sulphureted hydrogen; it first decrepitates and then melts before the blowpipe into a transparent glass, which becomes milky as it cools. By the combined action of heat and charcoal, it passes first into a red pulverulent oxide, and then into metallic lead. It consists, according to Klaproth, of 71 oxide of lead, 25 sulphuric acid, 2 water, and 1 iron. That specimen was from Anglesea; the Wanlockhead mineral is free from iron. The prevailing form of crystallization is the rectangular octahedron, whose angles and edges are variously modified. The sulphato-carbonate, and sulphato tri-carbonate of lead, now called *Leadhillite,* are rare minerals which belong to this head.

7. *Phosphate of lead.*—This, like all the combinations of lead with an acid, exhibits no metallic lustre, but a variety of colors. Before the blowpipe upon charcoal, it melts into a globule externally crystalline, which, by a continuance of the heat, with the addition of iron and boracic acid, affords metallic lead. Its constituents are 80 oxide of lead, 18 phosphoric acid, and 1·6 muriatic acid, according to Klaproth's analysis of the mineral from Wanlockhead. The constant presence of muriatic acid in the various specimens examined is a remarkable circumstance. The crystalline forms are derived from an obtuse rhomboid. Phosphate of lead is a little harder than white lead; it is easily scratched, and its powder is always gray. Its specific gravity is 6·9. It has a vitreous lustre, somewhat adamantine. Its lamellar texture is not very distinct; its fracture is wavy, and it is easily frangible. The phosphoric and arsenic acids being, according to M. Mitscherlich, isomorphous bodies, may replace each other in chemical combinations in every proportion, so that the phosphate of lead may include any proportion, from the smallest fraction of arsenic acid to the smallest fraction of phosphoric acid, thus graduating indefinitely into arseniate of lead. The yellowish variety indicates, for the most part, the presence of arsenic acid.

8. *Muriate of lead. Horn-lead,* or *murio-carbonate.*—This ore has a pale yellow color, is reducible to metallic lead by the agency of soda, and is not altered by the hydrosulphurets. At the blowpipe it melts first into a pale yellow transparent globule, with salt of phosphorus and oxide of copper; and it manifests the presence of muriatic acid by a bluish flame. It is fragile, tender, softer than carbonate of lead, and is sometimes almost colorless, with an adamantine lustre. Specific gravity, 606. Its constituents, according to Berzelius, are lead, 25·84; oxide of lead, 57·07; carbonate of lead, 6·25; chlorine, 8·84; silica, 1·46; water, 0·54; in 100 parts. The carbonate is an accidental ingredient, not being in equivalent proportion. Klaproth found chlorine, 13·67; lead, 39·98; oxide of lead, 22·57; carbonate of lead, 23·78.

9. *Arseniate of lead.*—Its color of a pretty pure yellow, bordering slightly on the greenish, and its property of exhaling by the joint action of fire and charcoal a very distinct arsenical odor, are the only characters which distinguish this ore from the phosphate of lead. The form of the arseniate of lead, when it is crystallized, is a prism with six faces, of the same dimensions as that of phosphate of lead. When pure, it is reducible upon charcoal, before the blowpipe, into metallic lead, with the copious exhalation of arsenical fumes; but only in part, and leaving a crystalline globule, when it contains any phosphate of lead. The arseniate of lead is tender, friable, sometimes even pulverulent, and of specific gravity 5·04. That of Johann-Georgenstadt consists, according to Rose, of oxide of lead, 77·5; arsenic acid, 12·5; phosphoric acid, 7·5, and muriatic acid, 1·5.

10. *Red lead,* or *chromate of lead.*—This mineral is too rare to require consideration in the present work.

11. *Plomb vauquelinite. Chromate of lead and copper.*

12. *Yellow lead. Molybyate of lead.*

13. *Tungstate of lead.*

Having thus enumerated the several species of lead ore, we may remark that galena is the only one which occurs in sufficiently great masses to become the object of mining and metallurgy. This mineral is found in small quantity among the crystalline primitive rocks, as granite. It is, however, among the oldest talc-schists and clay slates that it usually occurs.

Treatment of the ores of lead.—The mechanical operations performed upon the lead ores, to bring them to the degree of purity necessary for their metallurgic treatment, may be divided into three classes, whose objects are:

1. *The sorting and cleansing of the ores;*
2. *The grinding;*
3. *The washing, properly so called.*

The apparatus subservient to the first objects are sieves, running buddles, and gratings. The large

sieves employed for sorting the ore at the mouth of the mine, into coarse and fine pieces, is a wire gauze of iron; its meshes are square, and an inch long in each side. There is a lighter sieve of wire gauze, similar to the preceding, for washing the mud from the ore, by agitating the fragments in a tub filled with water. But instead of using this sieve, the pieces of ore are sometimes merely stirred about with a shovel, in a trough filled with water.

The method of sorting and cleansing the ore consists in using a plane surface made of slabs or planks, very slightly inclined forwards, and provided behind and on the sides with upright ledges, the back one having a notch to admit a stream of water. The ore is merely stirred about with a shovel, and exposed on the slope to the stream. For this apparatus, formerly the only one used, the following has been substituted, called the *grate*. It is a *grid*, composed of square bars of iron, an inch thick, by from 24 to 32 inches long, placed horizontally and parallelly to each other, an inch apart. There is a wooden canal above the grate, which conducts a stream of water over its middle; and an inclined plane is set beneath it, which leads to a hemispherical basin, about 24 inches in diameter, for collecting the metallic powder washed out of the ore.

The apparatus subservient to grinding the ore are:

1. The beater, formed of a cast-iron plate, 3 inches square, with a socket in its upper surface, for receiving a wooden handle. In some localities crushing cylinders have been substituted for the beater

At the mines, the *knocker's* workshop, or *striking floor*, is provided either with a strong stool, or a wall 3 feet high, beyond which there is a flat area 4 feet broad, and a little raised behind. On this area, bounded, except in front, by small walls, the ore to be bruised is placed. On the stool, or wall, a very hard stone slab, or cast-iron plate is laid, 7 feet long, 7 inches broad, and 1½ inches thick, called a *knok-stone*. The workmen, seated before it, break the pieces of mixed ore with the beater.

Crushing machines are in general use in England, to break the mingled ores, which they perform with great economy of time and labor. They have been employed there for nearly forty years.

This machine is composed of one pair of fluted cylinders, and of two pairs of smooth cylinders, which serve altogether for crushing the ore. The two cylinders of each of the three pairs turn simultaneously in an inverse direction, by means of two toothed-wheels upon the shaft of every cylinder, which work by pairs in one another. The motion is given by a single water-wheel. One of the fluted cylinders is placed in the prolongation of the shaft of this wheel, which carries besides a cast-iron toothed-wheel, geared with the toothed-wheels fixed upon the ends of two of the smooth cylinders. Above the fluted cylinders, there is a hopper, which discharges down between them the ore brought forwards by the wagons. These wagons advance upon a railway, stop above the hopper, and empty their contents into it through a trap-hole, which opens outwardly in the middle of their bottom. Below the hopper there is a small bucket called a shoe, into which the ore is shaken down, and which throws it without ceasing upon the cylinders. The shoe is so regulated that too much ore can never fall upon the cylinders, and obstruct their movement. A small stream of water is likewise led into the shoe, which spreads over the cylinders, and prevents them from growing hot. The ore, after passing between the fluted rollers, falls upon inclined planes, which turn it over to one or other of the pairs of smooth rolls.

These are the essential parts of this machine; they are made of iron, and the smooth ones are case-hardened, or *chilled*, by being cast in iron moulds. The gudgeons of both kinds move in brass brushes fixed upon iron supports made fast by bolts to the strong wood-work base of the whole machine. Each of the horizontal bars has an oblong slot, at one of whose ends is solidly fixed one of the plummer-blocks or bearers of one of the cylinders, and in the rest of the slot the plummer-block of the other cylinder slides; a construction which permits the two cylinders to come into contact, or to recede to such a distance from each other as circumstances may require. The movable cylinder is approximated to the fixed one by means of iron levers, which carry at their ends weights, and rest upon wedges susceptible of adjustment. These wedges press the iron bar, and make it approach the movable cylinder by advancing the plummer-block which supports its axis. When matters are so arranged, should a very large or hard piece present itself to one of the pairs of cylinders, one of the rollers would move away and let the piece pass without doing injury to the mechanism.

Besides the three pairs of cylinders which constitute essentially each crushing machine, there is sometimes a fourth, which serves to crush the ore when not in large fragments.

The *stamp-mill* is employed in concurrence with the crushing cylinders. It serves particularly to pulverize those ores whose gangue is too hard to yield readily to the rollers, and also those which being already pulverized to a certain degree, require to be ground still more finely. (See STAMPERS.)

The sifting meshes of the sieve are made of strong iron wire, three-eighths of an inch square. This sieve is suspended at the extremity of a forked lever, or brake, turning upon an axis by means of two upright arms about 5 feet long, which are pierced with holes for connecting them with bolts or pins, both to the sieve-frame and to the ends of the two branches of the lever. These two arms are made of wrought iron, but the lever is made of wood, as it receives the jolt. Each jolt not only makes the fine parts pass through the meshes, but changes the relative position of those which remain on the wires, bringing the purer and heavier pieces eventually to the bottom. The mingled fragments of galena, and the stony substances lie above them; while the poor and light pieces are at top. These are first scraped off, next the mixed lumps, and lastly the pure ore, which is carried to the *heap*.

The poor ore is carried to a crushing machine, where it is bruised between two cylinders appropriated to this purpose; after which it is sifted afresh.

Washing apparatus.—For washing the ore after sifting it, the machine already described is employed

Smelting of lead ores.—The lead ores of England were anciently smelted in very rude furnaces, or *boles*, urged by the natural force of the wind, and were therefore placed on the summits or western slopes of the highest hills. More recently these furnaces were replaced by blast hearths, resembling smiths' forges, but larger, and were blown by strong bellows, moved by men or water-wheels. The principal operation of smelting is at present always executed there in *reverberatory furnaces*, and in furnaces similar to those known in France by the name of Scotch furnaces

The reverberatory furnaces called cupola are now exclusively used in Derbyshire for the smelting of lead ores. In the works where the construction of these furnaces is most improved, they are interiorly 8 feet long by 6 wide in the middle, and 2 feet high at the centre. The fire, placed at one of the extremities, is separated from the body of the furnace by a body of masonry, called the *fire-bridge*, which is two feet thick, leaving only from 14 to 18 inches between its upper surface and the vault. From this, the highest point, the vault gradually sinks towards the further end, where it stands only 6 inches above the sole. At this extremity of the furnace, there are two openings separated by a triangular prism of *fire-stone*, which lead to a flue, a foot and a half wide, and 10 feet long, which is recurved towards the top, and runs into an upright chimney 55 feet high. The above flue is covered with stone slabs, carefully jointed with fire-clay, which may be removed when the deposit formed under them (which is apt to melt) requires to be cleaned out. One of the sides of the furnace is called the laborers' side. It has a door for throwing coal upon the fire-grate, besides three small apertures each about 6 inches square. These are closed with movable plates of cast-iron, which are taken off when the working requires a freer circulation of air, or for the stirring up of the materials upon the hearth. On the opposite side, called the working side, there are five apertures; namely, three equal and opposite to those just described, shutting in like manner with cast-iron plates, and beneath them two other openings, one of which is for running out the lead, and another for the scoriæ. The ash-pit is also on this side, covered with a little water, and so disposed as that the grate-bars may be easily cleared from the cinder slag.

The hearth of the furnace is composed of the reverberatory furnace slags, to which a proper shape has been given by beating them with a strong iron rake, before their entire solidification. On the laborers' side, this hearth rises nearly to the surface of the three openings, and falls towards the working side, so as to be 18 inches below the middle aperture. In this point, the lowest of the furnace, there is a tap-hole, through which the lead is run off into a large iron boiler, (lea-pan,) placed in a recess left outside in the masonry. From that lowest point, the sole gradually rises in all directions, forming thus an inside basin, into which the lead runs down as it is melted. At the usual level of the metal bath, there is on the working side, at the end furthest from the fire, an aperture for letting off the slag.

In the middle of the arched roof there is a small aperture, called the *crown-hole*, which is covered up during the working with a thick cast-iron plate. Above this aperture a large wooden or iron hopper stands, leading beneath into an iron cylinder, through which the contents of the hopper may fall into the furnace when a trap or valve is opened.

Roasting.—The ordinary charge of ore for one smelting operation is 20 cwts., and it is introduced through the hopper. An assistant placed at the back doors spreads it equally over the whole hearth with a rake; the furnace being meanwhile heated only with the declining fire of the preceding operation. No regular fire is made during the first two hours, but a gentle heat merely is kept up by throwing one or two shovelfuls of small coal upon the grate from time to time. All the doors are closed, and the register plate of the chimney is lowered.

The outer basin in front of the furnace is at this time filled with the lead derived from a former process, the metal being covered with slags. A rectangular slit above the tap-hole is left open, and remains so during the whole time of the operation, unless the lead should rise in the interior basin above the level of that orifice; in which case a little mound must be raised before it.

The two doors in front furthest from the fire being opened, the head smelter throws in through them, upon the sole of the furnace, the slags swimming upon the bath of lead, and a little while afterwards he opens the tap-hole, and runs off the metallic lead reduced from these slags. At the same time his assistant turns over the ore through the back doors. These being again closed, while the above two front doors are open, the smelter throws a shovelful of small coal or coke cinder upon the lead-bath, and works the whole together, turning over the ore with the paddle or iron oar. About three-quarters of an hour after the commencement of the operation, he throws back upon the sole of the hearth the fresh slags which then float upon the bath of the outer basin, and which are mixed with coaly matter. He next turns over these slags, as well as the ore, with the paddle, and shuts all the doors. At this time the smelter runs off the lead into the pig-moulds.

The assistant now turns over the ore once more through the back doors. A little more than an hour after the operation began, a quantity of lead, proceeding from the slag last remelted, is run off by the tap; being usually in such quantity as to fill one-half of the outer basin. Both the workmen then turn over the ore with the paddles, at the several doors of the furnace. Its interior is at this time of a dull red heat: the roasting being carried on rather by the combustion of the sulphurous ingredients, than by the action of the small quantity of coal in the grate. The smelter, after shutting the front doors, with the exception of that next the fire-bridge, lifts off the fresh slags lying upon the surface of the outside bath, drains them, and throws them back into the furnace.

An hour and a half after the commencement, the lead begins to ooze out in small quantities from the ore; but little should be suffered to flow before two hours have expired. About this time the two workmen open all the doors, and turn over the ore, each at his own side of the furnace. An hour and three-quarters after the beginning, there are few vapors in the furnace, its temperature being very moderate. No more lead is then seen to flow upon the sloping hearth. A little coal being thrown into the grate to raise the heat slightly, the workmen turn over the ore, and then close all the doors.

At the end of two hours, the *first fire* or roasting being completed, and the doors shut, the register is to be lifted a little, and coal thrown upon the grate to give the *second fire*, which lasts during 25 minutes. When the doors are now opened the inside of the furnace is of a pretty vivid red, and the lead flows down from every side towards the inner basin. The smelter, with his rake or paddle, pushes the slags upon that basin back towards the upper part of the sole, and his assistant spreads them uniformly over the surface through the back doors. The smelter next throws in, by his middle door, a few shovelfuls of quick-lime upon the lead-bath. The assistant meanwhile, for a quarter of an hour, works the ore and the slags together through the three back doors, and then spreads them out, while the smelter pushes

the slags from the surface of the inner basin back to the upper parts of the sole. The doors being now left open for a little, while the interior remains in repose, the metallic lead, which had been pushed back with the slags, flows down into the basin. This occasional *cooling* of the furnace is thought to be necessary for the better separation of the products, especially of the slags, from the lead-bath.

In a short time the workmen resume their rakes, and turn over the slags along with the ore. Three hours after the commencement, a little more fuel is put into the grate, merely to keep up a moderate heat of the furnace during the paddling. After three hours and ten minutes, the grate being charged with fuel for the *third fire*, the register is completely opened, the doors are all shut, and the furnace is left in this state for three-quarters of an hour. In nearly four hours from the commencement, all the doors being opened, the assistant levels the surfaces with his rake, in order to favor the descent of any drops of lead; and then spreads the slags, which are pushed back towards him by the smelter. The latter now throws in a fresh quantity of lime, with the view, not merely of covering the lead-bath and preventing its oxydizement, but of rendering the slags less fluid.

Ten minutes after the third fire is completed, the smelter puts a new charge of fuel in the grate, and shuts the doors of the furnace to give it the *fourth fire*. In four hours and forty minutes from the commencement, this fire being finished, the doors are opened, the smelter pierces the tap-hole to discharge the lead into the outer basin, and throws some quick-lime upon the slags in the inner basin. He then pushes the slags thus *dried up* towards the upper part of the hearth, and his assistant rakes them out by the back doors.

The whole operation of a *smelting shift* takes about four hours and a half, or at most five hours, in which four periods may be distinguished.

1. The *first fire* for roasting the ores, requires very moderate firing, and lasts two hours.

2. The *second fire*, or the smelting, requires a higher heat, with shut doors; at the end the slags are *dried up* with lime, and the furnace is also allowed to cool a little.

3, 4. The last two periods, or the *third* and *fourth fires*, are likewise two smeltings or foundings, and differ from the first only in requiring a higher temperature. The heat is greatest in the last. The form and dimensions of the furnace are calculated to cause a uniform distribution of heat over the whole surface of the hearth. See article Metallurgy.

The lead is brought from the smelting works to any place where it is to be manufactured in the form of "pigs," each of which is an oblong mass, about three feet long, six inches wide, and weighing about one hundred weight and a half. As for the philosophy of the word "pig," applied to the masses of lead, we may remark that it forms another curious instance of the phraseology used in manufacture. It appears that in the iron-manufacture, when the metal flows from the furnace in which it has been reduced from the ore, it passes into a large trough excavated in sand, and from thence into smaller lateral channels on each side. This arrangement has been suggestive of a sort of simile: for the larger trough is called by the workmen the "sow," and the smaller the "pigs," who suck the metal from the "sow;" hence proceeded the names of "sow-metal" and "pig-metal;" and hence, in all probability, the name of "pig" is applied to the saleable masses both of iron and of lead.

The two principal articles into which lead is manufactured are *sheet-lead* and *water-pipes;* or at least they are the only two which need here be noticed, since the comparatively low temperature at which the metal fuses, and the ease with which it is beaten into various forms, enable the plumber to modify it in various ways. The sheet-lead here spoken of is that with which roofs and terraces are covered, and cisterns lined. It is sometimes made, and used formerly to be wholly made, by pouring the melted metal on a flat surface of sand, in a stratum of any required thickness; but the more modern method is that of rolling, or "milling," which we proceed to describe.

A furnace is provided consisting of a hemispherical melting-pot, four or five feet in diameter, and nearly as much in depth, heated by a fire beneath, and covered with an inclosed cap or chimney reaching above the roof of the building, for the purpose of conveying away the deleterious gases engendered during the melting of lead. Into this melting-pot is put about six tons (thirteen thousand pounds) of lead, new and old, which remains there till thoroughly melted. During this time all the impurities, being lighter than the metal, rise to the surface. Immediately adjoining the furnace is a cast-iron frame, called the "mould," being a flat vessel about six or seven feet square, and six inches deep. The bottom of this mould is also of iron, and the melted metal is allowed to flow into it from an opened valve near the bottom of the melting-pot. A shoot or trough conveys the metal from the furnace to the mould. The glistening liquid mass soon flows out, to the weight of about ten or eleven thousand pounds, the dross and impurities being for the most part left behind in the melting-pot. As, however, some impurities or oxidized portions enter the mould, a subsequent removal becomes necessary; and this is effected by drawing the edge of a board carefully over the surface of the hot and liquid metal, the board urging before it all the floating impurities, and leaving a surface very silvery and clear.

After some hours the mass of lead, technically called a "plate," is lifted out of the mould by a powerful crane, and placed upon the machine where it is to be rolled into the form of sheets. This machine is very peculiar in its action. It consists of a long frame or bench, about a yard in height, seven or eight feet wide, and probably seventy feet in length. At intervals of every foot or two are transverse rollers, all placed on the same level, so that a heavy body may be rolled from one end of the frame to the other with great facility. About midway along the frame is the milling or rolling machine, consisting mainly of two ponderous rollers, between which the lead is passed: these are made of iron, the upper one being fifteen or sixteen inches in diameter, with a weight of three tons, the under one being the same. The two rollers are placed at any required distance apart, the one above the other, and are also made to revolve in either direction. These being the mechanical arrangements, the process of milling proceeds thus: The plate of lead is brought between the rollers, which are opened so as only to receive the lead by compressing it; and the rollers being made to rotate, the plate is drawn in between them. This process is repeated over and over again, the plate passing first from right to left, and then from left to right, the opening between the rollers being gradually reduced by means of an

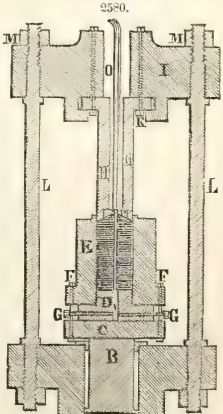
index and graduated dial-plate. The small wooden rollers facilitate the motion of the elongated lead to and fro; and when the length, obtained by reducing the thickness, has become inconveniently great, the piece is cut into two, and each half milled in a similar manner. Thus the lead continues to pass between the rollers to the number of seven or eight hundred times, having its thickness diminished and its length increased by regular degrees. From 300 to 400 feet in length, with a width of seven or eight, is the average quantity of roofing-lead produced by these means from one of the plates. The lead is then coiled up in a roll, and in that form is sold to the plumber, who adapts it to his various purposes.

The manufacture of lead-pipe, like that of sheet-lead, combines the processes both of casting and elongating, or drawing. Whatever be the required diameter and thickness of the pipe, it is first cast in a short piece of great thickness, and then elongated, by which the thickness becomes reduced. The diameter of the cast piece is, internally, the same as that of the required pipe, the external diameter being that which undergoes reduction. The first process is, therefore, to cast the short pieces of pipe. These moulds measure from two to four feet in height, and are fitted for casting pipe whose diameter varies externally from two to six inches, and internally from half an inch to four inches. The mould consists of two semi-cylindrical halves, which, on being brought together, form the external contour of the pipe, while a spindle or steel core, running down the centre of the hollow cavity, regulates the internal diameter of the pipe.

A small melting-furnace is appropriated for the pipe-casting, the lead being carefully skimmed from dross while melting; and when the fusion is complete the melted metal is poured into the mould, the upper end of which is open and the lower end closed. The quantity of lead required for each mould varies from about 24 to 200 pounds, according to the thickness of the pipe. The metal being solidified and sufficiently cool for handling, the two halves of the mould are drawn asunder and the lead removed, the technical name of the "plug" being applied to the short thick piece of pipe thus produced.

Next ensues the very singular method whereby the plug is elongated to the required dimensions. The "drawing-bench" is a frame about thirty feet long and three in height, having in the middle of its length mechanism for producing the elongation. An endless chain is kept in constant motion round two wheels or rollers, one near the end and the other near the middle of the draw-bench, insomuch that a hook or a clasp connected with one of the links would be forcibly drawn along the bench. A mandril, or steel rod, corresponding in size with the internal diameter of the pipe, is inserted into one of the short pipes or plugs, and then so connected with the endless chain as to be drawn along the bench; but in its progress the pipe has to pass through a hole in a steel plate, or die, rather smaller than the diameter of the lead itself, by which its external diameter becomes somewhat reduced and its length increased. Again and again is the pipe, with its contained mandril, drawn along the frame, the die being exchanged after each drawing and replaced by one of smaller diameter. In producing a two-inch pipe no fewer than sixteen dies are employed, the diameters of which descend in a regular series. The hole through the die is conical, that is, larger on one side of the die than on the other, and the lead enters the hole at the widest part, whereby a process of compression is undergone; but at a certain point in the operations a "cutting-die" is introduced, that is, one wherein the lead is at once exposed to a cutting edge, the result of which is that a thin film is cut or scraped from the whole surface of the pipe. By the time that all this routine is undergone the metal has become more dense and compact, the temperature so high as scarcely to be bearable by the hand, the length greatly increased, and the external diameter proportionably diminished. After this the elongated pipe is removed from the mandril, and is then ready for disposal to the plumber.

2580.



Lead-pipe is also manufactured by forcing it through dies, and the process, as improved by Mr. Corneil, of New York, is thus described by him in the specifications of his patent:

My invention consists of certain improvements in the arrangement and combination of the machinery or apparatus heretofore used for similar purposes, and in the construction and application of certain additional machinery or apparatus, and the combination thereof with the other apparatus, as herein described.

My machine is applicable to the manufacture of pipes and tubes of lead, and such other metals and their alloys as are capable of being squeezed or forced by means of great pressure from a cylinder or receiver through or between apertures, dies, cores, or mandrils, when in a solid or semi-fluid state, and is mainly referable in its general construction and purposes to the machine patented by Thomas Burr in Great Britain, and described in the first volume of the first series of the "London Journal of Arts and Sciences."

In my machine I use the hydraulic press, the lead cylinder or receiver, the columns or pillars connecting the hydraulic press with the lead cylinder, the movable ram for pressing the piston upon the lead in the cylinder or receiver, the dies and cores to give the pipes the required form, and calibre, and dimensions, and such other parts of the old machines as may be necessary, substantially similar to the machine of the said Thomas Burr.

Fig. 2580 represents my invention, showing how, by different arrangements of the machinery, the power may be applied to the lead cylinder, which in this case is movable, while the piston is stationary.

This figure is a sectional view of the hydraulic press and pipe machinery in which the long movable core is used. In the figure, A is the hydraulic cylinder, and B the ram rising therefrom. A cross-head is attached to the hydraulic cylinder in the usual manner, and is

connected with the upper cross-head I, by means of the rods L L, which are secured at the top and bottom by the nuts M M M M, turned on the screws at the ends of the rods. On the top of the ram a head-block C is placed, and there secured. A foot-block D is attached to the bottom of the lead cylinder E, and the head-block, the foot-block, and the lead cylinder are secured firmly together by the bolts F F. By this arrangement the lead cylinder will be moved upwards and downwards by the ram of the hydraulic press. To the upper cross-head I the hollow piston H is attached, and secured by means of the bolts K K having screws and nuts at the ends. The die P is placed in the lower end of the piston, which is hollowed throughout, and communicates with the aperture O made through the upper cross head. The long movable core N which is used in this case, is firmly secured to the head-block of the ram, extending upwards through the centre of the lead cylinder, and a short distance above it, to be inserted through the die in the end of the piston. The position of the core is regulated by means of the set-screws G G, four in number, which move the core laterally, and set it centrally in the die. When all the parts are thus arranged, the lead cylinder is raised up to the lower end of the piston, the end of the core passing through the die, and being there adjusted centrally by the set-screws, the lead cylinder is charged, and the power of the press applied.

The ram is forced upwards, carrying the lead cylinder before it, which passes over the piston. The pipe is formed at the point of pressure, as before, passing through the hollow piston through the aperture O, and out at the top of the machine. The core in this arrangement moves upwards with the lead cylinder through the die and the hollow piston. A strong metallic ring is placed and firmly secured on the lower cross-head, encircling the ram B, to act as a guide for the ram, keeping it steady and giving it the precise direction.

LENS. In optics, a piece of glass, or other transparent substance, having its two surfaces so formed that the rays of light have their direction changed by passing through it; so that they either converge, tending to a point beyond the lens, or diverge, as if they proceeded from a point before the lens; or become parallel, after converging or diverging.

A double convex lens, Fig. 2581, is bounded by two convex spherical surfaces, whose centres are on opposite sides of the lens. It is equally convex when the radii of both surfaces (that is, the distances from the centres to the circumferences of the circle they belong to) are equal, and unequally convex when their radii or distances are unequal.

A plano-convex lens, Fig. 2582, is bounded by a plane surface on one side, and by a convex one on the other.

A double concave lens, Fig. 2583, is bounded by two concave spherical surfaces whose centres are on opposite sides of the lens.

A plano-concave lens, Fig. 2584, is bounded by a plane surface on one side, and a concave one on the other.

A meniscus, Fig. 2585, is bounded by a concave and a convex spherical surface; and these two surfaces meet, if continued.

2582.

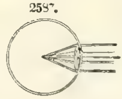
2583.

2584.

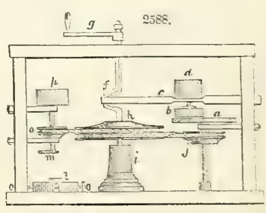
2585.

2586.

2587.



2588.



The focal distance, or distance of the focus from the surface of the lens, depends both upon the form of the lens and of the refractive power of the substance of which it is made; in a glass lens, both sides of which are equally convex, the focus is situated nearly at the centre of the sphere of which the surface of the lens forms a portion; it is at the distance, therefore, of the radius of the sphere. Fig. 2587.

Plano-convex lens and rays converging.—Fig. 2586. Lenses that have one side flat and the other convex, (plano-convex,) have their focus at the distance of the diameter of a sphere, of which the convex surface of the lens forms a portion, as represented in the figure.

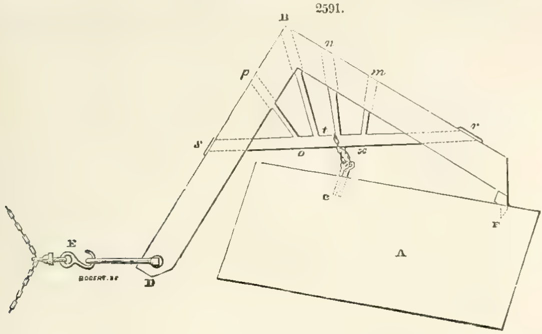
According to some opticians, the greatest diameter of a lens is half an inch; if it exceed that thickness they do not call it a lens, but a lenticular glass. Lenses are made either by blowing or grinding. Blown lenses are small globules of glass melted in the flame of a lamp; ground lenses are reduced by grinding and polishing. A variety of simple apparatus is employed in the processes of grinding and polishing lenses, among which the one shown in Fig. 2588 is much used. *a* shows the edge of a circular lap or slab, used for grinding flat glasses upon; *b* a circular tool or block, upon the under surface of which the glasses to be ground are cemented; *c* is a reciprocating bar; *d* a box containing any weighty matter; *e* a long mortised aperture in the frame, through which the bar *c* freely works; *f* a crank; *g* a winch; *h* a double pulley-wheel, the axis of which rests in the block *i*; *j* a single pulley-wheel. Now on turning the crank by the winch *g*, the bar *c* gives to *b* an eccentric motion; the attrition of *b* on the surface of the lap *a* being increased or diminished at pleasure by increasing or diminishing the load in the box *d*. It should be noticed that the cord which passes round the pulley *h* is crossed previous to its embracing the periphery of the pulley *i*, consequently a motion is given to the lap *a* the reverse of that given to *b*, which is considered to produce the best effect of grinding. The apparatus described is

devoted to the producing of plane surfaces to optical glasses; but the apparatus on the other side of the machine is, at the same time, by similar arrangements, employed in grinding concave or convex surfaces. For this purpose a variety of laps and other tools are so made as to fit on the bed *l*, which bed is adjustable by four equidistant screws. The pulley *o* is driven by another band on the pulley *h*, and the required pressure given by another loaded box *p*. The several tools used are screwed on at *m*, and are adapted for ready changing, that the operations may be performed with celerity.

LEVER. One of the MECHANICAL POWERS, which see.

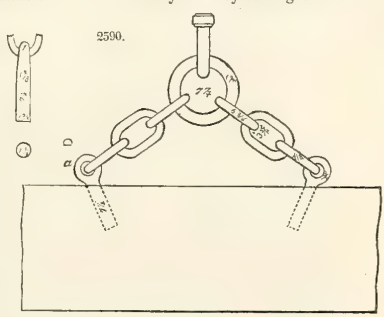
LEWIS. When stone are to be laid into masonry, that are too heavy for the workmen to handle

2591.



without resort to machinery, it becomes necessary to provide means for suspending them so as to leave the lower surface and two of the joints unobstructed. This is usually done by drilling a hole in the upper surface, in which is placed an iron bolt secured by a key. The bolt has an eye or ring, by which it may be attached to the machine which is to suspend the stone. This bolt and key is called a "Lewis," from the name of the inventor.

2590.



The single lewis is in the form of Fig. 2589, and is generally used to suspend stone not exceeding 500 pounds weight.

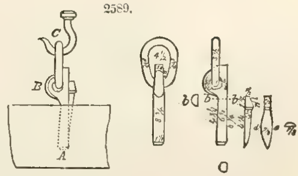
The double, or chain lewis, is in the form of Fig. 2590. This was the form of the lewis which was chiefly used on the U. S. Dry Dock at Brooklyn, for suspending stone from 500 pounds to 10,000 pounds; and stone of twice this weight were suspended with two lewises of this description.

The floor of this dock is an inverted arch, and the sides are made up of alter courses, the top surface of which show as coping stone. To suspend stone of this description, as well as steps and coping, without marring the upper surface, has been long a desideratum.

In Fig. 2591 is exhibited a drawing of Lidgewood's lever lewis, by means of which all this description of stone were set on the dock—some of them weighing seven tons.

The mitre sills on the same work were enormously heavy: the centre stone weighed nearly twenty-five tons, and two others over twenty tons, and several others nearly as large. These stone were suspended by a frame, as shown in Fig. 2591.

2589.



LIGHT. The cause of those sensations which we refer to the eyes, or that which produces the sense of seeing. The phenomena of light and vision have always been regarded as one of the most interesting branches of natural science; though it is only since the days of Newton that they have been examined with such care as to afford grounds for any safe speculation respecting the nature of light, and the mode of its propagation through space.

Experiments of the simplest and most familiar kind suffice to show that light is propagated from

luminous bodies in all directions. Provided nothing intervenes to intercept the light, they are seen in all situations of the eye.

Another property of light is, that it requires time for its propagation. The velocity with which it passes from one point to another is, however, so great, that, with respect to any terrestrial distances, the passage may be considered as instantaneous. But astronomy furnishes the means, not only of detecting its propagation, but of measuring its velocity with great precision. The eclipses and emersions of Jupiter's satellites become visible about 16 min. 26 sec. earlier when the earth is at its least distance from Jupiter, than when it is at its greatest. Light, therefore, occupies above a quarter of an hour in passing through the diameter of the earth's orbit. Now the sun's distance from the earth being nearly 95,000,000 of miles, it follows that light must travel through space with the prodigious, though finite, velocity of 192,500, or nearly 200,000 miles in a second of time, and consequently would pass round the earth in the eighth part of a second. Astounding as this conclusion is, no result of science rests on more certain evidence. It is also proved, by the phenomena of aberration, that the light of the sun, planets, and all the fixed stars, travels with one and the same velocity.

Theories of light.—Two different theories have long divided the opinion of philosophers respecting the nature and propagation of light. One of these consists in supposing it to be composed of particles of excessive minuteness, projected from the luminous body with a velocity equal to nearly 200,000 miles in a second. This hypothesis was adopted by Newton, and, till recently, has been acquiesced in by the greater number of writers on optics. The other hypothesis supposes light to be produced by the vibrations or undulations of an ethereal fluid of great elasticity, which pervades all space and penetrates all substances, and to which the luminous body gives an impulse which is propagated with inconceivable rapidity, in spherical superficies, by a sort of tremor or undulation, as sound is conveyed through the atmosphere, or a wave along the surface of water. Both of these hypotheses are rendered probable by the great number of phenomena of which they afford a mechanical explanation; but they are both, also, attended with very great difficulties. Other theories have also been proposed; but they have not met with such general attention from philosophers as to make it necessary to explain them in this place.

Corpuscular theory of light.—Sir John Herschel, in his admirable *Essay on Light*, in the *Encyclopædia Metropolitana*, states the principles of the Newtonian or Corpuscular theory as follows:

1. "That light consists of particles of matter possessed of inertia, and endowed with attractive and repulsive forces, and projected or emitted from all luminous bodies with nearly the same velocity, about 200,000 miles per second.

2. That these particles differ from each other by the intensity of the attractive and repulsive forces which reside in them; and in their relations to the material world; and also in their actual masses, or inertia.

3. That these particles, impinging on the retina, stimulate and excite vision: the particles whose inertia is greatest, producing the sensation of red; those of the least inertia, of violet; and those in which it is intermediate, the intermediate colors.

4. That the molecules of material bodies and those of light exert a mutual action on each other, which consists in attraction and repulsion, according to some law or function of the distance between them; that this law is such as to admit, perhaps, of several alternations or changes from repulsive to attractive force; but that when the distance is below a certain very small limit it is always attractive up to actual contact; and that beyond this limit resides at least one sphere of repulsion. This repulsive force is that which causes the reflection of light at the external surfaces of dense media; and the interior attraction that which produces the refraction and interior reflection of light.

5. That these forces have different absolute values or intensities, not only for all different material bodies, but for every different species of the luminous molecules, being of a nature analogous to chemical affinities or electric attractions; and that hence arises the different refrangibilities of the rays of light.

6. That the motion of a particle of light, under the influence of these forces and its own velocity, is regulated by the same mechanical laws which govern the motions of ordinary matter; and that therefore each particle describes a trajectory, capable of strict calculation as soon as the forces which act on it are assigned.

7. That the distance between the molecules of material bodies is exceedingly small in comparison with the extent of their spheres of attraction and repulsion on the particles of light.

8. That the forces which produce the reflection and refraction of light are, nevertheless, absolutely insensible at all measurable or appreciable distances from the molecules which exert them.

9. That every luminous molecule, during the whole of its progress through space, is continually passing through certain periodically recurring states, called by Newton fits of easy reflection and easy transmission, in virtue of which they are more disposed, when in the former states or phases of their periods, to obey the influence of the repulsive or reflective forces of the molecules of a medium; and when in the latter, of the attractive."

Such are the postulates on which the corpuscular theory of light depends. Most of them may be admitted without difficulty; and they afford data for the application of mathematical reasoning to the phenomena, which may be investigated by the same sort of analysis with which mathematicians are already familiar in the theories of heat, capillary attraction, and other molecular forces.

Undulatory theory.—The principles of the undulatory theory are thus stated by Sir J. Herschel:

1. "That an excessively rare, subtle, and elastic medium, or *ether*, fills all space, and pervades all material bodies, occupying the intervals between their molecules; and either by passing freely among them, or by its extreme rarity, offering no resistance to the motion of the earth, the planets, or comets, in their orbits, appreciable by the most delicate astronomical observations; and having inertia, but not gravity.

2. That the molecules of the ether are susceptible of being set in motion by the agitation of the particles of ponderable matter; and that when any one is thus set in motion it communicates a similar

motion to those adjacent to it; and thus the motion is propagated further and further in all directions, according to the same mechanical laws which regulate the propagation of undulations in other elastic media, as air, water, or solids, according to their respective constitutions.

3. That in the interior of refracting media the ether exists in a state of less elasticity, compared with its density, than in vacuo, (*i. e.*, in space empty of all other matter;) and that the more refractive the medium, the less, relatively speaking, is the elasticity of the ether in its interior.

4. That vibrations communicated to the ether in free space are propagated through refractive media by means of the ether in their interior, but with a velocity corresponding to its inferior degree of elasticity.

5. That when regular vibratory motions of a proper kind are propagated through the ether, and, passing through our eyes, reach and agitate the nerves of our retina, they produce in us the sensation of light, in a manner bearing a more or less close analogy to that in which the vibrations of the air affect our auditory nerves with that of sound.

6. That as, in the doctrine of sound, the frequency of the aerial pulses, or the number of excursions to and fro from the point of rest made by each molecule of the air, determines the pitch or note; so, in the theory of light, the frequency of the pulses, or number of impulses made on our nerves in a given time by the ethereal molecules next in contact with them, determines the *color* of the light; and that as the absolute extent of the motion to and fro of the particles of air determines the *loudness* of the sound, so the *amplitude* or extent of the excursions of the ethereal molecules from their points of rest determines the brightness or intensity of the light."

Whichever theory we adopt to explain the phenomena of light, we are led to conclusions which strike the mind with astonishment. According to the corpuscular theory, the molecules of light are supposed to be endowed with attractive and repulsive forces, to have poles, to balance themselves about their centres of gravity, and to possess other physical properties which we can only ascribe to ponderable matter. In speaking of these properties it is difficult to divest one's self of the idea of sensible magnitude, or by any strain of the imagination to conceive that particles to which they belong can be so amazingly small as those of light demonstrably are. If a molecule of light weighed a single grain, its momentum (by reason of the enormous velocity with which it moves) would be such that its effect would be equal to that of a cannon-ball of 150 pounds, projected with a velocity of 1000 feet per second. How inconceivably small must they, therefore, be, when millions of molecules, collected by lenses or mirrors, have never been found to produce the slightest effect on the most delicate apparatus contrived expressly for the purpose of rendering their materiality sensible!

If the corpuscular theory astonishes us by the extreme minuteness and prodigious velocity of the luminous molecules, the numerical results deduced from the undulatory theory are not less overwhelming. The extreme smallness of the amplitude of the vibrations, and the almost inconceivable, but still measurable rapidity with which they succeed each other, were computed by Dr. Young, and are exhibited by Sir J. Herschel in the following table:

Colors.	Length of undulation in parts of an inch.	Number of undulations in an inch.	Number of undulations per second.
Extreme Red	0·0000266	37640	458,000000,000000
Red	0·0000256	39180	477,000000,000000
Orange	0·0000240	41610	506,000000,000000
Yellow	0·0000227	44000	535,000000,000000
Green	0·0000211	47460	577,000000,000000
Blue	0·0000196	51110	622,000000,000000
Indigo	0·0000185	54070	658,000000,000000

Extreme Violet	0·0000167	59750	727,000000,000000
			The velocity of light being assumed at 192,000 miles per second.

On a cursory view, it must appear singular that two hypotheses, founded on assumptions so essentially different, should concur in affording the means of explaining so great a number of facts with equal precision and almost equal facility. This, however, is the case with respect to the corpuscular and undulatory theories of light, from both of which the mathematical laws to which the phenomena are subject may be deduced, though not in all cases with the same degree of facility.

LIGHT, ARTIFICIAL. The importance of obtaining a brilliant and economical light for public and domestic purposes, has exercised the ingenuity and scientific research of eminent men for a century past. And although their labors have resulted in discoveries of great value, the desideratum so steadily sought after has not yet been attained.

The introduction of coal-gas, in 1798, by Mr. William Murdock, engineer to Messrs. Bolton and Watt, was an invention of the highest order, and one that has conferred most important benefits upon society. The subsequent use of oil and resin, as substitutes for coal, to avoid the difficulties of purification required by the latter, did not result in any improvement of economy or illuminating power. The discovery of the voltaic and oxy-hydrogen lime light was a brilliant addition to our stock of chemical science, but neither of them have yet been reduced to any thing like a practical form suited to public or domestic uses.

The requirements of the case may be stated thus: 1st, intense illuminating power; 2d, economy; 3d, portability; 4th, small radiation of heat; 5th, perfect ventilation; 6th, simplicity in the production and steadiness of combustion, so as to insure uniform power of light.

To obtain an artificial light combining all these requisites, is now one of the most interesting problems of this era of useful inventions, and its solution will place the discoverer on the same eminence with Newton, Watt, Fulton, and Morse. There is, therefore, no field of research that promises more substantial rewards to the successful than the invention of a simple, economical, and powerful light, as the want of it is felt by the whole civilized world.

That this subject has already attracted the attention of both scientific and practical men in this country, as well as abroad, we have abundant proofs in the frequent announcement of grand discoveries in the production of artificial light, that, upon investigation, prove to be either new discoveries of old chemical experiments, by some tyro or quack, or else are of no value practically, owing to the chemical or mechanical cost of production.

It is very easy to assure the public that water can be made to burn, or that a whole city is about to be completely illuminated with a single gas-light. The demonstration of such wonders is, however, probably reserved for a future age. At present we would only direct the attention of our ingenious countrymen to the simple fact, that this subject is one of universal public importance, presenting a broad scope for the exercise of their inventive faculties.

LIGHT-HOUSES. See SEA-LIGHTS, under which head the subject should be treated.

LIGHTNING CONDUCTORS are pointed metallic rods, fixed to the upper parts of buildings to secure them from strokes of lightning. They were invented and proposed by Dr. FRANKLIN for this purpose, and they exhibit a very important and useful application of modern discoveries in the science of electricity. See ELECTRICITY.

LIFE-BOAT. A boat originally made at Shields, in 1789, by Mr. Greathead, for saving the crews of shipwrecked vessels. The following are the general principles: The boat is wide and shallow; the head and stern are alike, for pulling in either direction, and raised, to meet the waves; it pulls double-banked, the oars being fir, for lightness, and fitted with thole-pins and grummets, and is steered with an oar. The boat is cased round inside, on the upper part, with cork, in order to secure her buoyancy with as many persons as she can carry, even though full of water; the cork likewise assists in maintaining, or, if overset, in recovering, the position of stable equilibrium. The boat is painted white, to be conspicuous in emerging from the hollow of the sea. It is a curious fact that the smugglers paint their boats white for the contrary reason, because dark-colored objects alone are discernible in dark nights.

The loss by fire constantly occurring on the western waters is a proof of the necessity for greater and more effective means of saving life, than are yet adopted in our mercantile marine of all classes nearly. That this should be so is doubly surprising, when, in our very midst, we have the remedy in Francis's galvanized iron life-boat, of which it may be stated, they are never leaky. They may be thrown overboard without injury, or lessening their usefulness; they right themselves, if swamped; and, when full of water, a thirty-foot boat will sustain forty people, so long as they can hold on to the beckets, with which each boat is provided. The non-inflammable material of their construction is another great safety on going alongside a burning wreck; and in a heavy sea their elasticity and buoyancy preserves them alongside a sinking wreck, in circumstances which invariably destroy a wood-boat at the time when she is most needed. These boats are manufactured by Mr. Francis, at the Novelty Works of Stillman, Allen & Co., on the East River.

LIME. Carbonate of lime is the substance forming the principal ingredient of all natural limestones, which may be classified, from their outward mineralogical characters, under the following arrangement:

Granular limestone, with a decidedly crystalline grain: the different varieties of marble, (Parian, Carrara,) and particularly the old mountain limestone, belong to this class.

Compact limestone occurs in quite as great a variety of colored species as the foregoing, but is never so white. It is found in all geological formations, and is named according to its age, or from the formations of which it is a member; we thus have transition limestone, graywacke limestone, carboniferous limestone, mountain limestone, shell limestone, lias limestone, fresh-water limestone, &c.

Limestone Breccia, consisting of lumps of limestone, cemented together by another limestone mass.

Limestone marl, more or less uniformly mixed with clay, of a dense earthy fracture. This and the foregoing variety belong to no particular member of the stratified rocks, exclusively.

Silicious limestone contains numerous silicious minerals, as quartz, hornestone, chalcedony, opal, &c. This variety is dense, and interspersed often with cavities; it is gray, or yellowish-white.

Fetid limestone is characterized by the bitumen which it contains, and which is rendered perceptible to the smell by friction. It is generally dense, and exhibits stratification. It is called *friable marl* when it occurs as a disconnected earthy mass, and is of a dark color.

Chalk is a dense, earthy rock, imparting color when rubbed, seldom other than of a white color. It is distinguished as being the matrix of flints.

Coarse lime is dense, earthy, approaching sandstone in appearance, and contains a large proportion of quartz-sand and clay, and is stratified.

Calcareous tufa consists of layers of lime which are pretty free from foreign matters, and is still in the process of formation. Generally unstratified. In some parts it is loose, porous, and earthy; in others dense, passing into a variety of dense limestone.

Calcareous tufa and Travertin belong to this class. Lime of similar origin is called calcareous sinter when the stratification contains crystalline particles (calcareous spar or arragonite) arranged like layers of bark, one above the other, often in the form of columns.

[These formations are produced by the solvent action of water containing carbonic acid upon carbonate of lime.

The *stalactites* and *stalagmites* which frequently cover the roofs and floors of certain caverns, are also

due to the same cause. The water which permeates the rocks above them dissolves the carbonate of lime, by reason of the carbonic acid which it contains. In dropping from the roof, however, it remains suspended for some time, and, losing a certain part of the acid, deposits also a portion of the carbonate of lime, previously held in solution. The accumulation of these minute portions of lime gradually form the stalactites. The same takes place on the floors of the caverns, giving rise to the formation of the stalagmites.]

Dolomite is characterized by a large amount of magnesia; it is generally granular, and seldom earthy or massive. It is not distinctly stratified, but sometimes bituminous.

The characters of limestone which stand in connection with the theory of the earth's formation, the geological characters, therefore, lead to a totally different classification. The examination of a limestone in one point of view only, must therefore lead to a very imperfect knowledge of its nature. The mere study of its chemical constitution, would also afford but a very partial means of judging it.

Many limestones exhibit clear indications of having been put in motion in the liquid state. Limestone of this kind must possess a high degree of purity, as, if this were not the case, (and clay or other substances were present,) the result of the fusion would certainly have been different, and would not have ended in the formation of crystals of pure carbonate of lime.

Other limestones, which have been formed by precipitation from soluble salts of lime, are more likely to contain foreign admixtures, which have been deposited by chemical or mechanical agency. Thus, some contain magnesia, iron, and manganese uniformly disseminated through them; others are mixed in the same manner with aluminous or silicious particles, or these are interstratified with them.

Others, again, and a whole series of limestones, have obviously been formed with the concurrence of the animal creation, and it is of importance to ascertain what part the living beings have performed in this general development. Thus, at the present moment, whole islands are being raised up in certain latitudes and oceans, from the calcareous coverings of the coralline animals, just as in former ages the range of the Jura and other mountains have been produced from the same agency. There are likewise limestones, as the shell limestones, which are composed of masses of shells of crustaceous animals. The shells of these animals have been filled with lime, and cemented together so as to form a more or less solid rock. The bodies of the animals have not, however, disappeared without leaving a trace behind them; for that which is denominated *bituminous* in these rocks, is generally the residue of decomposed animal matter permeating the entire mass of the stone.

While many limestone formations have been deposited from sea-water, others appear to have been decidedly formed in fresh water. Calcareous tufa is still being deposited in numerous places from springs, the carbonic acid in which, under greater pressure, dissolves lime, which is again precipitated, when the carbonic acid is evolved under the lesser pressure of the atmosphere.

Pure burnt lime absorbs water with great avidity, and occasions a great disengagement of heat, forming a dense, very soft paste, or, as it is called, becoming *fat;* the limestones containing magnesia are poorer in proportion as they approach to the composition of dolomite. The oxides of manganese and iron which are so frequently found in the limestones, have probably been formed by the action of the atmosphere upon the protoxides of these metals.

Besides the carbonates, the silica and alumina contained in the limestone rocks are also of interest. They exist in the most variable proportions, often combined in the form of clay, sometimes associated with magnesia, sometimes alone. The silica is often, but the alumina never in excess, so that both remain undissolved in acids. Their presence is without any perceptible influence when they are present in small quantity; but when their amount exceeds 10 per cent., the limestones are slaked very slowly and with difficulty after burning, their affinity for water is diminished, and they are then applicable to very different purposes. Of these we shall have occasion to speak under the head of *hydraulic lime.*

Lime burning—Chemical process.—Carbonate of lime is not decomposed at a low red-heat, but is converted at a bright red-heat into carbonic acid and lime. The temperature at which the decomposition is effected is, however, influenced by circumstances, or rather depends entirely upon the facility afforded the carbonic acid for escape when it has been expelled from the lime. If the limestones are constantly surrounded with an atmosphere of carbonic acid, the further evolution of carbonic acid from them is, according to Faraday, very much impeded; but if the gaseous acid is removed as quickly as it is expelled from the lime, the process of removing the future portions of acid is much accelerated. In close vessels, the decomposition is stopped as soon as the space not occupied by the lime has become filled with carbonic acid.

It will be proper to explain the processes employed in burning lime, which must be viewed as a preparation of the limestone for its numerous applications in the arts. The burning of lime is accomplished in three modes: 1. Without a kiln; 2. By an intermittent kiln; and 3. By a kiln in constant operation, or, as it is called, a *perpetual kiln.*

1. *Without a kiln.*—In Wales and Belgium lime is burnt precisely as we burn charcoal; the pile of limestone and fuel mixed is covered with turf, making a heap of about 16 feet in diameter at the base, and 12 feet at the summit, which occupies in burning from six to seven days.

Intermittent kiln.—One of the simplest, but at the same time crudest arrangements, is the following: The kiln is perpendicular, and constructed of the same limestone (in the dry state and without mortar) as that which it is intended to burn. It is placed at the side of a steep hill or declivity, so that the mouth is equally accessible for charging the kiln, as the fire-place for introducing the fuel. The shaft is round throughout, six feet in diameter at the top, and gradually expands to ten feet at about one-third from the bottom. A sudden contraction of the diameter is there introduced, forming a sort of projection inwards of one foot in width, and the size of the kiln then diminishes until it acquires a diameter of about 6½ feet at the bottom. A projection or ledge is carried in the form of a ring all round the interior of the furnace, but not at the same height from the ground, inclining towards the stoking-hole. The charging is carried on upon a certain fixed plan. The lime-burner begins by constructing a pointed

arch upon the ledge, with the large pieces of limestone which are selected expressly for this purpose. He forms in this manner a kind of support or foundation, upon which the other limestones are thrown in, at random, from above, the largest first and the smaller pieces afterwards, which are also piled up above the mouth of the kiln. When the charge has been thus arranged, a pile of wood is erected in the space below the arch, and ignited. The regulation of the fire is by no means an unimportant point, as the possibility of completing the burning depends upon the length of time that the arch, which acts as a support, will endure. The stones composing this arch being unconnected by any cement and unhewn, and only touching in a few places so as to leave a free ingress for the flames, a slight shock will often cause the downfall of the whole, and put a stop to the operation. The sudden and powerful action of the fire, by expanding the stones very rapidly, and driving out the moisture with such force as to rupture the stones, will often produce a sufficient shock to create a catastrophe of this kind. The art of burning lime, therefore, consists in bringing the mass of limestone as gradually as possible to a red-heat. The first period is called *the smoking*, because the gases evolved from the fuel, being too much cooled, are imperfectly burnt, and pass off in the form of a thick smoke. The temperature generally increases in a kiln of this kind during the first two-thirds of the time, until it attains a white-heat, and diminishes again in the last third. The firing must, however, be kept up until the uppermost stones have been completely burnt. During the firing the bulk of the stones is much diminished, and the heap above the mouth of the furnace sinks gradually down.

The evils of such a system of burning, which involves an enormous waste of fuel, (the loss of time not being taken into consideration,) are obvious. The furnace must be allowed to cool each time it is discharged, and the entire amount of heat, or, what is the same thing, the whole of the wood employed for raising the very extensive sides of the kiln to the temperature at which lime is burnt, must be sacrificed. It is also evident that, in such a system of burning, the lower half of the limestone must be thoroughly caustic, while the upper portions are still in the mild state. The upper part is at a very considerable distance from the fire, and removed from the direct action of the flames, is burnt, consequently, at a much greater cost of fuel than would otherwise be necessary. At the same time the lower layers in the kiln are exposed to the constant danger of becoming over-burnt, which very much injures the quality of the lime.

A great advantage is gained by constructing the kilns of brick-work, in a more solid manner, giving the shaft more appropriate dimensions and shape, and building the kilns in situations less subject to be obstructed in working by moisture, &c.

These improvements have been carried out in the kiln shown in Fig. 2592. Instead of a rudely constructed wall, an outer wall is erected in these furnaces, with an internal one of solid brick-work. The fire is placed upon the grate which separates the ash-pit *a* from the fireplace *b*. The grate is really a permeated brick arch.

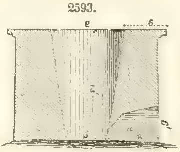
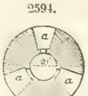
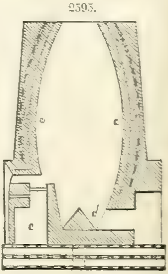
2593.



2594.



2595.

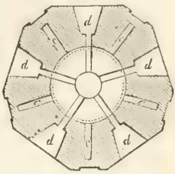


The *perpetual* or *draw kilns* are constructed as follows: Fig. 2593 represents a vertical section of a common form of perpetual kiln constructed for a coal-fire; Fig. 2594 is a horizontal section of the same through the drawing-holes. The actual burning-space is a shaft in the form of an inverted cone, wide at the top and narrow at the bottom. There is no separate hearth, the apertures *a a a*, of which there are three, serving only for drawing out the lime. A layer of brushwood is first placed at the bottom of the kiln, upon this some coal, then a layer of limestone, which is again covered with coal, and then another layer of limestone, and so on until the kiln is filled. The last layer of stone is heaped up above the mouth of the kiln, and the progress of the firing is judged of by the manner in which it sinks down; the sinking in this case being due, not only to the diminution in bulk of the stones, but also to the consumption of the fuel. As soon as the uppermost layer has sunk down to the level of the top of the kiln, another charge of coal and limestone is thrown upon it. In the mean time, at intervals of one-half to one-quarter of an hour, the lime which has sunk to the bottom of the kiln is drawn out through the holes. The lower the charges sink in the kiln the more the coal is consumed, and the less space they will occupy; for this reason the inverted conical form of the kiln is the most appropriate. The intensity of the fire can be regulated with perfect ease by adding more or less coal with each charge of limestone. The draught may be impeded by stopping the apertures entirely or in part. In a kiln of the above

dimensions, 500 cubic feet of lime are drawn in twenty-four hours, and the consumption of coal is about two tons.

Fig. 2595 represents a section, and Fig. 2596 a plan of one of the most approved forms of perpetual kilns in use in Prussia, in which one part of wood and four parts of peat are used. *d d d d d* are openings at bottom for drawing the lime as it is burnt; *c c c c c* fire-furnace for the fuel, whose mode of connection with the cavity where the limestone is placed may be seen at *c* in the vertical section, which also shows at *d* the manner in which the lime may be drawn. At *a a* is shown a lining of fire-brick, back of which is a cavity *b b* filled with cinders, which act as a non-conductor of heat.

2596.



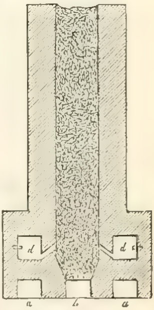
The outside is built of rough stone. It produces about 250 bushels of lime daily.

Scale, 12 feet to ½ inch.

Coal is a kind of fuel that is easily broken in small pieces, in a convenient state for spreading about between the layers of limestone. Another advantage arising from the use of coal is the small quantity of ash which it leaves, and which is easily removed from the kiln with the burnt lime. These remarks do not apply to wood which is reduced with difficulty into small pieces, and not being equally distributed amongst the lime stone, impedes the regular burning and delivery of the lime; nor to peat, which in general leaves so large a proportion of ash as to subject the kiln to the danger of becoming stopped. In those cases where a perpetual process must be combined with the use of wood and peat as fuel, the construction of the kiln must undergo a suitable modification. While the kiln retains its character as a perpendicular or shaft furnace, the fuel, instead of being interstratified with the limestone, is burnt on separate hearths at the sides of the shaft, and the flame is conducted into the latter, which, in this case, contains nothing but the material to be burnt. The number of the fires, which must always be symmetrically arranged round the circumference of the shaft, is regulated by the size of the kiln, so that kilns with three, four, and five fires are met with. The fuel consumed in furnaces of this construction must, of course, yield a long and lively flame, as from wood, peat, or coal; but for the latter, the arrangement is not so economical as the plan of stratification previously described.

Fig. 2597 is a vertical section of a plain perpetual kiln, built in Berkshire, Mass. It is 25 feet high, and built of alternate layers of fire-brick and stone. It is four-sided; consisting of a single chimney 4 feet square on the inside, and 8 feet on the outside, making the walls 2 feet thick. To the height of 7 feet from the bottom it is 12 feet in one direction, for the purpose of making room for the furnaces *d d*, in which wood only is burnt, and which are 2 feet high and 20 inches wide. For the passage of the heat into the limestone in the chimney the bricks are laid up like a grate; *a a* are ash-pits beneath the fires, *b* an opening for clearing the lime from the bottom of the chimney—being about 18 inches square. The kiln consumes from 2 to 2½ cords of wood daily, and produces 75 bushels of lime, which is drawn out at intervals of 8 hours. Scale, 12 feet to a half inch.

2597.



Consumption of fuel.—Notwithstanding the great saving of fuel, which is effected in perpetual kilns, yet it must be borne in mind, that these kilns demand the entire attention of the workman, and cannot be well attended to as a casual occupation, or as a secondary branch of husbandry, for instance; it must also be remembered that perpetual furnaces are always yielding, that is, they produce, in the same time, a much larger amount of burnt lime, and are, consequently, only economical where there is a large and constant demand for the produce. Every improvement in the construction of lime-kilns would be a great boon to the public, for they must be decidedly classed amongst the chief sources of the waste of fuel. The best mode of arriving at some sure foundation from which to calculate the amount of this waste, will no doubt be, by ascertaining the theoretical amount of fuel that is necessary to burn a given weight of lime, and making this result the standard by which to compare the real loss. It may be stated that 1 lb. of wood fuel is capable of heating 26 lbs. of water 100° C. If the specific heat of limestone and carbonic acid is taken at $\frac{1}{3}$ that of water, and the temperature at which lime is rendered caustic is calculated at 800° C., it results, first, that 1 lb. of wood will heat $3 \times 26 = 78$ lbs. of lime to 100°, and consequently $\frac{78}{8} = 9{\cdot}75$ lbs. of limestone to 800°; or in other words and round numbers, only $\frac{1}{10}$ of the weight of the lime is requisite. In practice from 4 to 6 times as much is consumed. The limestone, it is true, does not lose its carbonic acid all at once, as the calculation presupposes, even when it has acquired the proper heat, but the acid is evolved very gradually; it is, consequently, not only necessary to heat the kiln for a single instant to the proper temperature, but to keep up that temperature for a considerable time. But, even if the quantity of wood calculated as necessary be doubled, on account of this latter circumstance, yet there still remains a loss of an equal quantity, and it may be positively asserted, that the quantity of wood consumed in the lime-kilns is about as much again as it should be. The heating power of coal being to that of wood as 60 : 26, for every 10 lbs. of lime burnt there should be 0·43 lbs. of coal consumed. But, as was stated above, for every cubic foot of lime, from ½ to ⅓ cubic foot of coal is burnt, which is equivalent to from 2·4 to 3 lbs. of coal for 10 lbs. of lime, and consequently a very much greater waste.

Lime may be burnt, like bricks, in mounds; but the irregular form of the pieces, and the contraction which ensues, renders the process difficult, and it is consequently seldom practised.

Produce.—Chemically, pure carbonate of lime loses 44 per cent. of carbonic acid, and yields, after burning, 56 per cent. of caustic lime. The produce from the kilns upon a large scale is much less when the limestone is very moist, and greater when it contains a large proportion of clay, which loses nothing

in the kiln. The average amount of produce obtained, ranges between 45 and 77 per cent., the ordinary quantity being about 54 per cent. The contraction is not so considerable as might be expected, as the burnt lime is very porous. The specific gravity of limestone is diminished from $\frac{1}{3}$ to $\frac{1}{2}$ by burning, and its volume is reduced from 10 to 20 per cent. Triest found, by direct experiment, the weight of a solid cubic foot (Hessian) of Rüdersdorf limestone = 93 lbs., after burning = 48 lbs.; the loss was, therefore, = 45 lbs. or 48 per cent. 100 lbs. of fresh Rodheim limestone, to give another example, occupy a space = 209, after burning, (when they ought to weigh 60 lbs.) the space which they occupy is reduced to 183; the contraction, therefore, amounts to 12½ per cent.

Besides the lumps or shells of lime, there is always a portion leaves the kiln in the state of powder, which is in consequence of the stones splitting in the fire, or is due to the friction in charging and discharging the kiln.

Action of aqueous vapor in the kiln.—Moist limestone is said by old lime-burners to burn much more easily than dry limestone. This fact, which is so well established among them that they prefer burning stones fresh from the pit, or even moisten those which have become dry in the air with water before putting them into the kiln, is not without a true foundation, although it is often misunderstood in practice.

When, on the one hand, it cannot be denied that limestone is more easily burnt under the influence of a current of steam, yet on the other, it is very questionable whether the practice of burning moist stones is really advantageous. The practice of bringing moist stones into the kiln is equivalent to the exposure of limestone very much below a red-heat to the action of a current of vapor, as far the greater part of the water must be uselessly expelled (with a proportionate waste of fuel) before the stones acquire a red-heat.

Burnt lime.—Lime, when burnt, combines with the free silica at a red-heat, or enters as a constituent into the compound silicate of lime and alumina which is formed. It will be obvious from these facts, that the foreign substances must exercise considerable influence upon the quality of the burnt lime. In the purer varieties of limestone that contain but very little foreign matter, the influence is imperceptible. As the clay and silica are less prominent in these instances, the action of the magnesia is rendered still more obvious, and when present to the amount of 10 per cent., affects the heating of the lime, and diminishes its property of slaking and forming a soft impalpable paste; in short, renders it poor. When the amount of magnesia exceeds $\frac{1}{4}$, the poorness of the lime is so great as to render it useless. The nature of the limestones is not solely dependent upon the foreign substances which they contain, but also upon the mode of regulating the furnace; while one portion of the shells exhibits the proper amount of heat when slaked, other pieces will slake very slowly, and the water will often hardly act at all upon them; they are then said to be *dead-burnt.*

To convert oyster and muscle shells into lime, requires a higher temperature in the kiln than ordinary limestone, and they have a great tendency to produce a badly slaking lime. The gelatin in the shells is converted into charcoal which burns with difficulty, and is long retained in the interior of the stones while the lime is burnt. Now, if burnt lime is heated for some time intimately mixed with charcoal, the basic carbonate is produced—according to Fuchs.

The slaking.—Burnt lime is of a whitish-gray color, or often dirty white, seldom pure white; it is much more friable than fresh limestone, but yet sufficiently solid to bear carriage. The crystalline structure of many varieties of lime is often distinguishable after burning. It is light and excessively porous. In consequence of its porosity, burnt lime absorbs water (about 18 per cent.) with the greatest avidity, during which operation the air contained in the pores is evolved with considerable noise. In a few minutes (but much later with poor lime) the saturated lime is observed to become hot, and from that moment the combination of lime and water proceeds. The lumps of lime fall to pieces with a crackling sound, and the smaller pieces are reduced to powder with the evolution of much steam, until at last the whole is converted, with a greatly increased volume, into a soft uniform white powder, *i. e.*, into *hydrate of lime.* For building, it is customary to place the lime in *slaking tubs*, or into flat boxes constructed of boards, with a spout, and to pour as much water into them as will nearly cover the lime. During the slaking of the lime, the excess of water is heated to lively ebullition, and the workmen endeavor to mix the lime and water in a uniform manner with a hoe. If the proportion of water was correctly estimated, a uniformly thick semi-liquid mass results. In the formation of hydrate of lime, 100 parts of pure lime combine with 32 parts of water, or nearly $\frac{1}{3}$.

The conversion of liquid into solid water may be viewed as the proximate cause of the great evolution of heat which accompanies the slaking of lime, inasmuch as the water must be contained in this state in the solid hydrate of lime. Suppose 3 lbs. of lime to be slaked, these will combine with 1 lb. of water, for instance, and convert it into the solid form. In this process, a quantity of heat is liberated sufficient to bring 0·79 or $\frac{4}{5}$ lbs. of water to the boiling point. In practice the amount of heat is much greater, for a boiling temperature is attained when the lime is covered with three times the quantity of water. The conversion of water from the liquid to the solid state is, consequently, not the only source of the heat, the remainder must be accounted for by the chemical action which ensues. As a proof of this, the fact may be adduced that lime heats with snow or ice. When a large excess of water is used, the heat evolved is more diffused and less intense; it increases with a lesser quantity, and attains a maximum when no more is added than enters into combination with the lime. The heat has then been observed to attain the temperature required to ignite sulphur and gunpowder, or even wood. If the lime is moistened with water in the dark, it becomes red-hot and emits a lively luminous appearance; in this case, the heat is concentrated by the surrounding lime which is not in the act of being slaked. The heat is in general so much the more intense the more rapidly the lime is slaked; or, is in proportion to its purity and the proper degree of causticity attained in the kiln. The temperature of slaking must always be attended to, as it influences the quality of the lime, and must be regulated by a cautious addition of water; when no more water is added to the lime than it can absorb, it does not form a soft, but a sandy (coarsely crystalline) powder, and is said to have been rendered *poor by slaking.* The

builders have, therefore, a good reason for slaking the lime at once to the form of an impalpable, and not a coarse powder. Rather more than 3 parts of water are required for this purpose. If lime is only speedily dipped in water in a basket, so that it falls to powder, and is afterwards mixed with more water, it does not increase more than to 2½ volumes; if allowed to fall to powder, exposed to the air, and then made into a paste with water, it will only yield 1·7 volumes.

Influence of the air.—Exposed to the air, burnt lime is converted very slowly and without any elevation of temperature into a rough, coarse powder, containing small angular pieces; it then effervesces vigorously with acids.

As large quantities of lime must be kept ready slaked for the purposes of the builder, and it is necessary to protect it from the action of the atmosphere which would render it useless as mortar, it is customary to preserve it in deep pits. The slaking-tub is placed in front of a pit into which the slaked lime in the semi-liquid state is allowed to flow until the pit is filled. The lime becomes fatter and tougher in the pit, those pieces becoming gradually slaked which resisted the first action of the water. The excess of water collects on the surface and can be removed; the pit is then covered with a layer of sand two or three inches in thickness, and the lime is thus preserved totally unchanged. In removing the ruins of the castle of Landsberg in order to lay the foundations for a new building, it is stated by Jahn, that a lime-pit of considerable dimensions was found in one of the vaults. The surface of this mass of lime was carbonated to the depth of a few inches, but all below that was in the state of freshly slaked lime, only somewhat more dry. This lime, which was certainly more than 300 years old, and valued at several hundred florins, was consequently used in constructing the new building.

Hydraulic lime.—Those varieties of lime which contain about 10 per cent. of silica or silicates, assume different properties, and although they are only slowly slaked after burning and poor, yet when made into a dough with water, they soon become solid, and exposed in this state to the constant action of water, acquire a high degree of consistence, and are rendered hard, like stone, without being subsequently loosened or eaten away by the water, and are very appropriately called *hydraulic.* As the hydraulic property is solely due to a chemical process, it can only be explained and understood by reference to the chemical nature of the stones. The following are the results of Berthier's analyses, with the exception of the last number, which was analyzed by Kersten:

The fresh Limestones contained in 100 *parts :*

	1	2	3	4	5	6	7	8	9

The first five numbers yield lime of very moderate, the last four, of a very marked hydraulic character. It will be seen by the table below, that this property increases with the quantity of matter insoluble in muriatic acid. This substance consists chiefly of a combination of silica and alumina, but is often composed nearly entirely of silica in the soluble modification. It becomes of great importance to obtain a knowledge of this insoluble portion, as upon it the hydraulic properties depend. This has consequently received more attention in recent analyses, as will be seen by the following examples:

Burnt hydraulic lime is (with few exceptions) soluble in acids; and, in proof of the presence of a silicate that can be decomposed by acids, a thick jelly of silica is produced. This property of yielding gelatinous silica stands, therefore, in intimate connection with the property of becoming hard under water. Unburnt, pulverized stones do not harden, as is well known; and hydraulic lime, mixed with water, acquires a certain consistence much before it becomes hard. Moistened hydraulic lime produces, in the first instance, a connected, very soft, friable mass, which is easily scratched by the nail; at a much later period, this mass, when covered with water, acquires a hardness which is quite equal to, and often exceeds that of, the limestone itself. As a general fact, the time in which different hydraulic limestones become hard is very variable, and the chemical action, which is the cause of the hardening, is consequently very unequal. The degree of hardness which they acquire is also not the same; those that harden slowly are often more compact than those which harden in a shorter time. The time required for hardening varies from a few minutes to weeks and months, and bears some relation to the amount of the aluminous constituent in the lime. The more the limestones contain of this ingredient, the more quickly they harden. The hardening and solidification of the hydraulic stones being, therefore, dependent upon the chemical reaction of their two ingredients, the relative proportions of these cannot be a matter of indifference; and as there are varieties which, from the smaller quantity of the silicious constituents contained in them, approach the ordinary limestones in properties, so there are others, in

which this ingredient obtains so great a preponderance, and in which the amount of carbonate of lime is so small, that they no longer exhibit the hydraulic property. All mineral substances which possess the property of rendering ordinary limestone hydraulic, are very appropriately called *cements*.

Contains silicious clay.	Moderately good hydraulic lime.	Ordinary hydraulic lime.	Best hydraulic lime.	Intermediate lime.	Bad intermediate cement.	Ordinary cement.	Best intermediate cement.	Transition to Puzzolana.
Before burning (to 100 carbonate of lime.)	12	20	25	30	37	56	156	510
After burning (to 100 caustic lime.)	22	36	44	53	65	100	273	900

This division is of course quite arbitrary, no classes existing in nature, but only transitions; it is, however, convenient when its true signification is borne in mind. There must necessarily be numerous exceptions, for this reason, that the property of hardening in one and the same specimen of lime varies with the temperature at which it has been burnt; thus several varieties belonging to the third class when imperfectly burnt (*i. e.*, when the whole of their carbonic acid has not been expelled) yield an hydraulic lime of the second best quality. Vicat has determined in single cases the amount of imperfect calcination by the amount of carbonic acid not expelled from the lime, and has tested the property of hardening in these different gradations. Thus one variety of limestone in which the carbonic acid remaining in it

amounted to	30 per cent.	27 per cent.	26 per cent.	23 per cent.	20 per cent.	10 per cent.
yielded a mortar which hardened in	15 minutes	12 minutes	7 minutes	9 days	30 days	9 days.

whence it is obvious, that in the course of calcination, and with the increase in the amount of caustic lime, a great diversity of relations between it and the aluminous constituent are created, upon one of which, or upon several at once, the property of rapidly hardening is chiefly dependent. Too much heat in the kiln and incipient fusion, renders the lime very much weaker than it should be when the process is properly conducted, and at last disqualifies it completely. It must be noticed lastly, that hydraulic lime never hardens, when it is immediately immersed in water, before having acquired a certain consistence. In this case, the particles never agglutinate properly together, but form a porous mass.

Many limestones, particularly those which form the boundary between the hydraulic limestones and the cements, possess the very objectionable property of containing portions which slake at a subsequent period, when the greater bulk has already solidified and become hard. The mortar then falls to pieces and is rendered perfectly useless. It would appear as if particles of lime were in this case so enveloped, as only to become penetrated by the water in the course of the process of hardening.

Calcination.—Hydraulic lime is burnt in a similar manner to ordinary limestone; a much less degree of heat, however, is required. Perpetual kilns are used; the burnt stones are reduced to powder under stampers or ground in a mill; the powder is passed through a sieve, and is then in a fit state for use.

Those varieties of hydraulic lime which slake easily, need not even be reduced to powder. A great error is, however, committed in exposing the hydraulic lime (particularly in the state of powder) for any length of time, during carriage, or in warehouses, to the moisture in the atmosphere; the greater part of its good properties are thus gradually destroyed, and it afterwards hardens very slowly or not at all. It need hardly be mentioned, that a larger stock of hydraulic lime should never be made than is intended for immediate consumption. With reference to this point, Vicat has shown, that hydraulic lime which has once attracted moisture, may be made to set, by renewed pulverization and mixture with water; but the action is much slower, and it is converted into an article of the worst quality.

Theory of hardening or solidification.—The solidification of hydraulic lime is supposed to be due to the presence and mutual action of the *silica* and *caustic lime* contained in it. The final result is derived from two operations. During *calcination*, the lime is rendered caustic by the evolution of carbonic acid, and this caustic lime then reacts upon the silicious clay, converting it into a compound that is easily decomposed by acids. The excess of caustic lime, as well as the compound into which the silicious clay has been converted, then react upon each other, when mortar is prepared from the ground burnt lime, in such a manner, that a *solid stone-like silicate* is produced in the *humid way*. The water here obviously has a double action. Dry substances, like lime and the silicate of alumina, act very little, or, under certain circumstances, not at all, upon each other, unless the solvent power of water is employed to bring them into intimate contact. During solidification, the water will constantly transfer the lime which it has dissolved, to the silicious particles; it will then dissolve fresh lime, which is again em-

ployed in the production of the silicate, and so on. The process of solidification is not so much the conversion of a ready formed silicate into a hydrate, as the *formation of a hydrated silicate in one and the same operation.*

The action of the clay.—The silica may be replaced, as is indeed the case in the greater number of dydraulic limestones, by different silicates. Amongst these, the clays are the most important.

The great diversity in the nature of the clays does not admit of the supposition that their action is always the same, but nevertheless they all yield a substance with lime which hardens well, and in some cases affords excellent mortar. All must be previously burnt, particularly potter's-clay. In some cases, it is necessary to calcine the clay with lime. The common ferruginous brick-earth hardly binds at all with lime when only slightly burnt, but when strongly heated, to the point of incipient fusion, the oxide of iron enters into combination with the clay, and a very powerful solidification then ensues with lime.

Artificial hydraulic lime.—Artificial mixtures of appropriate silicates with lime, under proper treatment, possess the hydraulic property in quite as eminent a degree as the natural productions. Experience has indeed anticipated theory in this fact by several centuries. The Romans were well acquainted with the use of lime-mortar, and applied it both in the construction of buildings and roads; they also soon made the important discovery that a certain soft, porous, almost earthy rock, containing pumice-stone, and resembling this in composition, and which was found on the coasts of the Bay of Bayæ and Naples, particularly in the neighborhood of Puteoli, possessed the valuable property of forming an hydraulic mortar with burnt lime. They called the rock *pulvis Puteolanus;* it is described by Vitruvius and by Pliny, and was employed, mixed with an equal quantity of lime, for building under water. The *pulvis Puteolanus* was precisely the same substance as is known in the present day under the name of Puzzolana. The modern name of the town Puteoli is Puzzuoli.

Trass, or tarras.—After entering Germany, and having taken possession of the Rhine, the Romans soon recognized, in the layers of trass, near Bonn, the well-known *pulvis Puteolanus,* and opened the quarries, whence this important material is distributed, far and wide, even to the present day. Both Puzzolana and trass are conglomerates of fragments of volcanic rocks, transposed by the agency of water from their original sites; they often contain fragments of basalt, pumice-stone, trachyte, clay-slate, &c., indicating at once the connection of the one with Vesuvius, and of the other with the volcanoes of Eifel. The trass in Brohlthal is derived from the constituents of the trachyte rocks in the neighborhood; it forms very thick beds, often filling entire valleys, and is in the form of a friable, easily pulverized stone, the color of which is generally light, passing from a yellowish to a greenish hue. It is ground in a number of stamping-mills in the neighborhood, and exported in the form of a fine powder. Like most other volcanic productions, as basalt, klingstein, &c., trass is resolved into two distinct silicates by chemical agency. The one is readily soluble in muriatic acid, the other resists solution.

Puzzolana.—Berthier found the Italian Puzzolana composed of 44·5 per cent. silica, 15·0 alumina, 8·8 lime, 4·7 magnesia, 12·0 oxide of iron and titanium, 1·4 potash, 4·1 soda, and 9·2 water.

Clay as cement.—All those substances which render fat, slaked lime hydraulic, are called *cements.* Puzzolana, trass, and all similar cements have the advantage of requiring no preparation by burning, but are capable of acting in the natural state—of course in fine powder, that they may be properly mixed. All varieties of clay, to be used for cements, must be disintegrated by burning, with or without a certain proportion of lime, according to their different characters. They then afford very powerful cements, which property, however, is very much influenced by the temperature to which they have been exposed, and the manner in which they have been burnt. Treussart made some bricks from a clay which is used in Strasburg for the manufacture of alum, and contains 50 silica, 32·7 alumina, 1·6 magnesia, with mere traces of oxide of iron; a part of these he burnt in the alum-furnace, and the others in a lime-kiln. When the burnt clays were made into mortar with half their weight of slaked lime, a great difference was observed in the two kinds; that which had been burnt in the alum-furnace hardened in two or three days, and would withstand a weight of 400 pounds without being crushed, while that from the lime-kiln did not harden for thirty days, and, placed in the same circumstances, broke under a weight of fifty or sixty pounds. A similar comparison, instituted with two mortars, also composed of one part slaked lime and two parts cement, the one of which consisted of simple clay, the other of clay that had been calcined with 2 per cent. of lime, led to the same result in favor of the latter mortar, which hardened in 17 days, while the former required 30 days.

The excellent hydraulic mortar of Tournay, known under the name of "*cendrée,*" is prepared from the refuse which is left on burning the lias limestone. This waste, which remains after removing the lumps of lime, consists of small fragments of lime and of the ash, (the coal there used yielding a large amount of ash,) in about the proportions of 1 : 3. The mixture is slaked in a small quantity of water, and before being used is well beaten and worked about.

Dr. Elsner has published the following analyses of certain iron slags which are found to afford excellent hydraulic mortar when mixed with burnt lime:

	I.	II.
Silica	40·12	40·44
Alumina	15·37	15·38
Lime	36·02	33·10
Protoxide of manganese	5·80	4·40
Protoxide of iron	1·25	1·63
Potash	2·25	2·07
Sulphur	0·70	0·76

These slags in the state of fine powder, when treated with a small quantity of muriatic acid, are rapidly converted into a uniform gelatinous mass.

It is easy to ascertain whether a slag is suited for the production of hydraulic cement, by pouring

over it, in the state of fine powder, a small quantity of hydrochloric acid; if it forms a gelatinous mass after a short time, it will then yield, with lime, a proper mixture for hydraulic mortar.

Roman cement.—It is a remarkable fact in the history of hydraulic mortars, which originates, as we have seen, with the Puzzolana and trass employed by the Romans, that the more the knowledge of their uses has been spread, the more substances have been discovered which either act as hydraulic mortars themselves, or can be mixed as cements in the preparation of artificial mortar; so that what appeared originally a privilege accorded to a few favored spots only, can now be obtained almost everywhere. A strong inducement to study the nature and modes of occurrence of hydraulic lime was created by the patent granted to Parker and Wyatt, in London, in the year 1796, for what they termed "Roman cement." The material employed in the manufacture of this cement are the nodules, of an ovoidal or globular form, which are found in the London clay, and known by the name of *Septaria.* They are calcined in perpetual lime-kilns with coal, in which a very moderate and well-regulated heat is carefully preserved. After calcination, the stones are ground under heavy edgestones to a very fine powder, which is sifted, and then packed in casks for sale. These nodules are found in many localities in this country.

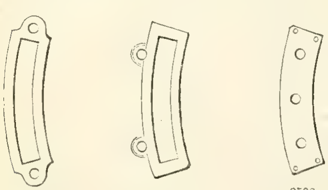
Roman cement is one of the most powerful hydraulic mortars, and is exceedingly valuable, not only on account of the rapidity with which it hardens, and this is effected in a very few minutes, but because when hardened in considerable masses it is not liable to crack.

All artificial or natural hydraulic limestones are soluble (before as well as after calcination) in muriatic acid with the separation of silica, except when sand or some similar substance has been added to them.

The hydraulic limestones, when they do not contain a sufficient quantity of lime to be capable of slaking with water, must be very finely pulverized; it is only by this high state of division that a proper action can ensue. A thorough penetration of the silicious portion by the lime is never entirely effected, but a certain proportion remains inclosed and removed from the sphere of action. See Mortar.

LINK MOTION.—Variable expansion gear, now generally used on locomotives for the movement of the steam valves, first invented by Mr. Williams of Newcastle. Williams' incipient link was a slotted straight bar, which connected the straps of the fore and back eccentrics, formed with ears to secure the linking pins. In the slot of the link, a slide-block hung on the end of a radius link from the valve spindle, was adjustable towards one end or the other, to receive the motion of the one or the other eccentric for fore or back gear; while the link would partake jointly of the two motions of the eccentrics, its horizontal motion would be smallest at the centre of its length, and increase towards the extremities: thus by shifting the block towards the centre, the travel of the valve would be reduced, and variable expansion thereby obtained.

The objections to the special arrangement here proposed are obvious; the idea has however been developed by Mr. Howe, into the more practicable arrangement first applied to the engines of Robert Stephenson & Co. in 1843, and from this time the link has been adopted generally by all other English manufacturers.



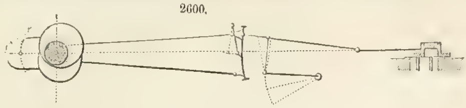
2600. 2599. 2598.

Link motions are all of two classes, in which, first the link is suspended directly from a fixed point as a stationary link, fig. 2601; secondly, the link is movable vertically, (fig. 2602,) carrying with it of course, the eccentric rods which are directly connected to it. In the first class, therefore, the variable expansion is accomplished by shifting the sliding blocks in the link: in the other class, the link is shifted upon the block. The link itself is employed under three general forms, distinguished as much by structural characteristics as by peculiarity of action. The box link, the open link joined to the eccentric-rods at the extremities, and the open link joined behind. The box-link, fig. 2598, is formed in two halves or sides bolted together at the extremities, enclosing a rectangular recess for the reception of the block as shown in section. The eccentric-rods are attached to the extreme stud pins, forged on the outside of the link, and thus a clear way is obtained for the blocks from one end of the link to the other; they may be shifted even to a position concentric with the eccentric rod ends. The two forms of open link are adopted with a view to simplify the parts, the one (fig. 2600,) with the extreme connections, is the form first used by Stephenson; by its form it does not permit of the block being placed concentric with the eccentric rod ends, the range being so limited, it is plain that the block never can receive and transmit the full throw of the eccentric to the valve, a feature in which the box-link has the advantage. With this link the throw of the eccentrics and therefore their diameters, must be greater than those required by the box-link for a given maximum travel of valve. The third form of link, (fig. 2599,) connected behind, permits of the same freedom for the block that is yielded by the box-link; the block may be shifted to a position level with the point of attachment at which it may transmit the whole throw of the eccentric. The overhung nature of this knuckle-jointed sort of link, and its peculiarly irregular movements in consequence, render it a more ticklish variety than the others; as, however, it combines the advantage of the box-link in respect of the transmission of the whole motion, with the simplicity of the other link, it is now most commonly employed, at least in locomotives, where vertical clearance is limited.

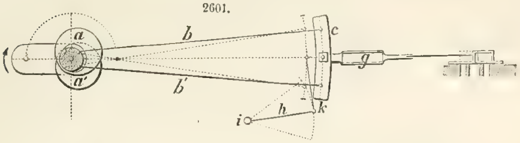
The first qualifications of expansion gear are to insure for every variation of expansive action, a free admission and free release for the steam; to render the periods of admission equal for the front and back

strokes, and to promote the expansive action of the steam sufficiently to extract the most if not the whole of its works for propulsion, excepting a per centage required for the purposes of the blast.

2600.



2601.



Lead. In the stationary link-motions, a constant lead throughout the forward and backward gear is obtained by circling the link to the radius of the valve-rod link, and the same lead may be for the front and back strokes. In the shifting link motion, the lead essentially varies with the expansion, the greater the degree of expansion—that is, the less the admission the greater also is the lead; the lead is thus least in full gear, and attains its maximum in the mid gear; it may however always be made the same for the front and back strokes, and thus equality is obtained by circling the link to the radius of the eccentric rod. Thus the conditions of constant lead and varying admission which are incompatible with the nature of the shifting link, motion are obtainable by the stationary link with a single valve. The longer the eccentric-rod, and the shorter the link, the less is the variation of lead in the shifting-link motion. The shifting-link motion may with advantage be set with the desired lead in half gear, which is the most ordinary working position of the mechanism; the evil of varying lead is thus divided and reduced.

Linear Advance. With the stationary link the linear advance of the eccentrics is in all cases less than that of the valve, and is a quality affected by the length of the eccentric-rods; these rods by their varying obliquity increase the advance while transmitting it to the link, and the shorter the rods the greater is the difference so caused. With the shifting-link, the linear advance of the valve is in all cases equal to that of the eccentrics in full gear, independent altogether of the length of the rods—expressly meaning by full gear, that the fore rod end is brought into the centre line of the valve rod; in other positions, however, the linear advance of the valve varies precisely with the lead, as the lead, in fact, partly constitutes the advance.

The Motion of the Link. The motion of the link is composed of the distinct motions of the eccentrics, and every part of the link is subject to this compound influence. The motion of each eccentric prevails in that half of the link to which it is coupled, and at the centre the motion of the link is equally composed of the two. The final result of this combined action is approximately the same as that available by the action of a single eccentric of variable throw. Thus the object which was proposed to be obtained by the spiral and wedge reversing motions of Fenton and Dodd's variable expansion, with (if possible) constant lead, is realized in the simplest manner by the combined operation of two eccentrics, and with an efficiency and precision which probably the original promoters of the link motion did not anticipate. Horizontal motion communicated to the link by the joint action of the eccentrics is a minimum at the centre of its length, where it is equal to twice the linear advance, and it increases towards the extremities various periods of the block in the link, or of the link on the block, on the general principle that admission varies with the travel of the valve. The distribution derived from the link is affected by the length of the connecting-rod relative to that of the crank; the shorter the rod, the greater is the front admission, and the less is the admission for the back stroke; therefore the term "link-motion" in so far as it involves the relation of the valve's motion to that of the piston, virtually includes the proportions of the piston motion. The quality of the motion derived from the link is modified by the positions of the working centres, and most especially of the centres of suspension and connection; the centre of suspension is the most influential of all in regulating the admission, and its transition horizontally is much more efficacious than a vertical change of place to the same extent. The periods of admission in half gear are much more sensitive to variation by mode of suspension and connection than those in full and mid gear. It is expedient to set the motion right for this position as regards the quality of the admissions, because these differences for other positions are then inconsiderable. There are certain neutral positions of the centre of the suspension, on which the link in vibrating yields equal admissions, and these may be found for any specific arrangement by the method of three trails. These neutral positions may be located either in the centre line of the link, vertically or horizontally in the neighborhood of the middle of the link. As the vertical movement of the body of the link with the consequent slip between the link and the block is the least possible when the suspended centre lies in the centre line of the link, increasing as the centre is removed laterally, the centre line of the link is, in this respect, the most favorable locality for the suspension, though not always practicable for equal admissions. It has been found that the stationary and shifting links have not the same neutral centres of suspension; that in general the stationary link should be hung by a centre in the neighborhood of the middle of its length, and the shifting link towards one of the extremities. The periods of expansion and release

increase as those of admission are diminished, and when the points of suppression are equally adjusted those of release do not considerably differ. It has been found in short, that in valves the admissions and the expansions may be made absolutely identical, as in the Great Western link, fig. 2601. An admission of 75 per cent. or three-fourths of the stroke is attended with a mean expansion of 16 per cent. of expansion, exhausting at 80 per cent. The utmost period of expansion obtained by a stationary link in mid gear is 38 per cent. for 12 per cent. of admission, in which case the steam is cut off at less than one-eighth of the stroke, and expanded into a volume of 50 per cent., or one half stroke 4 times the initial volume exclusive of clearance, after which it exhausts during the remaining half stroke. With the stationary link the shortest admission is 11 per cent., or one-ninth of the stroke, expanding into 50 per cent., or 4½ times the initial volume, before the release takes place. With the shifting-link, the smallest attainable admission is about 17 per cent., or one-sixth of the stroke; this is about one-half more than what is obtained by the stationary link, the difference being due to the excess of lead yielded by the shifting. As the release takes place at half stroke, the shifting-link cannot expand the steam above three times its initial volume, exclusive of clearance. The average period of admission in full gear does not exceed 75 per cent., or three-fourths of the stroke, according to the examples before us. More than this should not be required, nor indeed could it be beneficially employed at regular speed; the admission may, however, be increased by forcing the mechanism of the valve beyond full gear: that is, by causing the block to work in the extreme overhung parts of the link, which must be extended for the purpose beyond the centres of connection; by this expedient the throw of the valve is increased, and it is practicable with the box and back hug links, and may in many cases be usefully employed when a ready start with a heavy train is required.

The open link connected by its extremities in its own centre line, is identical in its motions with the box-link: in the use of that link it is imperative that the throw of the eccentric should be greater than that designed for the valve, as in full gear the block is of necessity placed nearer to the centre of the link than the rod centres.

LITHOGRAPHY. The art of transferring from stone writings or drawings made thereon, which is of quite modern invention. Unlike other kinds of printing, this is strictly chemical, and is in consequence called, in Germany, *chemical printing*. A drawing is made on the stone, either with ink containing oleaginous matter, or with chalk containing similar substances, but in a more concentrated and indurated state. The drawing is then washed over with water, which sinks into those portions of the stone that are untouched with the grease of the drawing. A cylindrical roller, charged with printing-ink, is then passed all over the stone, and while the drawing receives the ink, the rest of the stone is preserved from it by the water, on account of the greasy nature of the ink. This art is said to have been invented by mere accident, by ALOIS SENEFELDER, of Munich.

The stones, and the manner in which they are prepared to receive the drawings.—The stone most used in England is found at Corstan, near Bath; it is one of the white lias beds, but not of so fine a grain, nor so close in texture as the German stone, and therefore inferior; but it is good for transfers, and does tolerably well for ink drawings or writings. All calcareous stones may be used in lithography, because they imbibe grease and moisture; but a stone entirely calcareous does not answer well: there should be a mixture of alumina and silex. One of the most certain indications of lithographic properties is the conchoidal fracture; all stones of this kind will be found good, if they are also hard, have the fineness of grain, and the homogeneousness of texture that are necessary. It is, however, said that none have yet been found equal to those obtained from the quarries of Solenhofen, near Pappenheim, in Bavaria, and that the lithographers of eminence in Paris use no other. In order to sustain the pressure used in taking impressions, a stone, 12 inches square, ought not to be less than 1¼ inch thick, and this thickness should increase with the area of the stone. The stones are first sawn to a proper size, and are then ground smooth and level by rubbing two of them face to face, with water and sand. They must be very carefully examined with a straight-edge, to ascertain that they are perfectly level in every direction. This applies only to the side which is afterwards to receive the drawing, as the natural division of the stone is sufficiently true for the back. When the stones have thus been ground perfectly level, they are well washed, to free them from any of the coarser grains of sand which may have been used in smoothing them. They are then placed on a board over a trough, and they are again rubbed face to face with sand and water, but with a sand of much finer texture than that previously used. The greatest care must be taken to have the sand sufficiently fine; and for this purpose it must be sifted through a small close sieve, as a single grain of sand of a coarser texture than the rest will scratch the stone, and these scratches will afterwards appear in the impression taken from the stone. When the stones have been rendered sufficiently fine, and their grain sufficiently smooth, they must then be carefully washed and afterwards wiped dry with a clean soft cloth. This is the plan adopted to prepare the stones for chalk drawings, but to prepare them for ink drawings or writings the following method is the best: After the process just described has been completed, the stones are well washed to get rid of the sand, and they are then rubbed together, face to face, with powdered pumice-stone and water. After they are made perfectly smooth, they are again washed and wiped dry, and are then separately polished with a large piece of pumice-stone.

To clean the stones after they have been fully used, sand is strewed over the surface, which is sprinkled with water and rubbed with another stone, until the writing or drawing upon it has completely disappeared. It must then be washed in aquafortis, diluted with twenty times its bulk of water, and the stone is then prepared for a new drawing or writing, by being rubbed with fine sand or pumice-stone as before. The longer drawings remain on stones the deeper the ink or the chalk penetrates into their substance, and consequently the more of the stone must be ground away to remove them; this is also more necessary with ink drawings or writings than with chalk, owing to the greater fluidity and consequent penetrability of the former.

The substances used by the artist upon the stone are either lithographic ink or lithographic chalk.

The ink for making transfers should be somewhat less burned, and therefore softer than that used for writing or drawing directly upon the stone.

Lithographic chalk should have all the qualities of a good drawing crayon. It should be even in texture, and carry a good point. The following proportions are recommended: 1½ oz. of common soap, 2 oz. tallow, 2½ oz. virgin wax, 1 oz. shell-lac. The rest of the process is the same as in making the ink. Less black should be mixed with the chalk than with the ink, its only use being to color the drawing, that the artist may see the lines he traces. When the whole is well mixed it should be poured into a mould and very strongly pressed, to expel any air that may collect in bubbles, which would render it spongy.

Mode of drawing.—Previous to drawing or writing, the stone must be well wiped with a clean dry cloth. The ink is rubbed with water, like Indian ink, and is almost wholly used on the polished stone. The chalk is used only upon the grained stone; the polished surface of the other would not hold it. In drawing with ink, a gradation of tints is obtained either by varying the thickness of the lines, or their distances from one another, as in engraving. The ink lines on polished stones, being solid and unbroken throughout, receive the printing all over; and if the lines be drawn as fine and as uniform as they are usually on copper, the print from them will be in no respect inferior; but it requires a greater degree of skill to execute as well upon stone as is usually done upon copper or steel.

In using chalk, the grained stone should be very carefully dusted, and the utmost attention be paid to prevent any lodgment of the smallest particle of grease upon the surface; personal cleanliness is therefore absolutely necessary to the perfection of his work, especially in chalk drawings. The chalk is used upon the stone precisely in the same manner as crayon upon paper; but it is of essential advantage in lithography to finish the required strength of tint *at once*, instead of going over the work a second time, the stone being impaired in its ability to receive the second lining clearly, by the absorption of the first. Some practice is requisite to use the chalk cleverly, as there has been no chalk hitherto made that will keep so good a point as is desirable. There is likewise some difficulty experienced in obtaining the finer tints sound in the impression; and in order to obtain the lighter tints properly, it will be necessary to put the chalk in a rest, as the metal-port crayon is too heavy to draw upon the stone. A good lithographer is in the habit, before he commences his subject, of pointing 20 or 30 pieces of chalk, stuck in quill-holders, and placing them beside the stone in a little box, taking them up successively as the points become worn off, so as to avoid, if possible, the cutting off chalk during the work, which endangers the soiling of the stone. When a very sharp and delicate line is required, he sharpens the point of the chalk upon paper, by pushing it forward in an inclined position, and twirling it round at the same time between the fore-finger and thumb. As the chalk softens by the warmth of the hand, it is quite necessary to have several pieces, to be able to change them. Some artists cut their chalk into the wedge form, as being stronger. Those portions that break off in drawing should be carefully taken off the stone by a camel-hair brush.

Preparation of the stone for printing.—The drawing being finished on the stone, it is sent to the lithographic printer, on whose knowledge of his art depends the success of the impressions. The first process is to *etch* the drawing, as it is called. This is done by placing the stone obliquely on one edge, over a trough, and pouring over it very dilute nitric acid. It is poured on the upper part of the stone, and runs down all over the surface. The stone is then turned and placed on the opposite edge, and the etching water being collected from the trough, is again poured over it in the same manner. The degree of strength, which is usually about one per cent. of acid, should be such as to produce a very slight effervescence; and it is desirable to pass the etching water two or three times over the darkest parts of the drawing, as they require more etching than the lighter tints. Experience alone can, however, guide the lithographer in this department of the art, as different stones and different compositions of chalk will be differently acted upon by the acid, and chalk drawings require a weaker acid than the ink. The stone is next to be carefully washed by pouring clean rain-water over it, and afterwards with gum-water; and, when not too wet, the roller charged with printing-ink is rolled over it in both directions, sideways, and from top to bottom, till the drawing takes the ink. It is then well covered over with a solution of gum-arabic in water, of about the consistency of oil. This is allowed to dry, and preserves the drawing from any alteration, as the lines cannot spread, in consequence of the pores of the stone being filled with the gum. After the etching it is desirable to leave the stone for a day, and not more than a week, before it is printed from. The effect of the etching is first to take away the alkali mixed with the chalk or ink, which would make the drawing liable to be affected by the water, and, secondly, to make the stone refuse more decidedly to take any grease. The gum assists in this latter purpose, and is quite essential to the perfect preparation of the surface of the stone.

Printing.—When the intention is to print from the stone, it is placed upon the platen or bed of the press, and a proper sized scraper is adjusted to the surface of the stone. Rain-water is then sprinkled over the gum on the stone, which being dissolved gradually, and a wet sponge passed lightly over all, the printer works the ink, which is on the color-table placed beside him, with the roller in all directions, until it is equally and thinly spread on the roller. The roller is then passed over the whole stone, care being taken that the whole drawing receives a due portion of ink; and this must be done by giving the roller an equal motion and pressure, which will of course require to be increased if the drawing does not receive the ink readily. When the drawing is first used it will not receive the ink so readily as it will afterwards; and it is frequently necessary to wet the stone, and roll it several times, before it will take the ink easily. After this takes place care must be taken not to wet the stone too much; the dampness should not be more than is necessary to prevent the ink adhering to the stone where there is no drawing. After the drawing is thus rolled on, the sheet of paper is placed on the stone, and the impression taken. Upon taking the paper off the stone, the latter appears to be quite dry, owing to the paper having absorbed the moisture on the surface; it must therefore be wetted with a sponge, and again rolled with ink, the roller having been well worked on the color-table before being applied. During the printing some gum must always remain on the stone, although it will not be visible, other

wise the ink will be received on the stone as well as on the drawing, by which the latter would be spoiled; so that if by too much wetting, or by rubbing too hard with the sponge the gum is entirely removed, some fresh gum-water must be laid on. If the stone has in the first instance been laid by with too small a quantity of gum, and the ink stains the stone on being first applied to it, gum-water must be used to damp the stone, instead of pure water. Sometimes, however, this may arise from the printing-ink being too thin, as will afterwards appear. If some spots on the stone take the printing-ink, notwithstanding the above precautions, some strong acid must be applied to them with a brush, and, after this is washed off, a little gum-water is dropped in the place. A steel point is here frequently necessary to take off the spots of ink. The edges of the stone are very apt to get soiled, and generally require to be washed with an old sponge after rolling in; they must also frequently have an application of acid and gum, and sometimes must be rubbed with pumice-stone. If an ink is too thin, and formed of a varnish not sufficiently burned, it will soil the stone, notwithstanding the proper precautions are taken of wetting the stone, and preparing it properly with acid and gum; and if, on the other hand, the ink is too thick, it will tear the lighter tints of the chalk from the stone, and thus destroy the drawing. The consideration of these circumstances leads at once to the

Principles of the printing.—The accidents just mentioned arise at the extreme points of the scale at which the printing-inks can be used, for it is evident that the only inks that can be used are those which are between these points; that is, thicker than that which soils the stone, and, at the same time, thinner than that which takes up the drawing. Lithographers are sometimes unable to print in very hot weather, the reason of which may be deduced from the foregoing. Any increase of temperature will diminish the consistency of the printing-ink; the stone will therefore soil with an ink which could be safely used at a lower temperature—hence a stiffer ink must be used. Now, if the temperature should increase so much that the stone will soil with any ink at all less thick than that which will take up the drawing, it is evident that the printing must cease till a cooler temperature can be obtained; for as the drawing-chalk is affected equally with the printing-ink, the same ink will tear up the drawing at the different degrees of temperature. This, though it sometimes occurs, is a rare case; but it shows that it is desirable to draw with a chalk or ink of less fatness in summer than in winter, and also that if the printing-room is in winter artificially heated, pains should be taken to regulate the heat as equally as possible.

Other difficulties in printing, not referable to the foregoing general principle.—If the pressure of the scraper be too weak, the ink will not be given off to the paper in the impression, although the drawing has been properly charged with it. Defects will also appear from the scraper being notched, or not correctly adjusted, or from any unevenness in the leather or paper. After printing a considerable number of impressions, it sometimes happens that the drawing takes the ink in dark spots in different parts. This arises from the printing-ink becoming too strongly united with the chalk or ink of the drawing, and if the printing be continued, the drawing will be spoiled. The reason of this is easily ascertained. The printing-ink readily unites with the drawing, and being of a thinner consistency, it will, by repeated applications, accumulate on the lines of the drawing, soften them, and make them spread. In this case it is necessary to stop the printing, and let the stone rest for a day or two, for the drawing to recover its proper degree of hardness. If the drawing should run smutty from any of the causes before enumerated, the following

Mixture for cleaning the drawing while printing must be used: Take equal parts of water, spirits of turpentine, and oil of olives, and shake them well together in a glass vial until the mixture froths; wet the stone and throw this froth upon it, and rub it gently with a soft sponge. The printing-ink will be dissolved, and the whole drawing will also disappear, though, on a close examination, it can be distinguished in faint white lines. On rolling it again with printing-ink the drawing will gradually re appear, as clear as at first.

Bleached paper unfit for lithographic printing.—Accidents sometimes occur in the printing from the qualities of the paper. If the paper has been made from rags which have been bleached with oxymuriatic acid, the drawing will be incurably spoiled after thirty impressions. Chinese paper has sometimes a strong taste of alum; this is so fatal as sometimes to spoil the drawing after the first impression. When the stone is to be laid by after printing, in order that it may be used again at a future period, the drawing should be rolled in with a

Preserving ink—as the printing-inks would, when dry, become so hard that the drawings would not take fresh printing-ink freely. The following is the composition of the printing-ink: Two parts of thick varnish of linseed oil, four parts of tallow, one part of Venetian turpentine, and one part of wax. These must be melted together, then four parts of lamp-black, very carefully and gradually mixed with it; and it must be preserved for use in a close tin box.

Autographic ink, or that which is suitable for transferring on to the stone the writings or drawings which have been executed on paper prepared for that purpose, should possess the following properties: The ink ought to be mellow, and somewhat thicker than that used immediately on stone; so that when it is dry on the paper, it may still be sufficiently viscous to cause adherence to the stone by simple pressure. The following is the composition: Dry soap, and white wax free from tallow, each 100 drachms, mutton suet, 30 drachms, shell-lac and mastic, each 50 drachms, lamp-black, 30 to 35 drachms; these materials are to be melted together.

Autographic paper.—The operation by which a writing or drawing is transferred from paper to stone, not only affords the means of abridging labor, but also of producing the writings or drawings in the same directions in which they have been traced; whereas, when they are executed immediately on stone, they must be performed in a direction opposite to that which they are eventually to have. Thus it is necessary to draw those objects on the left, which, in the impression, are to be on the right hand. To acquire the art of reversing subjects when writing or drawing, is both difficult and tedious; while, by the aid of transparent, and of autographic paper, impressions may be readily obtained in the same direction as that in which the writing or the drawing has been made. In order to make a transfer

on to stone of a writing, or drawing in lithographic ink, or in crayons, or an impression from a copper plate, it is necessary, 1st, that the drawing or transcript should be on a thin and flexible substance, such as common paper; 2d, that it should be capable of being easily detached from this substance, and transferred entirely on to the stone, by means of pressure. But as the ink with which a drawing is traced penetrates the paper to a certain depth, and adheres to it with considerable tenacity, it would be difficult to detach them perfectly from each other, if, between the paper and the drawing, some substance was not interposed, which, by the portion of water which it is capable of imbibing, should so far lessen their adhesion to each other, that they may be completely separated in every point. It is to effect this that the paper is prepared, by covering it with a size, which may be written on with facility, and on which the finest lines may be traced without blotting the paper. Various means may be found of communicating this property to paper. The following preparation has always been found to succeed, and which, when the operation is performed with the necessary precautions, admits of the finest and most delicate lines being perfectly transferred, without leaving the faintest trace on the paper. For this purpose, it is necessary to take a strong, unsized paper, and to spread over it a size prepared of the following materials: starch, 120, gum-arabic, 40, and alum, 21 drachms. A moderately thick paste is made with the starch, by means of heat; into this paste is thrown the gum-arabic and the alum, which have been previously dissolved in water, and in separate vessels. The whole is mixed well together, and it is applied warm to the sheets of paper, by means of a brush, or a large flat hair-pencil. The paper may be colored by adding to the size a decoction of French berries, in the proportion of ten drachms. After having dried this autographic paper, it is put into a press, to flatten the sheets, and they are made smooth by placing them, two at a time, on a stone, and passing them under the scraper of the lithographic press. If, on trying this paper, it is found to have a tendency to blot, this inconvenience may be remedied by rubbing it with finely powdered sandarac. Annexed is another recipe, which will be found equally useful, and which has the advantage of being applicable to thin paper, which has been sized. It requires only that the paper be of a firm texture: namely, gum-tragacanth, 4 drachms; glue, 4; Spanish-white, 8; and starch, 4 drachms.

The tragacanth is put into a large quantity of water to dissolve, thirty-six hours before it is mixed with the other materials; the glue is to be melted over the fire in the usual manner. A paste is made with the starch; and after having, whilst warm, mixed these several ingredients, the Spanish-white is to be added to them, and a layer of the sizing is to be spread over the paper, as already described, taking care to agitate the mixture with the brush to the bottom of the vessel, that the Spanish-white may be equally distributed throughout the liquid. We will hereafter point out the manner in which it is necessary to proceed, in order to transfer writings and drawings. There are two autographic processes which facilitate and abridge this kind of work when it is desired to copy a fac-simile, or a drawing in lines. The first of these methods is to trace, with autographic ink, any subject whatever, on a transparent paper, which is free from grease and from resin, like that which, in commerce, is known by the name of *papier végêtal*, and to transfer it to stone; this paper to be covered with a transparent size: this operation is difficult to execute, and requires much address, in consequence of the great tendency which this paper has to cockle or wrinkle when it is wetted. Great facilities will be found from using tissue paper, impregnated with a fine white varnish, and afterwards sized over. In the second process, transparent leaves, formed of gelatin, or fish glue, are employed, and the design is traced on them with the dry point, so as to make an incision; these traces are to be filled up with autographic ink, and then transferred. We will describe, in their proper places, these processes, as well as that of transferring a lithographic or a copper-plate engraving.

Autographic processes.—To transfer a drawing or writing to stone, it is made with ink on paper, both prepared in the way we have described. A crayon drawing may, on an emergency, be executed autographically; but this mode of procedure is too imperfect to admit of procuring, by its means, neat and perfect proofs; besides, it is as expeditious to draw immediately on the stone.

In order to write, or to draw on autographic paper, a little of the ink of which we have given the composition is diluted with water, taking care to use only rain-water, or such as will readily dissolve soap. The solution is facilitated by slightly warming the water in the cup; and the ink is dissolved by rubbing the end of a stick of it in the manner practised with Indian ink. There should be no more dissolved at a time than will be used in a day, for it does not redissolve so well, neither is the ink so good, particularly for delicate designs, after it has been left to dry for several days. This ink should have the consistence of rather thick cream, so that it may form very black lines upon the paper: if these lines are brown, good impressions will not be obtained. A sheet of white paper is placed under the hand while writing, in order that it may not grease the autographic paper.

The stone used for autography should be polished with pumice-stone, and the impressions will be neat in proportion as the stone is well polished. Autographic work may be executed either cold or warm; that is, taking the stone at its ordinary temperature, or making it warm by placing it near to the fire, or exposing it to the heat of the sun: if the first means of warming be used, care must be taken that the fire be not too hot, or it will crack the stone; the temperature given to it should be about that of an earthen vessel filled with lukewarm water. The work may be done, though less perfectly, without warming the stone. When the stone is thus prepared, it is fixed in the press, and the paper on which the writing is made is applied to it. The stone may be rubbed with a linen cloth, slightly moistened with spirits of turpentine; and in every case it is necessary that it be made perfectly clean. The turpentine is left to evaporate; and from five to eight minutes before the paper is applied, it is wetted with a sponge and water on the reverse side to that on which the writing is done, so that the moisture may penetrate throughout every part. The water, however, must not appear on the paper when it is about to be laid on the stone; but any superabundance which may remain on it must be removed by a pressed sponge. When the paper is brought to the proper state, it is taken by both hands at one of its extremities, and placed lightly and gradually upon the stone, so that there may be no plaits formed in it, and that it may be equally applied over its whole surface. Care must be taken so to fix the scraper

that it may bear steadily on the autographic paper; for if it removes it at all it will change the place of pressure, and the lines will be doubled. There should be at hand five or six sheets of very even mackle paper, so that they may be changed with each impression. The paper on which the writing or drawing is made being placed on the stone, it is covered with a sheet of mackle paper, and subjected to a slight action of the press; then to a second, a third, or even to more, until it is believed that the writing is perfectly transferred. At each stroke of the press the mackle paper, which has imbibed moisture, is withdrawn, and a dry sheet substituted in its place. All these operations require to be performed with expedition and dexterity, particularly when the stone is warm. The next thing is to detach the autographic paper, which will be found adhering closely to the stone. To effect this, it is well wetted with a sponge, so that every part of it may be perfectly penetrated by the water; it may then be removed with facility, entirely detached from the writing, which will remain adhering strongly to the stone. If this operation, which requires much practice, be well performed, there will not be found the slightest trace of ink remaining on the paper. Should there be any lines not well marked on the stone, they may be retouched with a pen; or, which is better, with a hair-pencil and ink; but when this is done, care must be taken that the stone is quite dry. A part of the sizing of the paper may be found dissolved and adhering to the stone; this may be removed by washing or slightly rubbing it with a wet sponge. The stone is then prepared with aquafortis, and the impression taken.

Autography is not confined to the transferring of writings or drawings done with autographic ink; by its means a transfer may be obtained from a sheet of ordinary printed paper, and with such exactness, that it would be impossible, excepting to well-practised eyes, to perceive the least difference between that printed in the usual way, and that which was the result of the autographic process. This mode is very useful when it is desired to unite Oriental characters, which might not be possessed with words, phrases, or lines composed in ordinary typography. In this way have been executed, in the office of the Count M. C. de Lasteyrie, at Paris, (from whose papers on this subject, contained in the *Journal des Connaissances Usuelles*, and translated by the learned editor of the *Franklin Journal*, our account of this art is largely indebted,) many pieces, in which the French or the Latin language was intermixed with words or phrases in Chinese or Arabic. In the same way have also been executed typographic maps, in which all the details were lithographic, while the names of places were at first produced by typography, and afterwards by autography. This operation is begun by composing and arranging, in a typographic form, the words, the phrases, or the lines, as they ought to stand. The autographic paper is printed on by this form, and the words in the Oriental languages are afterwards written in the spaces which have been left for them; the whole is transferred to a stone, which is prepared for the purpose, and from which the impression is taken in the usual manner. The same mode is pursued in making geographical maps. After having printed the names on autographic paper, the other parts of the map, but without the names, are drawn immediately on the stone; and after having printed the names on white paper, the map drawn upon the stone is printed on this same paper.

Maps, or line engravings on copper, where the work is not very close, may be multiplied in a similar way. For this purpose the plate of copper is covered over with the autographic ink, diluted to a convenient consistence. Instead of the autographic ink, a composition is sometimes used, made of one ounce of wax, one ounce of suet, and three ounces of the ink with which the ordinary impressions in lithography are taken. The whole is warmed and mixed well together, and there is a little olive-oil added to the composition, if it is not liquid enough to spread itself over the plate; the plate ought to be warmed as usual. After having taken the impression in the rolling-press on a sheet of autographic paper, the transfer may be immediately made on to the stone, after having rubbed it with a sponge, dipped in turpentine. It is necessary to give three, four, or even more strokes of the press, increasing the pressure at every successive stroke; the other processes, which we have already described, are likewise to be followed. It is well to wait twenty-four hours before *preparing* the stone, in order that it may be better penetrated by the transferring ink; it is then gummed and washed, and is ready for use. This process, which has not yet come much into use amongst lithographers, merits the attention of artists; for it affords the means of reproducing and multiplying geographical charts, and some kinds of engravings indefinitely, so that they might be furnished at a quarter of their present actual value; in fact, all those which are done in lines, or those in which the shadows are boldly executed, are capable of reproducing good impressions by means of autography. The operation becomes extremely difficult when it is necessary to transfer fine line engravings; the lines of these are so delicate, and so near to each other, that they either do not take well on the stone, or are apt to be crushed and confounded together by the effect of the pressure. Much practice and address are necessary to obtain tolerable impressions; and this part of the art requires improvement. In the office of M. de Lasteyrie, they had succeeded in transferring to stone a small highly finished engraving, which had been printed on common half-sized paper. After having dry-polished a stone very perfectly, it was warmed, rubbed with spirits of turpentine, and then the engraving was applied to it. This had, however, been previously dipped into water, then covered on the reverse side with turpentine, passed again through the water, so as to remove the superfluous turpentine, and then wiped with unsized paper. In this state the engraving, still damp with the turpentine, was applied to the stone and submitted to pressure, when it afforded very good impressions; the *preparation* not being applied until it had remained on the stone for twenty-four hours. The difficulties increase, of course, in proportion to the size of the engravings which it is desired to transfer to the stone. Attempts have been made to transfer old engravings; they have, however, succeeded but imperfectly. It would be rendering an essential service to the art to discover a mode of reproducing old engravings by means of autography; the undertaking presents difficulties, but from the attempts made, success does not seem improbable.

Printing from two or more stones with different colored inks.—This is managed by preparing a composition of two parts of wax, one of soap, and a little vermilion. Melt them in a saucepan, and cast them into sticks; this must be rubbed up with a little water to the thickness of cream, and applied to the surface of a polished stone. An impression is taken in the common way from a drawing, and ap-

plied to a stone prepared in this manner, and passed through the press, taking care to mark, by means of this impression, two points in the margin corresponding on each of the stones. The artist, having thus on the second stone an impression from the first drawing to guide him, scrapes away the parts which he wishes to remain white on the finished impression. The stone must now be etched with acid stronger than the common etching water, having one part of acid and twenty of water; the whole is then washed off with turpentine: this plan is generally used in printing a middle tint from the second stone; the black impression being given from the first stone, a flat transparent brownish tint is given from the second, and the white lights are where the paper is left untouched. The dots are necessary to regulate the placing of the paper on the corresponding parts of the two stones.

LOCKS. *From the Proceedings of the Institution of Mechanical Engineers.* It was conceded about twelve years since in the United States, by all locksmiths, that a lock having a series of tumblers or slides, such as was used at that time in Europe, and more particularly those of Barron and Chubb, was secure against all known means of picking, or of forming a false key by any knowledge that could be obtained through the key-hole. The only point that seemed desirable was to make it secure against the maker, or any party who might have had possession of the key, and from it taken an impression.

The first step, therefore, was to construct the lock so that the party using it could change its form at pleasure. Mr. Andrews constructed a lock similar to that made by Mr. Chubb, having a series of tumblers and a detector; but before placing the lock on the door, the purchaser could arrange the tumblers in any way, so that the combination suited his convenience; the key being made with a series of movable bits, was arranged in a corresponding combination with the tumblers. In order to make a change in the lock without taking it from the door, each tumbler was so constructed that *in locking the lock* the tumbler could be raised, or drawn out with the bolt. A series of rings was furnished with the key, corresponding with the thickness of the movable bits of the key; and any one, or as many more of the bits could be removed from the key, and rings substituted. These bits being removed, and the rings taking their place, the corresponding tumblers would not be raised by the turning of the key, and consequently would be drawn out with the bolt, (*becoming, in fact, a portion of the bolt itself.*) Therefore, when a bit was removed and a ring substituted, so much of the security of the lock was lost as depended on the tumbler that was not raised; consequently, a lock having twelve tumblers, being locked with a key with alternate bits and rings, would evidently become a six-tumbler lock; but should a tumbler that was drawn out with the bolt be raised in the attempt to pick or unlock it, or should any one of the *acting tumblers* be raised too high, the detector would be thrown, and prevent the withdrawing or unlocking of the bolt. This lock was in great repute in the United States, and was placed on the doors of nearly all the principal banking establishments of the country; a large reward was offered by its maker to any one who could pick it; and from its great repute it consequently called out many rivals.

Mr. Newell constructed what he termed his Permutating Lock, which was composed of a series of first and secondary tumblers, the secondary series being operated upon by the first series. Through the secondary series there was passed a screw termed a clamp-screw, having a clamp overlapping the tumblers on the inside of the lock; each tumbler in the series having an elongated slot to allow the screw to pass through. On the back side of the lock was a small round key-hole, in which the head of the screw rested, forming, as it were, a receptacle for a small secondary key; so that when the large key gave the necessary form to the tumblers, the party took the small key and operated on the clamp screw, clamping and holding together the secondary series, retaining them in the relative heights or distances imparted to them by the large key; the door was then closed, and the bolt projected, and the first series of tumblers fell again to their original position. The objection to this mode of constructing a lock was, that it required the insertion of the small secondary key; and should the party neglect to release the clamp-screw every time he unlocked the lock, the first series of tumblers would be held up by the secondary series. Consequently, an exact impression of the lengths of the several bits of the key could be obtained through the key-hole while the lock was unlocked. This lock and Mr. Andrews' were both picked by Mr. Newell, who demonstrated that this lock as well as all others based on the tumbler principle was insecure.

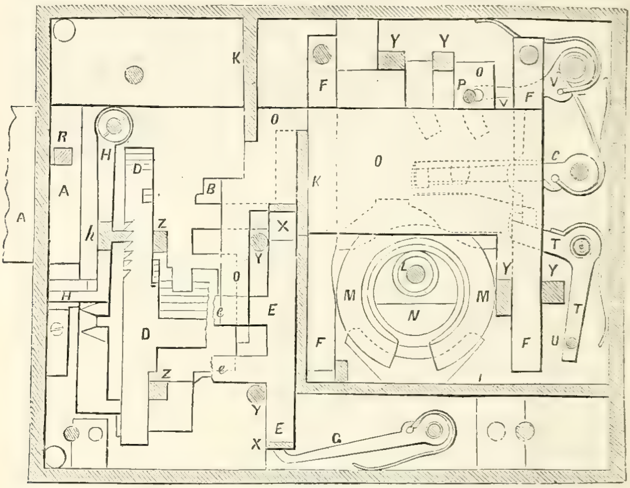
The first step taken to make a secure lock, was to add a series of complicated wards to the locks; but it will be readily seen, that what can be reached with a key, could be reached by some other instrument; and, although it required an instrument of a different form, yet the operation was just as certain and fatal to the security of the lock.

The next step taken, and one which was considered effectual, for a time, was the notching of the abutting parts of the first and secondary series of tumblers, or of the stump face and the ends of the tumblers. So that if a pressure was put upon the bolt, the tumblers could not be successively raised by the picking instrument, being held fast by these "false notches." This lock baffled the skill of all the country for a time, and was considered perfectly safe, until an ingenious engineer of the name of Pettis picked this lock.

The Parautoptic Lock was then invented by Mr. Newell, retaining all that was deemed good in the locks previously made, and, at the same time, guarding against all the defects proved by actual experiment.

The annexed figure shows it locked, with the cover and the detector-plate removed, and the auxiliary tumbler in its place; A A is the bolt; B B are the first series of movable slides or tumblers; C, the tumbler springs; D D the secondary series of tumblers; and E E the third or intermediate series, which form the connections between the first and secondary series of tumblers; F F are the separating plates between the first series of tumblers; G, the springs, for lifting the intermediate slides or tumblers to make them follow the first series when they are lifted by the key. On each of the secondary tumblers D D, is a series of notches, corresponding in distance with the difference in the lengths of the movable bits of the key; and as the key is turned in the lock to lock it, each bit raises its tumbler, so that some one of these notches presents itself in front of the tooth *h*, on the dog or lever H H. As the bolt A is projected, it carries with it the secondary tumblers D D, and presses the tooth *h* into the notches in the

tumblers, withdrawing the tongues *d*, from between the jaws *e e*, of the intermediate tumblers E E, and allowing the first and intermediate tumblers to fall to their original position: whilst the secondary tumblers D D, are held in the position given to them by the key, by means of the tooth *h* being pressed into the several notches, as shown. Should an attempt be made to unlock the bolt with any but the true key, the tongues *d* will abut against the jaws *e e*, preventing the bolt from being withdrawn; and should an attempt be made to ascertain which tumbler binds and requires to be moved, the secondary tumbler D D, that takes the pressure, being behind the iron wall I K, which is fixed completely across the lock, prevents the possibility of its being reached through the key-hole, and the first tumblers B B are quite detached at the time, thereby making it impossible to ascertain the position of the parts in the inner chamber behind the wall I K. The portion I I of this wall is fixed to the back plate of the lock, and the portion K K to the cover.



L is the drill pin on which the keys fits; and M M is a revolving ring or curtain, which turns round with the key, and prevents the possibility of inspecting the interior of the lock through the key-hole; and should this ring be turned to bring the opening upward, the detector plate is immediately carried over the key-hole S, by the motion of the pin P upon the auxiliary tumbler O O, which is lifted by the revolution of the ring M, thereby effectually closing the opening of the key–hole. As an additional protection, the bolt is held from being unlocked by the stud R bearing against the plate Q: also the lever T T holds the bolt when locked until it is released by the tail of the detector-plate Q pressing the pin U. V is a dog, holding the bolt on the upper side when locked, until it is lifted by the tumblers acting on the pin W. X X are the separating plates between the intermediate tumblers E E; Y and Z are the studs for preserving the parallel motion of the different tumblers.

There are several features in the construction of this lock which are deserving of particular attention. The most novel and extraordinary is, that the lock changes itself to the key; in whatever form the movable bits on the key are changed, the lock answers to that form, without moving any part of it from the door.

The party purchasing the lock can change it to suit his convenience. If a 6-tumbler lock, to 720; if 7 tumblers, 5,040; if 8, 40,320; if 9, 362,880; if 10, 3,628,800; and if 12, 479,001,600. Therefore it will be perceived that, by changing the numerical position of the bits in the key, the lock can be altered, or in fact alters itself to any number of new locks, equal to the permutation of the number of bits on the key. Two extra bits are supplied with each key, which add very greatly to the number of changes. As the key turns round, each bit raises its tumbler to a point corresponding with its length, imparting to the first and secondary series the exact form of the key. The secondary series of tumblers being carried out with the bolt, and the tooth on the lever or dog being pressed into the several notches on the front face of the secondary series, holds them in the position given them by the key, while all the other portions of the lock fall again to their original position.

Should a pressure be put on the bolt to ascertain the obstruction, it will be readily seen that it will be brought to bear on the third or intermediate tumblers. To prevent the possibility of reaching these, there is a wall of metal fixed across the lock, which confines the operator wholly to the key-chamber. By detaching the portion of the tumbler that takes the pressure given to the bolt, from the parts that can be reached through the key-hole, leaving that portion always at liberty, the possibility of ascertaining what is wrong is cut off; so that instead, as in the former lock, having only a first and secondary

series, Mr. Newell here introduced a third or intermediate series; thereby throwing the whole security of the lock into a chamber beyond the wall of metal, which is wholly inaccessible, and forming as it were another lock without a key-hole. These are the principal features of security in Mr. Newell's Parautoptic Lock.

There is another source of insecurity that has still to be provided against; when the first tumblers can be seen through the key-hole, if the under side of them is smoked by inserting any flame, the key will leave a distinct mark upon each tumbler the next time it is used, showing where it began to touch each tumbler in lifting it. This can be seen by inserting a small hinged mirror into the lock through the key-hole, and the exact length of each bit of the key measured, from the centre-pin to the point where it touched the particular tumbler, from which a correct copy of the key can be made. (An electric light from a small portable battery, has been employed for this purpose, to illumine the interior of the lock.)

The possibility of seeing the tumblers is entirely prevented, by surrounding the inside of the key-hole with a ring or revolving curtain; and when this curtain is turned, to bring the opening opposite the tumblers, the key-hole is shut on the outside by the detector tumbler, which tumbler would also detect all attempts at mutilating the interior parts of the lock.

Should the lock be charged with gunpowder through the key-hole, for the purpose of blowing it from the door, the plug in the back of the key-chamber yields to the force, leaving the lock uninjured, whilst the curtain protects the interior of the lock from injury, thereby effectually preventing all known means of opening or forcing the lock.

LOCKS OF CANALS. A contrivance by which boats may pass from a lower to a higher level, or the reverse, by the buoyancy of the water.

The least length that can be allowed between the locks should be such that 12 inches of depth, over and above what a loaded boat will draw, will only lower the water 6 inches without the navigation being interrupted: and if it be required to draw the contents of each lock from the interval above, the distance for the locks must be so regulated that the quantity of water expended by one should not lower that of the upper interval more than 6 inches at most: thus the distance should be greater in proportion to the contents of the chamber of the locks and the width of the canal; that is to say, when the chambers are large and the canal is narrow, the distance between the locks should be greater. Chambers 110 feet in length between the gates, by 17 feet in width, contain 1870 superficial feet; therefore 11,843 cubic feet when the fall is 6 feet 4 inches, 15,859 cubic feet when it is 8 feet 6 inches, and 19,635 cubic feet when 10 feet 6 inches. If the canal be 48 feet in width, at 3 feet below the ordinary level of the water, the length of the interval should be 446 feet, in order that the expenditure of locks of 6 feet 4 inches of fall should not lower the water more than 6 inches; this length should be 607 feet when the locks are 8 feet 6 inches of fall, and 755 feet when they are 10 feet 6 inches: the distance then between the lower gate of one lock, and the upper gate of the other, should be always about 624 feet for ordinary canals. If two locks of 8 feet 6 inches fall were only distant 160 feet, the water drawn from the interval, for the purpose of mounting the boat, would lower it nearly 26 inches, and there would not remain sufficient to keep it afloat; consequently, it would be necessary to draw a lockful from the upper interval, and then a second, to cause it to rise, whilst only one would be required if the locks were at a sufficient distance.

This example will show the inconvenience of having locks too near each other, which is still further increased when they are contiguous. It frequently happens that several boats arrive together in the same interval, particularly where the bargemen stop or sleep, and that so water may be lost, the interval where they stop should be sufficiently long to admit more than one. If circumstances will not permit this, a greater width must be given, that the lockful which the rising boats draw from the interval should not cause the water to lower so considerably as to prevent their floating, or the descending boats force in such a quantity as to make it run over the gates. If the interval has only the ordinary width of 48 feet, it should be 6398 feet in length, so that ten rising boats could stop, if none were descending at the same time, otherwise a part of the water must be drawn from the other intervals to keep them afloat: if there were as many ascending as descending boats, this need not be so great, but this observation proves that in forming a canal it is necessary to have basins at those situations where boats are required to stop any length of time.

Quantity of water expended by boats in traversing a canal.—It was the opinion of MM. Gabriel and Abeille, that the passage of a boat through the whole length of a canal always cost twice the quantity of water necessary to fill a lock. Belidor thought the same, and it is still the common opinion. M. Thommason has nevertheless maintained that this idea is erroneous, and that when one boat passes several locks one after another, the second boat only expends two locksful in its whole passage; but when they pass alternately, one up and the other down, that it costs as many locksful as there are locks in the ascension of each boat. He founds this assertion on two statements, one of M. Caligny, the other of M. Regemorte, asserting that the expenditure of the water is the same, whether contiguous or separated; but this distinction not having been sufficiently examined, a second error has been committed; but it is undoubted that when locks are contiguous, they often expend more than two locksful; and it has not been remarked that when the locks are more than 640 feet apart, they often expend only a single lockful for the whole journey. When locks are distant from each other, and the boats pass alternately, one up and the other down, the boat which passes after the first frequently finds in mounting all the locks empty, and to fill them it must draw a lockful from each interval and one from the starting point; in descending, as it finds the locks full, it does not draw any from the starting point, consequently it will only expend a single lockful in its whole voyage.

When the locks are distant from each other, and the boats follow, the second boat will find all the locks full going up, and to ascend it must first empty all, and then fill them with water drawn from the intervals, and the highest from the starting point; in descending, all the locks will be empty, and the first lock will be filled with water from the starting point, which will serve to fill all the others, so that this boat will expend two locksful in its journey.

When the locks are so near each other that the water of one taken into the interval between the two diminishes the depth of this interval sufficiently to impede the navigation, or when the locks are contiguous and the boats pass alternately, the second boat in ascending finds all the locks empty, and as it cannot draw water from the intermediate intervals from the contiguity of the locks, all are filled with water from the starting point. Thus in ascending each boat expends as many locksful as there are contiguous chambers; in descending, all the locks being full, no water need be drawn from the starting point, consequently in a whole journey as many locksful may be expended as there are contiguous locks in ascending. When the locks are contiguous, and the boats pass each other in succession, the second in ascending will find all the locks full, and to enable it to enter the intervals, it must empty them successively to fill them with the water from the intervals, except the last, which it fills with water from the starting point; in descending, another lockful is taken from the starting point, so that in this case two locksful are taken from the latter.

Although the four above cases contain the whole theory of the working of locks, it may be remarked that if two boats meet at the starting point, and two others before or after the starting point, the four will expend five locksful; if two boats meet at the starting point, and the two following meet there also, the four will only expend four locksful; if the two last boats that have passed meet before or after the starting point, and the two succeeding meet also before or after the starting point, they then will only expend four locksful, had the first come in an opposite direction to that which had passed previously, and five if it had come in the same direction; and it has been generally observed, that a boat always takes a lockful from the starting point to ascend, but that it often does not take any to descend on the other side: consequently, when there are no contiguous locks, the boats will only expend a lockful for their whole journey, when they pass the starting point alternately, one going up, the other down: in like manner, where there are contiguous locks, the boats will expend in their journey as many locksful as there are contiguous locks in ascending; when one boat follows another, it will expend two locksful, whether the locks are contiguous or isolated. It must be remarked that the passage of those boats only can be considered relatively to the locks which join the starting point. When the locks are not contiguous, and their fall is equal, which happens in the lower intervals, it has no influence on the expenditure of water, especially when the boats do not stop any length of time; in giving 640 feet length to each interval, it is evident, when two boats follow each other, they will never be together in the same interval, since, while the second passes the lock, the first will have time to pass the interval and enter the following lock; thus two boats cannot meet in the smaller intervals, except when one ascends and the other descends, and in this case, as one takes a lockful from the interval, while a second pours one into it, consequently the water does not diminish or increase in it. It must be observed that we can never have above a lockful, more or less, in an interval, unless several boats remain in them together, which should be avoided when they are small; further, when the contiguous locks are distant from the starting point, it often happens that the lockful is not immediately taken; but when there is no second quantity of water before the contiguous locks, it is always the starting point which furnishes that of the canal above them.

Form to be given to the chambers of locks.—The most convenient is the parallelogram, a little wider than the boats that require to pass, and sufficiently long to admit of the gates being moved with facility. The chambers of the canal of Languedoc are of an oval form, to give greater strength in resisting the banks contiguous to them; but as this causes an increase of expense in construction as well as in the quantity of water necessary to fill it, it will be useful to inquire if, in avoiding one inconvenience, a greater is not produced. The oval chambers of the canal of Languedoc contain an area of 3636 feet, while if the side walls were parallel, they would only be 2248 superficial feet. Thus the expenditure of water in the oval chamber exceeds more than a third that of the parallelogram, the proportion being about 5 to 3. The inconvenience is considerably increased by want of water, which frequently occurs. Another result of the oval form is, that the passage of the lock is also longer than in the rectangular; in the same proportion the expense of the timber platform is also increased. It is, however, certain that a curved wall is stronger against a pressure of earth than a straight one, and if the cost of masonry requisite to give the same strength to a straight wall is greater, the expense is compensated for by the diminution of the cost of the timber platform, which is two-fifths stronger. It is very essential to prevent the filtration of water through the side walls, and the best method to effect this is to place on their thickness a lining of beton, or of brick laid in cement, which will be impervious to water; but as this will destroy the bond, a greater thickness of wall is requisite; thus there are many circumstances where it might be necessary to give to curved walls as great a thickness as to straight. The thickness of straight walls which support earth should be a third of their height, while those which resist the thrust of water should be one-half; if the walls of the chambers of locks have a thickness relative only to the thrust of the earth, they may give way when the earth is put in motion, which often occurs from a slight filtration behind the wall. Gauthey has a rule for finding the thickness to be given to the wall of a basin intended to support water throughout its whole height, and in the chambers of locks it must be remembered that the thrust of the water against the vertical surface is equal to the product of these surfaces by half the height of the water. Call h the height of the wall, $x =$ its thickness, supposing its length to be 1 metre, the acting power will be $1000 \times \frac{1}{2} h^2$; supposing the cube metre of water to weigh 1000 kilogrammes, and the centre of impression of this thrust being at a third of the height of the wall, the arm of the lever of the acting power will be equal to $\frac{1}{3} h$.

The resisting power will be the wall itself $= h\,x \times 2000$, supposing that the cube metre of masonry generally weighs 2000 kilogrammes. The arm of the lever will be half the thickness of the wall $= \frac{1}{2} x$, consequently the momentum of the acting power will be $1000 \times \frac{1}{2} h^2 \times \frac{1}{3} h$, and that of the resisting power $2000 \times \frac{1}{2} h\,x^2$; and as in the state of equilibrium these two powers should be equal, we shall have $167\,h^3 = 1000\,h\,x^2$, from whence we have $x = \sqrt{0{\cdot}167\,h^3} = 0{\cdot}41\,h$; but as something should always be allowed above the equilibrium, by adding $\frac{1}{5}$, we shall have $x = \frac{1}{2} h$ nearly. Hence it is evident that

the thickness of a wall intended to support water should be at least equal to half the height of the water which acts against it.

The length and width of chambers of locks must necessarily be regulated in conformity with the boats used on the canal; these are generally longer and narrower than those on rivers, where the shallows which occasionally occur require flatter bottoms to be given them. With regard to the length of the chambers, it should be such as to enable the gates at the lowest ends to open and shut easily; if the rudder of the boat cannot be unshipped, or occupies any portion of the length of the chamber, then the chambers must be made sufficiently long to prevent them from interfering with the opening of the gate, on which account the most proper rudders for navigable canals are those like broad oars, which can be taken out while passing through the locks. The height of the water in the intervals is regulated by the mean height of the waters of the river which communicate with the canals. It is, however, customary to allow the latter a sufficient height of water to receive boats of the same tonnage as those which navigate the river; another advantage in giving an extra depth of water to canals is the greater ease with which the boats can be drawn, the weeds at the bottom causing less inconvenience, and the evaporation being of course less than in a shallower body of water; in summer also, when the boats can only carry half a load, two loads may be put into one boat, and the transport rendered less expensive.

The quantity of water expended by locks is found to be in direct proportion to the height of the fall, and the time employed in going through them, and the expense of construction nearly in the same proportion; this is greater as the locks are least elevated, because they are more in number, but the increase is not in proportion to the number.

Gates of locks are composed of two posts placed vertically, and united by horizontal rails; the former, being supported throughout their height, are not subject to much wear, although they are of larger scantling than the other timbers of the gate, which is necessary, as they sustain the entire framework. The horizontal rails resist the weight, and as that weight is greater where the rails are placed below the level of the water, it would seem natural that their dimensions should vary in proportion to the weight. To determine these dimensions it must be recollected that the thrust of water against vertical surfaces is equal to the weight of a prism of water having its surfaces as a base, and its height half that of the water. It must next be considered that the rails of the gate are at least 26 inches apart, and 38 inches from centre to centre, so that, on account of the casing of plank in the first instance, 12 inches of height support 26 inches of water, and in the second 38 inches. The weight supported by each rail will be found by multiplying their length, the interval from one to the other, the height of the water above the centre of the rail, and the whole by 62 pounds, the weight of a cube foot of water; the product of these measures will be the number of pounds which the rails ought to support throughout their whole length.

Timbers from 4 to 5 inches square would be sufficient for small gates, and for larger from 8 feet 6 inches to 10 feet 6 inches of fall; with a width of 17 feet between the hanging-posts, the rails would be sufficiently strong if from 7 to 8 inches square, putting six rails in the height. They are generally from 9 to 10 inches at least, which is double the strength required; it is true that the gates are more durable, but the weight is greater, which is sometimes injurious to the collar and the masonry to which it is attached, requiring more reparations than lighter gates.

The frames or styles of gates should be at least 5 inches in thickness more than the rails, and the joint covered by a fillet, as well as the edge of the planks, which are affixed perpendicularly to the rails, and mortised into the styles, increasing the strength of the rails and the framework by their greater thickness. Braces are also introduced between the rails, which aid materially in strengthening them, and by their inclined position transfer the stress to the hanging-post.

Great gates should always have a line of braces placed diagonally, and making an angle with the lower rail; all the braces above should have the same effect, and consequently the same inclination; those below resting on the lower rail tend to depress it, and, even when properly framed and pinned into the rails, their inclination towards the hanging-post renders them insufficient to sustain the lower rail; but they may be made useful by giving them an inclination in a contrary direction, and uniting them by pins to the rails.

Instead of inclining the braces below the diagonals on the side of the strutting-post, a bar of iron is sometimes placed diagonally from the collar to the lower end of the strutting-post, which is an excellent contrivance; or the planks may be placed diagonally, inclining them from the side of the hanging-post, and crossing them solidly, especially that of the diagonal above the hanging-post, and at the extremity of the lower cross-piece; or instead of a plank, a piece may be let in in an opposite direction to the cross-pieces, which must not be mortised into, or very little, that it may not be in any way weakened; this piece united carefully to the lower cross-piece would tie it to the post, and give more solidity to the framework; the diagonal position of the planks gives them more strength to resist the pressure. There is a little loss of material, but, on the other hand, plank of different kinds may be used after cutting out the knotty or defective portions.

Gates are opened by means of large timbers fixed above the posts, forming a counterpoise to the gate, and preventing it from grinding the collars and racking the framework; for this purpose the tail of the balance-beam must be very large. Trees are sometimes used with their butt ends not cut off, to which it is easy to add any additional weight. The hanging-posts often allow much water to be lost, in consequence of being obliged to give them sufficient play, and this could scarcely be prevented if the pivot had not a little motion, and the collar fitted exactly; but the weight of water occasions the gate to unite by pressing it considerably against the hanging-post; still as this is cut circularly, it only leans against a small portion of its surface, and the water easily passes, notwithstanding the great pressure. To remedy these defects, the posts should be partly cut in a circular form, and partly bevelled; the latter leaning along its whole length upon the rebate made to receive it, which having a corresponding bevel interrupts any filtration; the circular part should not touch the masonry, but have sufficient play without affecting the ease of the motion.

The gates of locks of navigable canals are made in a right line, but in great sea-locks they are curved: Belidor has demonstrated that these latter are not more solid than the former, but this must only be understood when the curved timbers are made out of straight pieces; for it is undoubted that, if naturally curved, they are much stronger, and will resist more pressure than straight pieces, especially when resting on their two extremities. The collars embrace the whole heel-post, which being generally 12½ inches in diameter, produces considerable friction, especially when the balance-beam does not act as a counterpoise; a large bolt may be placed in the axis of the post, and a smaller collar be substituted to confine it; but this method can only be applied to chamfered posts; round posts must have a motion in their collar to lean against the hanging-posts, which could not be effected by an axis; the collars must be attached to iron anchors strongly bedded into massive masonry. The pivots often get deranged, the posts, as generally made, causing considerable play; if these were bevelled, the pivots might be fixed and bedded in large stones cramped to those adjoining, or united with anchors to the surrounding masonry. Formerly the pivots were made of copper, but cast-iron is equally efficient; they should be the same size as the ends of the posts, and terminated at the lower end in a spherical form. The other iron work of the gates consists of squares laid on at right angles, which must be very strong; it is also well to lay on the rails of each sluice a band or two of iron to bolt them securely together.

Lock-gates measuring 8 feet from the centre of one heel-post to that of the other, are in some canals on a segment of a circle, the chord of which is about the sixth of the span, or a little more: these proportions not only allow of the gates being smaller, lighter, and stronger, but also increase the pressure of the heel-post against the hollow quoins, which renders them quite water-tight. Where canals are narrow, the paddles of both the upper and lower gates are usually kept open by an iron pin inserted between the teeth of a rack and pinion which raises them: when the paddle is required to be shut, the pin is withdrawn, and the paddle falls by its own weight.

Hollow quoins, or upright circular grooves, are formed in the side walls, at the ends of the timber sills, serving as the hinge for the gates; the upright post that turns within them is called the heel of the gate, and the other the head. The former are retained in their position by a gudgeon or pivot turning in a cup let into the foundation stones for the purpose; sometimes the pivot is fixed, and the cup revolves upon it. The upper part of the post is retained by an iron ring or strap let into the side wall, and made very secure; the hollow quoins should be worked with great attention; they are usually of stone or brick, though cast-iron has been found well suited for the purpose.

Lock-gates of large dimensions are now usually opened and shut by machinery, and the boom or spar attached to the head-post entirely dispensed with: on many canals a rack-bar of wrought-iron is connected with the gates, which are furnished with rollers to run in a groove fitted into the sill, and by working a wheel and pinion, they can be opened and shut at pleasure. We ought not to omit mention of several gates formed like boats, upon the principle of the camel, which rise and fall in deep recesses prepared to receive them as water is pumped out or admitted into them: such boat-gates are sometimes constructed with three parallel keels, which fit into as many grooves in the side walls of the lock; they are maintained in their position by admitting the water, and raised by pumping out their contents, after which they are floated away; for the stop-gates of docks such a contrivance is well adapted, but where the navigation is regular, as on a canal, they are not found to answer, from the time requisite to open and replace them. See Floating Gates of Dry Dock.

The angle to be given to double lock-gates has long occupied the attention of engineers, but the strongest position may be taken when the angle at the base is 35° 16′ nearly, and the sally of the gate is $\frac{7}{20}$, or a trifle more than one-third of the breadth of the lock.

Valves.—Some lock-gates have their paddles, or valves, made to open and shut by the movement of a lever, the lower end of which being loaded, keeps it always over the aperture in the lower part of the gate: when it is required to be moved, the upper part or handle of the lever is pulled back, and the water forcing its passage through, keeps it open until its weight overcomes the power, and it is balanced back into its original position.

The crank and pinion working in a toothed-rack are now generally applied to raise the paddle.

Screws are sometimes used for this purpose, formed of wood, sliding up and down in a rebated frame, fixed in the stone mouth of the conduit or paddle-hole; the lateral pressure of the water occasions it to adhere closely to the frame, so that it is not only necessary to make it run with the grain of the wood, but also to have considerable power to move it: this is occasionally effected by means of a long iron lever, with an eye at one end that spans the square end of the screw, and allows a sufficient force to be applied to raise the paddle.

There are several applications of the screw, one of which, as used at the gates of Dunkirk, is very simple, and was for a long time adopted throughout Europe. To overcome the hydrostatic pressure and friction at the mouth of the paddle-hole was a horizontal circular opening, within which was inserted an open cylinder of wood or iron ground to fit it, which could be raised by a lever; the waste water of the canal could then escape over the upper lip of the cylinder and afterwards pass out by the paddle-holes.

The following figures represent the latest improvements for the valves or sluices of a lock-gate. Fig. 2598 is an elevation. Fig. 2599 a vertical section through G G. Fig. 2600 a horizontal section through A A.

The object of this improvement is, that while the gate is kept close and tight by the pressure of the water forcing it against its seat, the effort of lifting the gate shall at the same time relieve the seat from the pressure of the water; and this is effected by means of friction-rollers h h, which immediately, upon the commencement of the lifting of the gate, act as short inclines, thus taking the pressure from the seat, and throwing it upon the friction-rollers or wheels, easing the lifting of the gate. When the gate is closed, the wheels have run off the inclines, and the gate bears against its seat with the pressure due the head of water

Iron lock-gates.—The frames of those at the Wet Dock at Montrose are of cast-iron, and entirely covered on both sides with wrought-iron boiler-plate: where they are placed the entrance is 55 feet wide in the clear, and the centre of the heel-post is 1 foot within the face of the wall, the distance between their centres being 57 feet: the height of the gates is 22 feet 6 inches; they point 10 feet, and their ribs have a curvature on the hollow side of 18 inches. The heel-posts are 21 inches in diameter, and in form a little more than a semicircle; after casting they were turned in a lathe: the thickness of the metal is $1\frac{1}{4}$ inch; they each fit into a cast-iron socket, and work on an iron gudgeon 10 inches in diameter, cast on a sole-plate 4 feet 6 inches long, 21 inches wide, and 2 inches thick; this is dovetailed and riveted firmly into the stone, and afterwards so keyed as to press the heel-posts into the quoins, which are of Kingoodie stone, polished as nearly to the circle as possible, and the stone and iron are in such close contact, that the water is effectually prevented from passing throughout any portion of their height.

The mitre-posts are $18\frac{1}{2}$ inches in breadth, $1\frac{1}{2}$ inch thick: holes are cast in them for the introduction of the iron bars, of which there are eleven to each leaf, 2 inches thick, 16 inches broad at the ends, and 18 in the middle; their cross ends are 18 inches in height and 2 in thickness, with $4\frac{1}{4}$ inch screw-bolts to each, which pass through the heel and mitre posts. The clap sill was cast in two pieces for each leaf; it is 8 inches in depth and $1\frac{1}{2}$ inch thick; the height of the sill above the platform is 15 inches. The bottom bar is of oak 12 inches thick, 17 inches broad at the ends, and 19 in the middle; this is bedded on felt to the lowermost cast-iron bar, and securely fixed by $1\frac{1}{4}$ inch bolts. The boiler-plates which line both sides of the gates are so arranged that they break joint; for 6 feet in height their thickness is $\frac{3}{8}$ of an inch—above, only $\frac{5}{16}$; they overlap each other about $2\frac{1}{2}$ inches, and were riveted on while hot, that the rivets might completely fill up the holes. The collars of the heel-posts are of wrought-iron, 4 inches by 2 inches, keyed through the

anchors, which are of cast-iron, 3½ inches square; they are dovetailed into the quoins, and run with lead The roller segments or railways are 10 inches in breadth by 1¼ inch, 4 inches in thickness; they are sunk into the stone, and securely bolted, and bedded with felt and white lead.

The rollers are of cast-iron and conical, 18 inches in diameter, and 5 inches in thickness, with turned steel axles; the roller-boxes are of cast-iron 1¼ inch thick, moulded to the bevel of the gates, and fastened by screw-bolts through the flanks of the horizontal bars: cast-iron covers confine the roller-blocks, which slide up and down withinside the boxes by the action of the top screws; the roller-bars are of wrought-iron, 3 inches in diameter, keyed into the blocks at the bottom, each being steadied by three plummer-blocks; each bar near the top has a coupling, with a square threaded screw, and a brass nut at the top, working in a cast-iron bracket, which bears the whole weight of the outer end of the gate, and is fastened by three screw-bolts through the flanges of the horizontal bars. Each leaf has a sluice, 3 feet by 2, the frames of which are 7 inches broad and 1¼ inch thick; the sluice-valves are also 1¼ inch thick; all the screwed bolts have zinc nuts, to prevent the iron from rusting: the sluice-rods are 2 inches in diameter, and have a square threaded screw, and a brass nut at the top; these are worked by a wheel and pinion, and bevelled geer, with a crank-handle, nearly level with the hand-rail.

The gangway is 42 inches in width, and is supported on cast-iron brackets for each leaf; cast-iron ballusters and a wrought rail is attached to the convex side of the gates, with movable iron stanchions and chains on the other; in each heel-post is a pump with a brass chamber and boxes, 2½ inches in diameter, with a lead pipe down to the bottom.

The gates are worked by four double-purchase capstans, and geering with seven 8-inch chains. Their weight is as follows:

	Tons.	Cwt.
Cast-iron work in the gates	64	14
Wrought-iron	22	15¾
Brass	0	5
Zinc	0	1¼
Cast-iron in segments and other fittings	19	0
	107	0

At Woolwich the clear opening of the dock-gates is 65 feet, and the weight of each of the two iron gates is 150 tons. See Gates of Dry Dock, Brooklyn Navy Yard.

LOCOMOTIVE ENGINE.—1. A locomotive engine is a steam-engine with two cylinders, formed on the high-pressure principle, without a condenser. The motion of the pistons is caused by the introduction of steam into, and its alternate escape from, the cylinders, which is transmitted by means of connecting-rods to an axle, furnished with two cranks.

In boilers of locomotive engines the fire is inclosed in a box having a double casing, with a body of water between. The air enters between the grate-bars. The smoke, flame, and gas, produced by the combustion of the fuel pass through, in their way to the chimney, a great number of tubes, which are situated in the cylindric part of the boiler, and extend from the fire-box to the smoke-box, and are surrounded by water. These tubes, being of very small diameter, would not pass off the flame and gas with sufficient rapidity if they were not urged by a powerful draught; this is also rendered necessary to overcome the friction, and the resistance offered by the cold air within them.

2. *Of the draught.*—The draught is employed to produce a fresh supply of air in the fire-grate, and thereby supply the oxygen necessary for the combustion of the fuel; it is accomplished by allowing the waste steam to escape at a tolerably high pressure, after it has fulfilled its office in the cylinders. This steam is conveyed from the cylinders to the chimney by a pipe, the upper end of which is contracted for the purpose of confining it, and checking its too rapid escape. It passes off at regular intervals, according to the velocity of the engine, and the force of each puff depends upon the pressure of the steam. The velocity of the steam in the blast-pipe is equal to that due to the initial pressure of the steam, whatever may be the size of the mouth of egress; but the pressure is at once reduced if the size of the orifice of the blast-pipe be considerable. The great speed with which the steam escapes in the chimney imparts to the air around it a corresponding velocity; and this air can only be replaced by a current passing from the grate through the fire and tubes.

We should observe that the contraction of the blast-pipe at its upper extremity, being for the purpose of checking the escape of the steam, and prolonging the time of its engagement, a continued pressure of waste steam is consequently the result, which should be regulated by proper rules or laws, as it ought not to exceed more than is necessary. This pressure is therefore an obstacle to the progress of the engine, in consequence of the draught invariably having the effect of absorbing a part of the power of the engine. Its influence, however, is not felt when moving at a slow velocity, on account of the intervals being longer, which gives more time for the steam to escape; but when the speed is great, the piston-strokes are so rapid that the pressure of steam in the blast-pipe is almost continuous. This pressure, consequently, forms a resistance to the motion of the piston.

3. *Of the boiler.*—The boiler is the most important part of the engine. There is a fire-box connected with it, the bottom of which supports the grate-bars, and the four sides are formed double, in such a manner as to allow of a space of 2½ to 4 inches between them, which is occupied by water; the fire-box is therefore surrounded by water. It is very important to preserve a sufficient width of water space, otherwise the velocity of the steam at this part of the boiler would prevent the water being replaced with sufficient rapidity, the great heat to which the fire-box is exposed producing steam of very great force the walls, also, from not being sufficiently cooled by the water, would acquire a high degree of temperature, which would likewise promote the formation of incrustations—the space would consequently become filled up, and the casing soon destroyed from the action of the fire. This serious inconvenience has occurred in boilers where the water-space has been made 2 or 2½ inches. The top of the

fire-box is strengthened by pieces of iron, that the force of the steam may not rupture it; and the whole of the flat portions of the boiler, being unable to resist the pressure of the steam within, are also strongly secured together by bolts to prevent their giving way; but this is unnecessary with the cylindric portion of the boiler, which resists the pressure without the tendency to rupture. This part is traversed by 100 to 150 or more copper tubes, through which the flame and the gas produced from the fuel escape. The extremities of these tubes are secured to the plates at each end of the boiler.

Considering the complication of this casing, one can readily conceive the great play of expansion and contraction produced by the rise and fall of the temperature, and how much the action of such powerful forces tends to wear it out, and to occasion shocks which the several surfaces exposed to the pressure of the steam are unequal to withstand, their form being unfavorable to it; thus, the flat parts become the soonest deranged. Another circumstance which increases these defects arises from the two extreme parts of the boiler being secured together, partly by the frame and partly by the rails or cross-pieces. The latter are attached to the lining of the fire-box at one end, and to the smoke-box at the other, and are kept cool by the air, and therefore are not subjected to those alternate changes which the body of the boiler undergoes. As long as they remain fixed in their original position, they offer resistance to the play of the other parts; but when at length they become unfastened, they afford a passage of escape to the water of the boiler. We must conclude, from all these forces acting against each other, that locomotive engines possess some degree of elasticity in their several joinings and fastenings, although difficult to be perceived, and which, so far from impeding their progress, actually renders it, after a time, more easy than before.

The surface of the grate varies. The economy attending great fires arises from the heat being proportionately much more regular than with small ones. It is possible that the rise of temperature, produced by the burning of a large body of fuel, exerts an unfavorable influence on the flat sides of the fire-box, the dimensions of which are so considerable. It is probable that an increase in the depth of the grate, combined with the employment of a fuel so little inclined to cake as coke, would be found more advantageous than enlarging its surface, since the passage of the air through a great thickness of coke would raise a large quantity of it to the temperature necessary for its combustion, instead of passing through the fire unconsumed, as it does when filled with too large pieces or laid too thin. This remark applies equally well to the employment of anthracite coal.

We have only to remark, in addition to our description of the boilers of locomotive engines, that the casing should, at the same time, possess great strength and pliability: thus, where a very powerful draught is created from a rapid succession of *puffs* of high-pressure steam, the heat of the fire gives a high temperature to the several surfaces of the fire-box and tubes, and steam of extraordinary power is generated; but if the door of the fire-box be opened, a large quantity of cold air is admitted, or if the pumps be held open too long, the air introduces itself into the boiler, and instantly checks the generation of steam; the pressure is consequently diminished, and at length becomes unequal to a rapid transit of the engine.

In locomotive, as in stationary engines, the whole of the parts in contact with fuel, flame, and hot air, should be covered with water. The most serious consequences occur if the uncovered portions are allowed to become red-hot, and a quantity of water sufficient to cover them is suddenly let into the boiler; the production of steam is so rapid, that it becomes too considerable to be wholly carried off by the valves, and an explosion consequently follows.

Another very essential point for the preservation of boilers is to prevent the formation of deposits. These arise from the calcareous matter disengaged from the water when it is converted into steam, and which is not wholly carried away with it; but an earthy matter is left, which is constantly increasing in bulk. These incrustations become fixed principally on those parts where the greater portion of the steam is generated; and, as they acquire thickness, it results that less steam is produced, from their being bad conductors of heat: the metal upon which they are fixed is heated to a much higher degree than the other parts, as it is not cooled by immediate contact with the water. This rise in the temperature of the metal increases the action of dilatation, and renders it less able to resist the pressure; it also has the effect of burning it; the boiler, therefore, requires to be often cleaned.

This incrustation is the most powerful destroyer of locomotive engines, and it is of the greatest importance to find some means of getting rid of it.

When the escape of steam from the cylinder is sufficiently strong to cause a powerful draught, then the power of generating steam attains its maximum; at which instant the bulk of the water in the boiler rises artificially to the height of two or three inches. This is caused by the rapid passage of the particles of steam through the water, which has the effect of increasing its volume. As soon as the throttle is shut, the emission of steam is suspended and the water takes its natural level; also when cold water is injected into the boiler, which, in proportion as it is introduced, condenses those particles of steam with which it comes in contact in the mass of heated water, and thus restores the density it had lost. It results that the level of the water remains constantly at the same mark as long as it continues to be fed, and that the introduction of water is only perceivable by the reduction of the pressure.

Another fact equally important is the disposition of all locomotive engines, more or less, to carry away a quantity of water into the cylinders with the steam, called *priming*. This inconvenience arises from various causes. Among them may be reckoned particles filling the boiler so full that the water rises up beneath the dome over the steam entrance, and is conveyed into the steam entrance-pipe with the same velocity as the steam, and introducing greasy matters, which, becoming mixed with the water, give it a property analogous to that of milk when submitted to an ebullition, and the quantity of water engaged by the steam in this case is very considerable.

It may also result from the small diameter of the dome, its want of height, or the space reserved for steam above the surface of the water being too small, or the dome being placed over the fire-box, which

is too often the case; that is to say, it is placed at that part where the evaporation is greatest, and the particles of water are in the strongest agitation.

Of the draught.—One of the means employed in regulating the draught consists in placing a disk valve at the extremity of the blast-pipe, which was the invention of Stephenson. This valve is open in the middle, by which it does not offer any obstacle to the passage of the steam; but it can be made to close the passage whence the flame or gas produced by the fuel issues, when required. This damper is managed by the engine-driver by means of a lever-rod.

This valve is also useful for another purpose. Thus, when the men extinguish the fire of the engine after it has finished work, the grate being done with and removed, the air enters at this part with great freedom, the heat of the engine maintaining a very strong draught. Now the effect of this passage of cold air is detrimental to the boiler, for the reasons before stated; therefore, if Stephenson's damper be fitted in the chimney, and care be taken to shut it close on these occasions, the current of air would be checked, and an excellent effect would result from it.

Of explosions.—We have few remarks to make on the subject of explosions connected with locomotive engines. Accidents of this kind are wholly attributable to the wilfulness of the engine-driver, or a want of care on his part. His first duty is to notice that the safety-valve does not emit steam exceeding a given pressure.

It is probably from these explosions being so rare, that the cause of them has been a question up to the present time; we can give none other than that they are owing to the imprudence of the engine-drivers, from their endeavors to raise the power too high, and thus impeding the escape at the safety-valves. Perhaps this imprudence may be combined with a bad system of closing and bolting the iron plates, and defectiveness in the large interior iron bolts of the front plate. We do not, however, mean to affirm this, but only mention it to our readers, inasmuch as we know that the *joinings* and arrangement of the plates of some boilers are much less skilfully contrived to resist internal pressure than others.

One observation will be sufficient to prove to mechanics the uselessness, generally speaking, of increasing the pressure, and of tightening the safety-valves. When they thus increase the pressure of the steam in the boiler, the engine simply acquires the power of propelling a heavier train, but it has not any sensible effect upon the speed. They should, therefore, remember that they do not derive any advantage from committing this very great offence. As the steam in the cylinders acts at a less pressure than that in the boiler, of what use is it to increase the latter, when, by opening the regulator a little more, sufficient additional strength is obtained in the cylinders? The most essential thing for the speed is the generation of a large quantity of steam at once, and of the requisite force—sufficient for the discharge of a great number of strokes, and not steam generated under a greater pressure than there is any occasion for.

Distribution.—The steam entrance, or the aperture by which the steam is introduced into the pipes of distribution, is situated in the interior of the boiler, and opens at the upper part of the dome surmounting it. The object of the dome is to carry the steam as high as possible, that the water held in suspension may have time to drain from it. The pipe by which the steam is introduced (steam-pipe) is carried along to the extremity of the boiler, and passed through into the smoke-box, where it is divided into two, to supply each of the cylinders. This pipe may be contracted in the interior, by means of an apparatus termed a regulator, which is inserted for the purpose of regulating the transmission of steam to the cylinders; this apparatus will also entirely close the passage of the steam-pipe, if required. The steam entrance is placed either at the head of the boiler, above the fire-box, or, otherwise, towards the extremity near the chimney. In the first case, where the pipe traverses the entire length of the boiler, it is attached to the plates at each extremity; and, in order that it may readily yield to the action of expansion, it is furnished with a stuffing-box.

The joints of that portion of the steam-pipe within the boiler should be made with the greatest care, that the water may not gain admittance into the pipe. It is generally formed with a section equal or superior to that of the steam-ports in the passage to the cylinders, and the same as the apertures opened and shut by the regulator.

Throttle-valves are constructed of various forms; but that generally employed consists of two separate disks, one being made movable; and they are cut in such a manner that the open parts of one will either correspond with or cross those of the other, so that the steam passage may be left either open or closed.

The movable disk is secured to the fixed disk by the pressure of the steam, also by a screw and a spring. The spring is rendered necessary from the steam within the steam-pipe being sometimes of greater pressure than that in the boiler.

Other forms of throttle have also been employed—and the principle of safety-valves has been applied in some cases, and in others the principle of cocks—again, that of slides; those which present the least surface-friction, and in which the apparatus is brought into action upon the least degree of force, are the best, for it is important to counteract the effort required to overcome the pressure of the steam by suitable contrivances, as by equilibrating it by a pressure nearly equal; the friction resulting from the unequal expansion of the several pieces fixed and inclosed within each other should also be reduced as much as possible. Throttles formed with cylindric surfaces exposed to the action of friction, possess this inconvenience in the highest degree. There also appears to be some ground for rejecting regulators which require helixes in the interior of the boiler, upon which the pressure of the steam would act.

Of the cylinders, slide-boxes, and slides.—The steam passes along the breeches-piece leading to the cylinders through the slide-boxes, from whence it is distributed alternately upon each side of the piston.

The mode of introducing the steam may be readily comprehended: the bottom of each slide-box is pierced by three holes called *ports;* the two extreme *ports* convey the steam into the interior of the cylinders at their extremities. A sort of cover, called a slide, is placed over them, which is subjected to an alternating motion when at work, and thus leaves each port alternately uncovered; and as the

slide-boxes are kept constantly filled with steam, the latter passes through these ports into the cylinders at the moment of each being uncovered. It will therefore be perceived that the system of introducing steam is very simple. The ejection of the steam from the cylinders remains to be explained every time that steam enters upon one side of the piston, that which has effected the preceding half-stroke escapes at the third port, which is pierced in the bottom of the slide-box, and is not in communication either with the cylinder or the slide-box, where the steam is lodged, but is separated from these and is constantly covered with the movable slide, which covers and uncovers alternately the two other ports; it is furnished with a pipe at the extremity which leads into the chimney. Now, the movable cover or slide being hollow, it results from its alternate motion that when it uncovers one of the steam-ports and admits steam into the cylinder, it puts the other steam-port in communication with the waste steam-port situated between them, by means of the cavity beneath it; and the steam admitted into the cylinder, at the preceding *half-stroke* of the piston, by the port then uncovered, enters the interior of the slide, forces itself through the waste steam-port, and thence escapes; therefore the slide-box constantly answers as a passage to conduct the steam into the cylinders, and the cavity within the slide serves only for a passage to convey the steam away from them. The true steam-ports admit steam when they are uncovered, and they alternately convey steam to the waste steam-port when they are covered by the slide; thus the slide never leaves more than one of the steam-ports uncovered at a time for the passage of the steam, and it covers the other two at the same time, to allow of the waste steam escaping. The force of the steam lodged in the slide-box is therefore employed upon the piston. The waste steam, being put in communication with the atmosphere under the slide, instantly loses its force. The piston is then quickly carried along to the other end by the force of the steam, and the resistance it encounters on the other side is quickly overcome. Now it is the difference between these two forces which causes the engine to perform its several functions; if these forces were equal, the piston would remain in equilibrio, and without motion. In order that this difference shall be as great as possible, the force of the steam entering the cylinders should not be less than that which exists in the boiler, or the pressure of the steam that passes out of the cylinders greater than the pressure of the atmosphere into which it escapes; but this desideratum is difficult to be attained. The pistons of locomotive engines being impelled with great velocity, the steam is necessarily carried into the ports of introduction with a velocity which is in inverse proportion to the section of the uncovered part (of the port) with the area of the cylinders. This velocity is further affected by the irregularity attending the conversion of a rectilinear motion into a circular one. The latter is accomplished by means of a crank-arm, which follows every movement regularly, and transmits the motion to a rectilinear horizontal rod, the velocity of which is represented by 0·293 for the quarter of the revolution which approaches nearest to the vertical, and by 0·707 for the quarter nearest the horizontal. Thus, the total speed of the piston is composed of a minimum and of a maximum; the minimum takes place when the crank-arm passes above and below the horizon—the maximum, when it performs the quarter of the circle of the passage from one side to the other of the vertical; in other words, the more the direction of the movement of a crank-arm approaches to a parallel with the rectilinear rod which it works, the greater is the speed transmitted to the rod; and the more it moves from a parallel, and approaches the rod by a perpendicular movement, the slower is the motion imparted to the rod.

When the engine works at its greatest speed, or at about 38 miles an hour, or 1093 yards per minute, the size of the wheels being 5 feet 3 inches, and their circumference 16 feet 6 inches, the number of strokes of each of the pistons is about 200 per minute, and of their movements 400, the length of each being about 1 foot 6 inches, which gives the piston a velocity of 192 yards per minute, or 10 feet per second, instead of about one yard, which is the velocity given to the pistons of stationary engines. The dimensions of the ports are generally 1-10th the area of the piston; the velocity of the steam in the ports would be about 100 feet per second, if they were always entirely open when the piston was moving, which is not the case, the aperture being only fully open during the middle of its course, and at a point where the piston has a speed once and a half as fast as its mean velocity; the velocity of the steam through the ports would therefore be about 165 feet. Taking the contractions, also, into account, reduces the openings to two-thirds; we thus find that the steam has a mean velocity of 200 to 250 feet per second at the ports. This velocity, although very considerable, does not, however, produce the injurious effect that was at first imagined. The velocity of the waste steam, in passing into the void, is upwards of 1970 feet per second, and its velocity upon escaping into the atmosphere is about 1400 feet, when the absolute pressure of the steam is about two atmospheres.

This velocity is more than 870 feet for an effective pressure of a quarter of an atmosphere, or an absolute pressure of 1 at : 25; indeed, the generating pressure of a velocity of escapement equal to 290 feet does not exceed 1-50th part of the atmosphere alone.

The resistance arising from the steam-ports is, then, perfectly unaffected at high velocities, but if the latter were even considerable, it would not have a troublesome effect; indeed, with a speed of 37 miles an hour, the boiler cannot furnish the cylinders with any other than steam of reduced pressure; therefore, of what consequence is it that this reduction should be partly caused by the ports, instead of being wholly effected by the regulator?

But although we have no loss of force arising from the steam-ports, this is not the case with the waste steam-ports. The force which the steam exerts in its escape always diminishes the useful pressure—and it is very considerable, since the velocity is of necessity very great, in order that the cylinders may be instantly cleared. It is, therefore, necessary that the velocity of 250 feet, although sufficient when continued throughout the stroke, should be considerably increased, in order that it may be enabled to free one side of the cylinder instantly.

In the next place, the steam, after passing out of each of the cylinders, again unites in a pipe, which is contracted at the upper extremity, and presents another impediment to its passage. This peculiarly formed pipe is employed for the purpose of creating a draught. But the resistance which it produces is naturally detrimental to the moving-power, which may be accounted for as follows: Suppose that,

with a speed of 39 miles, the cylinders are filled with steam of 3 at : 75, which is successively held and dispersed. In calculating the volume of this steam, with successive stops, we should find that it is nearly double that of the cylinder. Taking the total volume of steam supplied, having the section of the blast-pipe, (whose conical shape does not present much contraction,) we arrive at this result: that, supposing the escapement to be incessant, the steam would have a mean velocity of 820 feet, corresponding to a generating pressure of a quarter of an atmosphere. This result shows that this great velocity of escape absorbs a considerable portion of the power of the engine; and if we remember that, at these same velocities, the motive steam must necessarily diminish the pressure, also that the air operates upon and at length overcomes it, we can easily conceive that there are certain limits to the velocity which cannot be exceeded with certain engines, even when running without a load. These limits, which were originally from about 39 to 44 miles an hour, have been increased, with engines made more recently, to nearly 53, or even upwards of 60 miles an hour.

Eccentrics.—The two pistons are each attached by fixed rods, to guide them in their rectilinear strokes, and by movable rods, called connecting-rods, to an axle furnished with two cranks, set square with each other; this axle is mounted upon two wheels, which are termed the driving-wheels, and receive a rotative movement direct from the pistons.

The readiest plan of distributing the steam, at the commencement of the action of the piston, consists in employing the rotative motion of the axle to conduct two eccentrics at the same time with the wheels, which, by their alternating motion, open and close the slides. The eccentrics are placed on the axles of the driving-wheels in such a manner as to disengage the slides from those ports whereby the steam is introduced into the cylinders, and to cover those reserved for its escape, at the commencement of the stroke of the piston; to accomplish which, each eccentric is mounted upon the axle of the wheels square with the crank of the cylinder, the slide of which it conducts. In order to understand perfectly what then transpires, it is necessary to bear in mind that, when a crank transmits motion to a horizontal rod, it impresses the rod with a rapid motion when it passes in a vertical, and with a slow one when it passes in a horizontal direction.

In accordance with this general law, when two crank-arms are mounted on the same axle, and transmit their motion to two rectilinear rods, the motion of each will be different, notwithstanding the cranks are both animated with the same velocity.

Now, the slow movement occurs precisely at the commencement and at the termination of each half-stroke of the piston, since the crank-arm crosses the horizontal at this particular period. Therefore, if the eccentric be mounted square with the crank, the instant that it crosses in a vertical direction, and transmits the greatest amount of velocity to the slide, the crank will be in a horizontal position, and the piston will be taking its slowest movement. The steam is introduced and let off uniformly every time the crank-arm is in a horizontal position—that is to say, every time the piston has finished one stroke and is commencing another—and it is performed with great precision, depending upon the uniform action of the slide. It may be further observed, in the case of one crank being placed on the same axle with another, when one is passing from one side to the other, in making a semi-revolution, the other is passing from the top to the bottom; or if each of these cranks transmits a rectilinear motion to a rod, the rod conducted by the first crank conveys a certain motion in one direction, and that conducted by the other conveys the same amount of motion, but distributed in the opposite direction. The results of this uniform principle in the construction of locomotive engines are as follow: At the instant one of the cranks is in a horizontal position, and the piston at the commencement of its stroke, during the first half (of this stroke) the slide moved by the eccentric, which is in a vertical position, conveys a motion which has the effect of uncovering one of the ports, and by the time the eccentric arrives at the horizon it becomes wholly uncovered. In the second half of the course of the crank, the slide returns to its original position, and the port becomes again covered. The slide is, therefore, always ready to uncover the opposite port at the commencement of the following stroke.

It further results, when the crank is horizontal, that the two steam-ports are shut, the eccentric being then in a vertical position.

Such is the principle of the distribution of steam. We shall not enter into the particulars of the several plans for effecting it at present, but their details, which do not differ essentially from each other, will be found in their proper place. The return motions, from the eccentrics to the slides, are constructed of slight rods, and are therefore readily shifted; yet, as the slides are drawn backwards and forwards under the pressure of the steam they are subjected to considerable friction, the rods are liable to be strained, and frequently become deranged by the eccentrics, also from the play of the points of the levers, and the several turning-joints being so very elastic. These circumstances of derangement have an important influence, by retarding the slide slightly, which has a powerful effect upon the regularity of the distribution; and since the course of the eccentric is similar to that of the slide, the detention of the action and the loss of speed occurring in the return movement from the above causes, show the necessity of the engine-man devoting the greatest attention to this point, and avoiding the evil as much as possible. The distribution of steam may be suspended whenever required, by means of hand-geer and reversing-handles, which detach the rods of the eccentrics from the levers which conduct the slides; the same levers are also employed to reverse the movement of the slides at the time of running, and in such a manner as to render it opposite to the direction the engine is running in.

This reversing the distribution of the steam is employed to stop the engine where other means are found insufficient, in which case the steam-ports on that side where the piston is returning become instantly uncovered, and the steam fills the whole cylinder, and thus opposes the progress of the piston; the latter returns the steam again to the boiler if it should not be arrested. At the same instant the waste steam-port is covered by the slide, and consequently put in communication with the air, which enters by the blast-pipe and fills the cylinders, being drawn in by the action of the piston. Thus, the advance of the engine against the steam has the effect of conveying the air into the boiler, and the safety-valves consequently emit steam mixed with air.

Of the feeding of the boiler.—Having described the means of generating steam, and of distributing it in the cylinders, we shall now consider those for renewing the water in the boiler in sufficient quantity, as it becomes absorbed by the work of the engine. There are two pumps employed in effecting this, which are on the lift-and-force principle; the pistons consist of plungers, similar to those employed in ordinary stationary engines. They transmit the water from the tender to the boiler. One of these pumps can deliver a volume of water in the course of about twenty minutes sufficient to supply the boiler for one hour's run. The quantity of water furnished by the pumps may be properly regulated, and the delivery of the same rendered continuous, but the latter is only accomplished in new engines, the boilers of the other engines are sure to be momentarily chilled, either in the operation of feeding with water, or in replenishing the fire with fuel; but the fires of new engines are not so liable to this.

Of the machinery and its disposal. We shall conclude our general observations on locomotive engines by referring to the disposal of the machinery connected with them. The power of the engine originates in the cylinders, the force produced within them proceeding through the smoke-box in which they are inclosed. This force or power acts in two ways, dependent upon the steam being on one side or the other of the pistons, and imparts to the rods an effort of traction or of pressure accordingly. The whole of this force is exerted upon the cranked axle, wherefore it becomes highly necessary that this axle should be attached to the cylinder-box by very strong framing; the boiler is for this purpose placed on a frame, with which it is connected by stays secured by strong bolts. There are many engines which, after a few months' work, manifest a sensible play, to an experienced eye, between the cylinder-box and the supports of connection between the boiler and the frame, from this reason. The carriages, or grease-boxes, which receive the gudgeons at the extremity of the axles, and thus support the entire weight of the engines, are situated beneath this frame, the gudgeons turning freely in them.

If these carriages were the only points of resistance to the cylinders, it is probable that not only the supports of the boiler on the frame would soon give way, but the axletree, being only secured at its extremities, would also be subjected to these vibrations, and the greater part of it so powerfully forced in each direction, horizontally, by the cranks, that they would be soon broken. It is to obviate this that the cylinder-box is attached to the cranked axle by four, or at least three iron rails. These rails are strongly fastened to the cylinder-box, and each carries a copper collar, in which the cranked axle is inclosed. This collar is capable of moving in a vertical direction, whereby it is enabled to accommodate itself to the play of the springs and countersprings, which frequently have the effect of separating the axletree from the boiler; but the collar is always secured horizontally, being that in which the cranked axle offers the greatest resistance, by means of suspended wedges, which operate similarly to keys, and tighten the carriages against the axletree. The cranked axle is secured in this manner at five or six places respectively, and further attached to the cylinder-box. The attention of the engine-driver should be directed to these rails of attachment, and he should constantly notice that they fulfil their office properly; and in furtherance of which he should tighten them, by heightening the wedges as the carriage of the axletree becomes worn.

The three principal rails or cross-pieces which we have noticed, are attached just at their extremities, next the axletree, to lugs fastened to the fire-box. It is of consequence that these joints should not be made too stiff, and that a little play be allowed for their extension in cooling, for the reasons before stated, viz., that these rails are not subjected to the same degree of elongation from the effects of expansion as the body of the boiler; and, upon this occurring, the boiler is forced upon the rails, and the joints connecting them with the fire-box consequently become deranged, and give passage to the water situated within the double casing surrounding the fire-box.

We have now to observe, that the necessity of reducing the weight of locomotive engines has led to the almost exclusive employment of iron in their construction, from which it results that the whole of the several pieces in friction against each other, from the effects of rotative or rectilinear movement and the sliding of one surface upon another, are proportionately weaker than those of ordinary stationary engines, the castings included, viz., the axeltrees, the beams, the connecting-rods, the guides, the eccentrics, &c., and formed of smaller proportions. Now, there is a very important fact connected with engines, viz., the circumstance that the friction does not depend solely on the pressure, but on the degree of fitness of the metal to support the pressure without alteration. Thus when the state of the carriages becomes altered, the friction acquires immense influence; the bodies become heated and reduced from the filing, arising from the grip they have of each other; they also sometimes become melted. The rubbing surfaces are therefore kept constantly oiled, to prevent any alteration taking place; and this is more especially necessary with locomotive engines, as these surfaces are generally reduced almost to the minimum limits commensurate with the amount of pressure which they have to support. The least negligence on this point is consequently attended with serious consequences; the first, from its increasing the resistance of the engine considerably, and often stopping its progress; secondly, from its increasing the wear of the carriages; and, thirdly, from its causing the rupture of the pieces in consequence of their becoming heated, and the strains to which they are subjected. If the carriages become heated in the smallest degree, they are subjected to great pressure, and the relative hardness of the metals in contact is instantly changed, and the adherence between their surfaces increased, so that they become full of holes and impaired, and oil will never restore the delicate finish which is thus destroyed.

A constant attention to the greasing, therefore, constitutes one of the surest means of preservation, and of insuring good work in the locomotive. Another circumstance no less necessary, is the maintenance of the whole of the several pieces in a condition as near their original form and mounting as possible. An engine is composed of so many pieces, and is subjected to such strong vibrations under the influence of shocks, and from the sudden and incessant strains that it is subjected to, that it yields in a certain degree at its joinings. The engine-driver should direct his attention to the prevention of this movement, and he should not allow of any more play in the carriages than is necessary; he should re-

place those pieces which become worn, and tighten those mountings as they become loosened. The several joinings are, moreover, disposed in such a manner as to counteract the difficulties connected with them, and exhibited with all the pieces thrown in friction with each other.

Respecting the frames of locomotive engines, we may remark, that the plan of arrangement has been a subject of much controversy, whether they should be placed on the outside or on the inside of the wheels. If a perfectly rigid shaft were urged in a rotative direction by a rectilinear force, it would revolve with a degree of firmness proportionate to the distance its carriages were placed apart. If a cranked axle be supported by carriages situated near its centre, and impelled by forces acting in contrary directions, as those transmitted to it from the cylinders, it would cease to be perpendicular to the movement of the pistons, upon the carriages becoming the least worn, and would form an angle proportionably large, accordingly as the carriages were placed near the centre. The flanges surrounding the wheels would therefore knock against the rails, and the engine undergo violent lateral movements from its direct course, which would be dangerous, on account of the great velocity. A like effect occurs when the cranks are placed at the extremities of the axle, instead of near the middle of it, as in the case of engines having the cylinders placed on the outside. The wear of the carriages, also, has the effect of increasing the force of the lateral movements considerably.

Of locomotives employed in conveying freight.—It is customary, in the conveyance of freight, to employ engines with their driving-wheels coupled to the fore ones, which is effected by connecting-rods; in which case the fore-wheels are of equal diameter with the driving-wheels. This coupling possesses no other advantage than that of increasing the power of adhesion, by allowing the fore-wheels to partake of the weight carried by the others.

Of the tender.—A sort of wagon is attached at the extremity of a locomotive engine when in motion, which is called a tender, and which is generally mounted on four wheels. and sometimes on six. It contains water and fuel sufficient to feed the boiler and grate during a run of about twenty-five miles as a maximum, and about fifteen miles as a minimum. In order to supply trips exceeding these limits, reservoirs of water and depots of fuel are arranged at convenient distances on the line, which enables them to extend their run to distances which are only limited by the strength of the engines.

The tender is joined to the engine which it accompanies by a bolt, which is adjusted to fit into a staple. This bolt should be capable of resisting the entire power of the engine. The reservoir of water communicates with the engine by the two pipes of the feed-pumps; the connection of the barrels of the pumps is made by means of a flexible pipe, denominated hosing, whose nature is such that it can readily yield to all lateral and vertical movements of both engine and tender; the movements are inevitable, for reasons before stated, from the little stability of the railway, the great velocity of the engines, &c. The bolt admits of every movement, except that of lengthening.

Tenders of good construction should present an appearance of lightness combined with solidity; the joints of the iron plates composing the reservoir of water should be well stopped; the cocks of the supply-pipes to the pumps also require to be made perfectly water-tight, which is a condition they do not always fulfil. The fuel in the tender is placed upon a level with that in the fire-grate. The wheels are wedged on the axletrees similar to those attached to the engine, and the weight of the tender is suspended on springs, to remedy the abrupt motion of the water. There is a hook at the back of the tender, which is attached to a powerful spring, to neutralize the effects of concussion, and for the purposes of traction, and it converts all shocks occasioned by the jerking of the engines, which are sometimes very abrupt, into pressures more or less strong accordingly.

Explanation of the principles which govern the power of locomotive engines.—The power of a locomotive engine is not to be estimated alone by the pressure of the steam in the boiler. and the diameter and length of stroke of the piston. In passing between the boiler and the cylinder, the elastic force of the steam is diminished, before it reaches the cylinder, by the smallness of the apertures of the steam-pipes, through which it has to pass. This difference is, likewise, more frequently produced by the evaporating power of the engine not being capable of keeping up a supply of steam to the cylinders, of an elasticity equal to that in the boiler; and, therefore, the pressure upon the piston is less than that against the steam-valve of the boiler; and this diminution of the elasticity of the steam, in the cylinders, as compared with that in the boiler, will, in many cases, be in the ratio of the increase of velocity of the engine. Thus, suppose an engine capable of evaporating a certain quantity of water per hour, or converting it into a certain bulk or quantity of steam, of the elasticity indicated by the valve on the boiler; if this production of steam is sufficient to supply as many cylinders full of steam, of the density of that in the boiler, as shall be equal to the number of strokes per minute of the piston, required to produce the given velocity; then, the elasticity of the steam in the cylinder will be the same as that in the boiler, except that which is required to force the steam through the steam passages with the requisite velocity; and, consequently, the pressure on the piston will be nearly the same as that in the boiler. But, if the velocity of the engine is such, that the number of cylinders full of steam required is greater than the evaporation of the boiler can supply, at the elasticity marked by the steam valve, then the elasticity in the cylinders is correspondingly diminished. Thus, suppose an engine capable of evaporating 50 cubic feet of water into steam per hour, and that the pressure on the steam valve is 50 pounds per square inch; this will supply a given number of cylinders full of steam of that elasticity. Suppose the resistance to the motion of the piston be equal to this pressure of the steam, or equal to the elasticity of 50 pounds per square inch of the surface of the piston; then the engine will travel at that rate, which the evaporating power of the engine will supply it with the requisite number of cylinders full of steam. But, suppose the resistance upon the piston increased by a change in the gradients of the railway, then the velocity of the engine will be diminished, until the evaporating power raises the elasticity of the steam in the boiler, so as to counterbalance the increased resistance of the piston, and the engine will consequently move more slowly. On the contrary, if the resistance be diminished by a change of the gradients of the railway, then steam of a less density will

be required, and, consequently, a greater number of cylinders full will be furnished by the boiler, and the velocity of the engine will be increased.

We see, therefore, that the only correct expression of power of these engines, is the evaporating power of the boiler, and that the velocity with which the engine will move, will depend entirely upon the quantity of water it can convert into steam in a given time; or the number of cylinders full of steam, of a given elasticity, which the boiler can produce in a given time. Having found, therefore, by experiment, the quantity of water which an engine, of given dimensions, can evaporate per hour, we then find the power which that engine is capable of exerting upon the piston, and the velocity, or number of strokes per minute, which that evaporation will produce, with a given load. The volume of steam which a cubic foot of water will produce, depends upon the elasticity; this has been ascertained by various experimentalists, and the following Table will show the result. The third column is the result of Mr. Pambour's later investigations:

Relative volume of the steam generated under different pressures, calculated by the proposed formula.

Total pressure of the steam, in pounds per square inch.	Volume of the steam, calculated by the ordinary formulæ.	Volume calculated by the proposed formula for high-pressure non-conducting engines.	Total pressure of the steam, in pounds per square inch.	Volume of the steam, calculated by the ordinary formulæ.	Volume calculated by the proposed formula for high-pressure non-condensing engines.

We propose now to give the formulæ for calculating the powers and proportions of locomotive engines, commencing with the values, as ascertained, of the various causes of retardation in the movement of a train on a railroad drawn by a locomotive engine; and, combining these values, exhibit a general formulæ for all cases of the movement of a locomotive, and under all circumstances.

1. *Resistance to motion caused by the atmosphere.*—The resistance against a body moving in an indefinite fluid, at rest, is less than the resistance experienced by the same body placed at rest in an indefinite fluid moving against it, which seems to denote that a fluid in motion separates itself less easily than a fluid at rest. The second is, that a thin plate meets with a greater resistance from the air than a prismatic body presenting in front the same surface, and that the resistance diminishes according as the prism is longer. This circumstance is occasioned thus: The air having glided over the edges of a thin body, rushes immediately behind it with great rapidity, and carrying in its motion the portion of fluid which we have mentioned above, produces a relative vacuum behind the opposed surface. But if the moving body be a lengthened prism, the air in passing along its sides loses a certain portion of its acquired velocity, and, consequently, on reaching the hind-face of the prism, extends itself behind it with a force more and more moderated; whence results that it produces there a partial vacuum, or non-pressure, less considerable than in the case of a simple surface. And as we have seen that the definitive resistance against a moving body is the difference between the pressure of the air in front and the partial vacuum created behind. it follows that longer bodies definitively suffer from the air a less resistance than bodies of inconsiderable thickness.

The experiments of M. Thibault have confirmed those of Borda, on the proportionality of the resistance of the air to the square of the velocity, within the limits of velocity that we have to consider. They have, moreover, demonstrated that if two square surfaces be placed so that one shall precisely screen the other, and at a distance apart equal to one of their sides, the resistance against the screened surface will be 7-10ths of the resistance suffered by the surface in front. It consequently results that, when two surfaces are separated by a considerable space relatively to their extent, the resistance of the air against the second is to be estimated nearly as if it were isolated in the air; but if, on the contrary, the two surfaces are very near each other, relatively to their extent, there is room to think that the screened surface may be almost entirely protected against the effect of the air, since a space equal to one side of the surface would be requisite for the air to exert against it a resistance equal to two-thirds of the resistance against an isolated surface.

Uniting the results, and limiting ourselves to the case of a body moving in the air at rest, we have, to determine the resistance of the air, the following formulæ, in which Σ represents the front surface of a body traversing the air in a direction perpendicular to that surface, V the velocity of the motion, ε a coefficient variable with the length of the body, and, lastly, Q the definitive resistance produced by the air against the body:

$Q = \cdot 0011896\, \varepsilon\, \Sigma\, V^2$. Resistance of the air expressed in English pounds, the surface Σ being expressed in square feet, and the velocity V in English feet per second.

And in applying these formulæ it will be necessary, according to the case, to give to the letter ε the following values.

For a thin surface .... $\varepsilon = 1{\cdot}43$
For a cube .... $\varepsilon = 1{\cdot}17$
For a prism of a length equal to three times the side of its front surface .... $\varepsilon = 1{\cdot}10$

Of the resistance of the air against the wagons, isolated or united in trains.—From what we have just seen, it will be easy to estimate the resistance of the air against a prismatic body in motion, when its front surface and dimension in length are known. But as a wagon does not present a regular prismatic form, it becomes necessary first to consider how we may find what surface it really offers to the shock of the air.

The front surface of a wagon may be directly measured; it consists of two distinct parts, the surface of the load, and that of the wagon itself. The former of these surfaces necessarily varies according to the nature of the goods which form the load; and the surface of the wagon, properly so called, includes the spokes of the wheels, the axletrees, axle-boxes, springs, and hind-wheels of the wagon.

We obtain, as the result of sufficiently extended experiments for separate wagons, the value of ε in the preceding formulæ to be $= 1{\cdot}15$.

As to the trains of several wagons, we see that for the resistance of the wheels, an addition must be made to the transverse section of the train; but as the wagons composing the same train, though very near each other, are not however in contact, it is necessary further to seek upon what extent of surface these wagons, thus united, still suffer the resistance of the air during their motion.

From the result of a number of experiments undertaken to determine this resistance, it was found that in order to estimate the effects of the resistance of the air against the progression of a train, to take as resisting surface that of the wagon of greatest section, augmented by 10 square feet per intermediary wagon, and by 6 square feet for the first wagon, including of course in this number the engine itself and its tender.

On railways of about 5 feet width of way, the surface of the highest wagon may, at a medium, be reckoned at 70 to 74 square feet; we may then esteem, in general, the resisting surface of a train of wagons at 70 square feet, plus as many times 10 feet as there are carriages in the train, including the engine and its tender.

If the road has a wider way, or if the carriages offer a surface different from that we have just indicated, the carriage of greatest section must be measured, and that measure used instead of the number 70. If the wheels of the wagon are more than three feet in diameter, there will likewise be an addition to make to take account of the greater surface which they expose to the shock of the air during the motion. This addition would be about 3 square feet per wagon, for wheels of 5 feet in diameter instead of 3. Finally, if the interval between the wagons, instead of being as it is at a medium on ordinary railways, considering the different kinds of carriages and the inequalities of their loading, were augmented by any important quantity, there might also be some addition to make for the effect of the air against the loads of the successive wagons; but as our determination in this respect gave something less than one square foot per wagon, and as the interval between the wagons could not be augmented by any thing considerable without being liable to inconveniences in practice, we deem that one square foot per wagon may comprehend nearly all cases.

When the effective surface presented to the shock of the air shall be known by the preceding calculation, it must be substituted for the letter Σ in the formulæ given above, putting at the same time for ε its value suitably to the length of the prism formed by the train of wagons. According to the variation of ε observed by Dubuat for prisms of divers proportions, it will be found that in the case of a train of 5 wagons, we must make $\varepsilon = 1{\cdot}07$, and that the case of a train of 25 wagons would require $\varepsilon = 1{\cdot}04$. In order then not to have to return continually upon these considerations we will take as a medium $\varepsilon = 1{\cdot}05$, which is suitable to a train of 15 wagons, and expressing at the same time, in the formula given above, the velocity in miles per hour, we shall have, in fine, to express the resistance of the air against a train of wagons in motion, the following formula:

$Q = {\cdot}002687\,\Sigma\,v^2$. Resistance of the air, in pounds, the effective surface of the train or the quantity Σ being expressed in square feet, and the velocity of the motion in miles per hour.

Table of the resistance of the air against the trains.—To dispense with all calculation relative to the resistance of the air, we here subjoin a table showing its intensity for all velocities from 5 to 50 miles per hour, and for surfaces of from 10 to 100 square feet. Were it required to perform the calculation for a velocity not contained in the table, it would evidently suffice to seek the resistance corresponding to half that velocity and to multiply the resistance found by 4; or, on the contrary, to seek the resistance corresponding to the double of the given velocity, and to take a quarter of the result. So the resistance of the air against a surface of 100 square feet, at the velocity of 50 miles per hour, is equal to four times the resistance of the air against the same surface at the velocity of 25 miles per hour. As to surfaces greater than 100 square feet, they must be decomposed into surfaces less than 100 feet, and then the table will still give the results required; for the resistance against a surface of 120 square feet is evidently nothing more than the sum of the resistances against one surface of 100 square feet and one of 20 square feet.

By means of the table in question will be obtained, without calculation, the resistance of the air expressed in pounds, for any velocity of the moving body; but it is to be observed that the table supposes the atmosphere at perfect rest. If, then, there be a wind of some intensity favorable to the motion, or contrary to it, account must be taken thereof. In order to effect this, it will suffice to observe that if the wind is favorable, the body will move through the air only with a velocity equal to the difference between its own absolute velocity and that of the wind; and that if on the contrary the wind is opposed to the motion, the effective velocity of the body through the air will be equal to the sum of its own velocity augmented by that of the wind. In this case, then, the velocity of the wind must first be measured, by abandoning a light body to its action, and noting the time in which it traverses a space previously measured on the ground; or else an anemometer may be used for the purpose. Then the

velocity of the wind must be subtracted from that of the train in motion or added to it, according to the case; and that difference or that sum is the velocity to be sought in the table, or substituted in the formula, to obtain the corresponding resistance against the whole train.

If the wind, instead of being precisely contrary or favorable to the motion, should exert its action in an oblique direction, it would tend to displace all the wagons laterally; and consequently, from the conical form of the wheels, all those on the further side from the wind would turn on a larger diameter than those on the side towards the wind. The resistance produced will therefore be the same as that which would take place on a curve on which the effect of the centrifugal force were not corrected, and that resistance would necessarily be very considerable.

Practical Table of the resistance of the air against the trains.

Of the friction of the cars of a train.—From experiments, the mean friction of the cars taken independently of the resistance of the air, amounts to $\frac{1}{389}$ of their gross weight, or to 5·76 pounds per ton; but to simplify the calculations we will take it at 6 pounds per ton, which makes $\frac{1}{373}$ of the weight of the cars.

These are the results which ought to be used when, for the resistance of the air, the determination deduced from the most recent and most exact experiments on the subject is used, and when account is

taken, as it ought to be, of the length of the prism formed by the train in motion, as well as of the effects of the air against the rotation of the wheels and the accessory parts of the wagons.

It appears from this result that for the mean velocity of trains it would be indifferent to compute the friction of the cars at 5·76 pounds per ton, taking account of the real resistance of the air and of its effects against the accessory parts noticed above, or to take the friction of the wagons at 7 pounds per ton, accounting merely for the resistance of the air against the wagon of greatest section. On the other hand, as during the work of the engines their velocity is so much the greater as the train they draw is less considerable, whence the resistance of the air increases as the friction of the train diminishes, it will be found that either of the two preceding calculations leads to very nearly the same result, for the total resistance opposed by the moving train, and that it is only in cases of extreme velocity that the two modes of calculation present a notable difference.

Without any important error, the second of the two modes of calculation may be used; but the first is introduced with a view to the exhibition of a *general formula.*

It should be premised that the valuation of the friction, which we obtained above, ought to be understood only of carriages similar to those which were submitted to experiment, and subject to like conditions, viz., with iron axles, turning on brass chairs, and provided with self-acting grease-boxes; with three-feet wheels and axle-bearings 1¾ inches; with the use of a well-kept railway, and finally with the usual proportions of about $\frac{5}{8}$ between the weight of the body of the loaded carriage and the total weight of the wagon. Were these conditions *materially* altered, a new determination of the friction would become necessary.

Of gravity on inclined planes.—We have seen how the resistance caused on a railway by the friction of the wagons may be valued. But it sometimes happens that this friction is the smallest part of the total resistance which the engine has to overcome, in order to effect the motion of the train. This case occurs when the way is not level, and the train is obliged to ascend an acclivity. The resistance then caused is, as every one knows, much greater than on a level line, and in consequence it becomes necessary to take account of it in the calculations.

When a body is placed on an inclined plane, the weight which urges it, and which always acts in a vertical line, is decomposed into two forces; one perpendicular to the plane, and which measures the pressure produced against the plane, by virtue of the weight of the moving body, and the other parallel to the plane, and which tends to make the body slide or roll along the declivity. The latter force, which we will call *the gravity* along the plane, would inevitably drag the body towards the foot of the declivity, were it not counteracted by a contrary force. When therefore a train of wagons has to ascend an inclined plane, the moving power must apply to it: firstly, a force able to overcome the friction of the wagons themselves; and again, another force able to overcome the gravity in the direction of the plane. If, on the contrary, the mover draw the train of wagons down the plane, then, in order to produce the motion, it will evidently have to apply only a force equal to the difference between the friction proper to the wagons and the gravity, since the latter force then acts in the same direction as the mover.

When a body of a given weight is set on a plane of a given inclination, we know that, in order to obtain the gravity of the body along the plane, its weight is to be multiplied by the fraction which expresses *practically* the inclination of the plane. Thus, for instance, on a plane inclined $\frac{1}{89}$, that is to say, on a plane which rises 1 foot on a length of 89 feet measured along the acclivity, the gravity of 1 ton, or 2240 lbs., is

$$\frac{2240}{89} = 25{\cdot}2 \text{ lbs.}$$

Moreover, when a train of wagons ascends an acclivity, the engine has not only to surmount the gravity of the wagons of the train, but likewise its own gravity and that of the tender which follows it; and these forces do not present themselves when the motion takes place on a horizontal line. It is then on the *total* weight of the train, that is, including engine and tender, that the resistance caused by gravity on acclivities is to be calculated.

If it be supposed, for instance, that a train of 40 tons, tender included, be drawn up a plane inclined $\frac{1}{89}$, by an engine weighing 10 tons, it is clear that the definitive resistance opposed to the motion by the train will be

40×6 lbs. $= 240$ lbs., friction of the carriages at 6 lbs. per ton	240 lbs.
$50 \times \frac{2240}{89} = 1258$ lbs., gravity of the 50 tons of the train (reduced to lbs.) on a plane inclined $\frac{1}{89}$, to be added	1258
Total resistance arising from friction and gravity	1498 lbs.

If, on the contrary, the same train had to descend a plane inclined $\frac{1}{1000}$, the resistance it would then offer would be

40×6 lbs. $= 240$ lbs., friction of the wagons	240 lbs.
$50 \times \frac{2240}{1000} = 112$ lbs., gravity of the train to be deducted	112
Definitive resistance arising from friction and gravity	128 lbs.

In general, let M be the weight of the train, in tons gross and including the tender; let m be the weight of the engine, expressed also in tons; k the friction of the wagons per ton, expressed in lbs., as has been explained; finally, let g be the gravity, in lbs., of 1 ton on the plane in question. It is clear in the first place, from what has been said above, that the quantity g will be equal to 2240, multiplied by the practical inclination of the plane; so that if $\frac{1}{e}$ express that inclination, or the ratio of the height of the plane to its length, we shall have, to determine g, the equation

$$g = \frac{2240}{e}.$$

This premised, the friction of the wagons will have for its value k M. Again, since g expresses the gravity of 1 ton, it is plain that g (M + m) will represent, in lbs., the gravity of the total mass, train and engine, placed on the inclined plane.

Thus, according as the motion takes place in ascending or in descending, the total resistance, in lbs., offered by the train on the inclined plane, will be

$$k\,\mathrm{M} \pm g\,(\mathrm{M} + m) = (k \pm g)\,\mathrm{M} \pm g\,m,$$

an expression in which the sign + belongs to the ascending motion, and the sign — to the descending motion of the train.

It will always be easy then to obtain the number of lbs., which represents the resistance opposed by a train in motion on a plane of a given inclination.

Of the effects of the blast-pipe.—We have just examined several of the resistances which are opposed to the engine in its motion, viz., that of the wagons along the rails, and that of the air against the trains. But among other resistances which the piston has yet to overcome, is one arising from the disposition of the engine itself, and of which it will be proper to treat before proceeding further.

The steam, after having exerted its action in the cylinder, might escape into the atmosphere by a large opening. It would then be possible for it entirely to dissipate itself in the air, during the time the piston takes to change its direction. Consequently the steam would in nowise impede the retrograde motion of the piston, whatever might be the velocity of the piston. But the disposition adopted is contrary to this. The steam, on leaving the cylinder, has no other issue towards the atmosphere than an aperture exceedingly narrow; nor can it, by that aperture, escape totally within the time of one stroke, except by assuming a very considerable velocity in its motion. For this, the steam in the cylinder must necessarily be at a pressure sensibly greater than that of the atmosphere into which it flows; and as the pressure of the steam while flowing acts in all directions, and consequently against the piston, it results that the latter, instead of having simply to counteract the atmospheric pressure, finds an additional one to overcome, which is to be added to the divers resistances already measured.

This new cause of resistance might, as has been said, be in a great measure suppressed, by enlarging sufficiently the outlet of the steam. But to do this would be to lose one of the most active causes of the definitive effect of the engine; for the object of the disposition of which we treat is to excite the fire sufficiently, and to produce, in a boiler of small dimensions, the very great quantity of steam requisite for the rapid motion of the engine. To this end, the waste steam is conducted to the chimney, and thrown into it by intermittent jets, through a blast-pipe or contracted tube, placed in the centre of the chimney and directed upwards. The jet of steam, as it rushes with force from this aperture, rapidly expels the gases which occupied the chimney. It consequently leaves behind it a vacuum; and this is immediately filled by a mass of air rushing through the fire-grate into the space where the vacuum has been made. At every aspiration thus produced, the fuel contained in the fire-box grows white with incandescence. The effect then is similar to that of a bellows continually urging the fire; and the artificial current created in the fire-box by this means is of such efficacy for the vaporization, that were the blast-pipe suppressed, the engine would become almost useless, which proves that the current of air attributable to the ordinary draught of the chimney is in comparison but very trifling.

Omitting the experiments and calculations from which it is derived, we obtain as the value of the resistance against the piston caused by the action of the blast-pipe, the formula

$$\cdot 0113\, v \frac{\mathrm{S}'}{o};$$

in which v is the velocity of the engine in miles per hour: S′ the *total* vaporization of the boiler in cubic feet of water per hour; o the area of the orifice of the blast-pipe expressed in square inches; and the result of the calculation will give the pressure in the blast-pipe expressed in pounds per square inch. The pressure per square foot will be 144 times as much.

With respect to the quantity represented here by S′, the experiment from which we deduced the formula shows, that the vaporization signified is the *total* vaporization effected in the boiler, that is to say, the vaporization counted before deduction of the water carried away in a liquid state with the steam.

Making in the preceding formula

$$\cdot 0113 \frac{\mathrm{S}'}{o} = p',$$

the pressure in the blast-pipe may be represented by the expression $p'\,v$, in which p' will be the ratio of the vaporization to the orifice of the blast-pipe, multiplied by a constant coefficient.

Now, for engines which vaporize as much as 60 cubic feet of water per hour, practice has established the use of a blast-pipe of 2·25 inches diameter, or 3·96 square inches of area, which gives for the value of the ratio $\frac{\mathrm{S}'}{o}$,

$$\frac{60}{3 \cdot 96} = 15 \cdot 2.$$

In constructing engines of a greater vaporizing power, it would be natural to increase the area of the blast-pipe in proportion to the quantity of steam to which it is to give issue. There is room therefore to think that the proportion thus established between the production of steam and the area of the blast-pipe, will not be notably changed by the different engine-makers. Consequently the ratio $\frac{\mathrm{S}'}{o}$ may be regarded approximatively as a constant quantity, given by the above proportion.

Then the preceding formula will be reduced simply to the expression ·175 v, which will be useful especially in valuing the pressure due to the blast-pipe in engines whose vaporization is

unknown. In this formula, v is the velocity of the engine, in miles per hour, and the result is the pressure in the blast-pipe, expressed in pounds per square inch. As the pressure per square foot is 144 times as much, it follows that if we require the pressure expressed in that manner, we shall obtain its value by the formula $25{\cdot}2\,v$.

We shall then represent generally the pressure in the blast pipe under the form $p'\,v$; and for the most ordinary cases, it will suffice to give to p', in this expression, one of the constant values above mentioned, according to the measures employed. But if the engine in question should differ too considerably from the proportions which we have just indicated with reference to the area of the blast-pipe, it would be necessary to substitute for that approximate value of p', its value function of S' and o.

In fine, to dispense with all calculation on this head, we here subjoin a table, in which will be found, on inspection, the pressures in the blast-pipe for given circumstances, and we continue that table beyond the actual effects of locomotive engines. It will there be recognized how, by augmenting the orifice of the blast-pipe, the resistance against the piston, arising from that cause, may be diminished at pleasure; and it may probably be found, in consequence, that in the regular work of locomotives, it might be useful to adopt a blast-pipe with a variable orifice, such as was employed temporarily in the experiments from which these values were deduced. Then, by contracting the orifice of efflux of the steam only just as much as is necessary, there will be no more resistance against the piston than what is indispensable for the proper action of the engine.

Practical Table of the pressures against the piston, due to the action of the blast-pipe.

Of the several elements of the friction of locomotive engines.—After having examined the resistance offered by the loads to be moved, it will be proper also to make known the passive resistance or friction of the movers which we have to employ; for it is only the surplus of their power over and above what is necessary to propel themselves, that these movers can apply to the drawing of burdens.

While a locomotive engine is performing the traction of a train, it evidently requires:—1st, a certain force to make the train advance, or to overcome the resistance of all the loaded carriages; and 2dly, another force to propel itself by overcoming its own friction. It is this second force, that which causes the engine to move, which represents the *friction of the engine;* whereas the first is *the resistance of the load,* and the union of the two efforts constitutes the *total force applied by the mover.*

The friction of a locomotive engine is then the force it expends to maintain itself in motion on the rails. But that force must clearly vary according to the weight or resistance of the load which the engine draws. In effect, the greater that weight, the greater also will be the pressure it causes on the axes of rotation, and on the divers moving parts of the apparatus; and as the friction is always in proportion to the pressure, it follows that the friction which takes place at these points, must augment with the load. Hence the friction of the engine, which is nothing more than the force resulting from the union of these different frictions, must equally increase with the load.

Thus we find a difference between the friction of an engine *unloaded,* and that of the same engine *loaded.* The value of the first is found to be 15 *lbs. per ton of their weight,* and of the second, ·137 lbs. *additional* per pound of traction in the case of uncoupled driving-wheels, and ·215 lbs. per pound of traction in the case of engines with wheels coupled.

It will readily be conceived, however, that it must vary some with the construction and state of every engine.

With reference to the manner in which the additional friction of engines ought to be calculated, we have to bear in mind that it is to be reckoned on every pound of the *total* resistance exerted against the motion; that is to say, *the resistance caused by the friction of the wagons, that of gravity, and that of the atmosphere, must first be calculated, and on the sum of these the additional friction of the engine is to be taken at the rate already indicated.*

Of the total resistance on the piston, resulting from the divers partial resistances just enumerated.—We have just estimated successively the divers resistances which oppose the motion of the engine. It is necessary now to seek the definitive resistance which results from them united, per square inch or per unit of surface of the area of the piston.

The resistances which we have hitherto considered are—the resistance of the air, the friction of the wagons, the gravity, the friction of the engines, and the resistance arising from the blast-pipe. But we must here add, besides, the atmospheric pressure; for the engines under consideration being high-pressure engines, it follows that the opposite face of the piston necessarily supports, like every other body in communication with the atmosphere, a certain pressure due to the elasticity of the atmospheric air.

Thus, the definitive resistance exerted against the piston consists of six resistances, which are—the friction of the wagons, the resistance of the air, the gravity of the train, the friction of the engine, the atmospheric pressure, and the pressure caused by the blast-pipe. Of these six resistances, the last two act immediately and directly on the piston. They must therefore be moved at the velocity of the piston itself; but it is not so with the other four. In an engine, the pressures exerted on different points by the same force, are in the inverse ratio of the velocities of those points. Here the engine and its train must be moved at a velocity greater than that of the piston, in the proportion of the circumference of the wheel, to twice the length of the stroke. The intensity of the pressure exerted by the resistance of the load, the air, the engine, and the gravity, is then increased by its transmission to the piston, in the above ratio of the velocity of the wheel to that of the piston.

Consequently, if M express the number of tons gross which compose the total load, that is to say, including the weight of the tender-carriage of the engine, and k the number of pounds requisite to draw one ton on a railway,

$$k\,M$$

will be the resistance, in pounds, resulting from the friction of the wagons which carry the load. If at the same time we call g the gravity of 1 ton on the inclined plane to be traversed by the engine, and if m represent the weight of the engine, in tons,

$$g\,(M + m)$$

will be the resistance, in pounds, produced by the gravity of the total mass, train and engine; so that, according as the motion takes place in ascending or in descending, the definitive resistance arising from friction and gravity will be

$$k\,M \pm g\,(M + m) = (k \pm g)\,M \pm g\,m.$$

Similarly, if we express by $u\,v^2$ the resistance, in pounds, exerted by the air against the train, at the velocity v of the engine,

$$(k \pm g)\,M \pm g\,m + u\,v^2$$

will be the resistance opposed to the motion of the engine by the friction, the gravity, and the shock of the air.

If, again, F represent the friction of the unloaded engine, expressed also in pounds, and δ its additional friction, measured as a fraction of the resistance, as has been already indicated, we see that

$$F + \delta\,[\,(k \pm g)\,M \pm g\,m + u\,v^2]$$

will be the total friction of the engine at the moment when it draws the resistance

$$(k \pm g)\,M \pm g\,m + u\,v^2.$$

Consequently

$$(1+\delta)\,[(k\pm g)\,\mathrm{M}\pm g\,m+u\,v^2]+\mathrm{F}$$

will be the total resistance opposed to the progression, along the rails, by the engine and its train.

As this force produces on the piston a resistance augmented in the ratio of the circumference of the wheel to twice the stroke of the piston, if D express the diameter of the wheel, l the length of the stroke, and π the ratio of the circumference to the diameter,

$$(1+\delta)\,[(k\pm g)\,\mathrm{M}\pm g\,m+u\,v^2]\frac{\pi\mathrm{D}}{2\,l}+\frac{\pi\,\mathrm{D\,F}}{2\,l}$$

will be the resistance on the piston, caused by that force, that is to say, caused by the resistance of the wagons, the gravity, the air, and the friction of the engine.

This resistance is that which is exerted on the totality of the area of the pistons. But representing by d the diameter of the cylinders, $\frac{1}{2}\,\pi\,d^2$ will be the area of the two pistons. Whence

$$\frac{(1+\delta)\,[(k\pm g)\,\mathrm{M}\pm g\,m+u\,v^2]\frac{\pi\mathrm{D}}{2\,l}+\frac{\pi\,\mathrm{D\,F}}{2\,l}}{\frac{1}{2}\,\pi\,d^2},$$

or, simplifying,

$$(1+\delta)\,[(k\pm g)\,\mathrm{M}\pm g\,m+u\,v^2]\frac{\mathrm{D}}{d^2\,l}+\frac{\mathrm{DF}}{d^2\,l},$$

will be the same force, divided according to the unit of surface of the piston.

Adding to this the atmospheric pressure p, and the pressure caused by the blast-pipe $p'\,v$, which are already measured per unit of surface, we shall have, in fine, for the *total* resistance R exerted on the piston,

$$\mathrm{R}=(1+\delta)\,[(k\pm g)\,\mathrm{M}\pm g\,m+u\,v^2]\frac{\mathrm{D}}{d^2\,l}+\frac{\mathrm{DF}}{d^2\,l}+p+p'\,v.$$

In this expression, the quantity g represents the gravity on the plane to be traversed by the train; if the plane be horizontal instead of inclined, we shall have $g=o$. The weights M and m of the train and the engine are expressed in tons gross; the quantity k, which is the friction of the wagons per ton, is equal to 6 lbs.; the value of δ is ·137 or $\frac{1}{7}$, for engines with uncoupled wheels; the velocity v of the engine is expressed in miles per hour; in fine, according as the dimensions D, l and d are expressed in inches or in feet, and the forces u, p and p', in pounds per square inch, or in pounds per square foot, the value R which will result from the calculation will be the resisting pressure on the piston, expressed likewise in pounds per square inch, or in pounds per square foot.

Applying this calculation to a train of 9 wagons and a tender, weighing 50 tons gross, and drawn at the velocity of 20 miles per hour, up a plane inclined $\frac{1}{500}$, by an engine with two cylinders of 11 inches diameter, stroke of the piston 16 inches, propelling wheels 5 feet, not coupled, weight 8 tons, friction 104 lbs., blast-pipe 2·25 inches in diameter; and referring, for the resistance of the air, to what has been said above, the proceeding will be as follows:

$50\times6=300$ lbs.	Friction of the wagons, in pounds, or value of $k\,m$.
$\frac{2240}{500}\times58=260$ lbs.	Gravity of the total mass, train and engine, or value of $g\,(\mathrm{M}+m)$.
194 lbs.	Resistance of the air against an effective surface of 180 square feet, at the velocity of 20 miles per hour or value of $u\,v^2$.
754 lbs.	Resistance of the train, or $(k+g)\,\mathrm{M}+g\,m+u\,v^2$.
$754\times1{\cdot}137=857$ lbs.	Resistance of the train, including the additional friction which it produces in the engine, or $(1+\delta)\,[(k+g)\,\mathrm{M}+g\,m+u\,v^2.]$
+ 104 lbs.	Friction of the unloaded engine, or F.
961 lbs.	Total resistance to the progressive motion of the engine, or value of the term $(1+\delta)\,[(k+g)\,\mathrm{M}+g\,m+u\,v^2]+\mathrm{F}$.

On the other hand, we have

$3{\cdot}1416\times60$ in. $=188{\cdot}5$	Circumference of the wheel, expressed in inches, or $\pi\,\mathrm{D}$.
2×16 in. $=32$	Double the stroke of the piston expressed in inches, or $2\,l$
$\frac{188{\cdot}5}{32}=5{\cdot}9$	Ratio of the velocities of the wheel and the piston, or $\frac{\pi\mathrm{D}}{2\,l}$

Thus,

$961\times5{\cdot}9=5670$ lbs.	Resistance produced on the piston, or value of the term $(1+\delta)\,[(k+g)\,\mathrm{M}+g\,m+u\,v^2]\frac{\pi\mathrm{D}}{2\,l}+\frac{\mathrm{F}\,\pi\,\mathrm{D}}{2\,l}$.

Again,

$\frac{3{\cdot}1416\times11^2}{2}=190$	Area of the two pistons, in square inches, or $\frac{1}{2}\,\pi\,d^2$.

Consequently, we obtain in fine

$\frac{5670}{190} = 29{\cdot}8$ lbs. Above-mentioned resistance, portioned per square inch of the surface of the piston.

$+$ 3·5 lbs. Effective pressure per square inch, arising from the blast-pipe, or $p' v$.

$+$ 14·7 lbs. Atmospheric pressure per square inch, or p.

48·0 lbs. Definitive resistance, per square inch of the surface of the piston of an engine with two cylinders of 11 inches in diameter, &c., when drawing a load of 50 tons under the given circumstances.

Were it desired to know that resistance per square foot, it would suffice to multiply the last result by 144, that is to say, the pressure required would be 6912 lbs. per square foot, which number would have been obtained directly, if instead of expressing the area of the piston in square inches, and the partial pressures in pounds per square inch, these measures had been referred to the square foot as unit of surface.

This example shows what is to be understood by the different quantities contained in the formula, and how each of them ought to be introduced into the calculation.

To know the evaporating power of which a given engine is capable, it suffices *to measure the number of square feet composing its total heating surface, without distinction between the fire-box and the tubes, and then to multiply that number by the vaporization which each square foot of surface is capable of producing.* It is then the latter quantity which we must now seek to determine; but, as we have seen that the vaporization produced per unit of surface varies with the velocity of the motion, it is necessary to specify at the same time the velocity at which we wish to measure the vaporization.

We find that in certain engines the vaporization per square foot of heating surface was ·198 cubic foot, at the velocity of 18·15 miles per hour. On the other hand, we know that the vaporization *varies in the direct ratio of the fourth roots of the velocities.* We may then deduce from thence, that at the velocity of 20 miles per hour, the vaporization of those engines will be

$$\cdot198 \left(\frac{20}{18{\cdot}15}\right)^{\frac{1}{4}} = \cdot203 \text{ cubic foot of water per square foot of heating surface.}$$

Operating in the same manner for the two following series, we obtain, for the velocity of 20 miles per hour, the determinations of the following table:

Experiments on the vaporization of locomotive engines, per unit of total heating surface of their boiler.

Number of the series.	Average velocity of the engine in miles per hour.	Vaporization per hour and per sq. foot of total heating surface, at the preceding velocity.	Vaporization per hour and per sq. foot of total heating surface, at the velocity of 20 miles per hour.
	Miles.	Cubic foot.	Cubic foot.
2d,	18·15	·198	·203
3d,	20·13	·200	·200
4th,	8·99	·172	·210
5th,	15·26	·194	·208
			Mean......·205

Thus, from these experiments, it appears that at the velocity of 20 miles per hour, the vaporization of locomotives may be valued at ·205, or, in round numbers, at ·2 cubic foot of water per hour, per square foot of total heating surface of their boiler; and it appears also that the different engines and different velocities lead to numbers almost identical, which tends to confirm the valuation we have just obtained.

This determination is, as we have said, suitable to the velocity of 20 miles per hour; but it is easy to deduce from it that which would take place at any other velocity, by multiplying by the fourth root of the ratio between the given velocity and the velocity of 20 miles.

It must, however, be observed, with respect to these determinations, that they are strictly suitable only to boilers constructed in proportions not very different from those used in the experiments; that is to say, according to what has been explained above, that the heating surface of the fire-box ought not to be under a tenth of the total heating surface of the boiler, and the orifice of the blast-pipe not much larger than we had it in our experiments, according to the adopted practice. Were any notable change made in this respect, were the fuel of an inferior quality, or the engine materially different in construction from what we have described, there would be grounds for a new determination of the vaporization.

In fine, we will again add, that the numbers obtained above indicate rather the consumption of water of the boiler, than the real *vaporization* produced; for we shall presently see, that out of the total water thus expended by the engine, there is a portion which is drawn into the cylinders, mixed with the steam, but without being itself vaporized. Consequently, to obtain the real vaporization of the engine, it will be necessary to take account of this circumstance, as we shall do further on.

Of the loss of steam which takes place by the safety-valves, during the work of locomotive engines.— Among locomotive engines there are a great number which are subject to a continual loss of steam by the safety-valves. This effect arises from the engine being designedly constructed with an excess of

power; that is to say, that according to the production of steam which takes place in its boiler, the engine could draw its regular load at a greater velocity than it is allowed to do. The result is, that to prevent the engine from acquiring too great a velocity, it becomes necessary partially to close the regulator, that is, to diminish the passage of the steam, till no more enters the cylinder than the quantity necessary to produce the desired velocity. Then the surplus accumulating in the boiler, at last raises the safety-valve and escapes into the atmosphere. When this loss takes place only on the regulator being somewhat closed, it is but a proof, as we have said, of a surplus of power which the engine holds in reserve. But if it takes place more or less under all circumstances, then it depends on the steam-ways being too narrow, and is consequently a defect in the engine; in either case, however, it is necessary to obtain a valuation of this loss.

There is yet another case in which engines are subject to a loss of steam by the valves; but this loss is owing to a different cause from the preceding, and exhibits itself much more abundantly; it is when the engine ascends a steep acclivity, with an apparently moderate load, or when it ascends a moderate inclination, with a very heavy load. At these moments the valves are always seen to emit an enormous quantity of steam. The reason is that, as soon as the engine reaches the inclined plane, its load instantly becomes extremely heavy, on account of the surplus of traction required by the gravity on the plane. It has been shown, in effect, that on a plane inclined $\frac{1}{100}$, every ton produces, by gravity alone, a resistance equal to that of 3·7 tons on a level. It happens therefore, at that moment, that the resistance of the train may become greater than the actual pressure of the safety-valve. Consequently the steam, instead of flowing by the cylinder, driving back the piston, raises the safety-valve, and escapes into the atmosphere. If then the passage which the steam thus opens for itself were sufficient for its total efflux, no more steam would pass through the cylinder, and the engine would inevitably stop.

Moreover, since, supposing even the steam in the cylinder at the same pressure as in the boiler, which is the most favorable supposition we can make, it still happens that the volume of steam expended by the cylinder is less than the volume of steam generated in the boiler, a part of the water must have been carried from the boiler to the cylinder, in its liquid state; and the comparison between the quantity of water consumed by the boiler and that which, in the state of vapor, corresponds to the velocity of the piston, shows that the quantity of water really converted into steam, is to the total quantity of water consumed, in the ratio of the numbers

$$\frac{11827}{15641} = \cdot76.$$

Thus, in this experiment, we see that ·24 of the water expended by the boiler was carried into the cylinders without being reduced to steam, or that the *real* vaporization of the engine was ·76 *of the total water expended.*

The results which have just been presented above show that the quantity of water carried away with the steam, varies in different engines, and ought to be determined for each separately; but as in taking the means between the different experiments, that loss is found to amount to ·24 of the total vaporization of the boiler, this proportion may be adopted approximatively for engines that have not been directly submitted to experiment in this respect; that is to say, in order to have the *effective* vaporization of a locomotive, *the total vaporization of which its boiler is capable must be first measured; from the result must be subtracted, if necessary, the loss, either accidental or permanent, which may be observed at the safety-valves, and the remainder must be multiplied by the fraction* ·76. Thus will be obtained the volume of water which passes into the cylinder, in the real state of steam, and produces the motion of the piston.

We have reason then to think, from the different experiments cited above, that with coke for fuel, and with the other circumstances of the work and the construction of the engines, the most advantageous ratio to establish between the total heating surface and that of the fire-box would be nearly that of 10 to 1: since for a less proportion there would be increase in the expenditure of fuel, without increase of vaporization; and for a greater proportion, on the contrary, there would be reduction in the vaporization of the engine per unit of surface, which would incur the necessity of a larger boiler, and consequently of a greater weight, which it is important to avoid.

In fine, to arrive at a general conclusion from the experiments which have been made in order to the determination of this question, it appears that, according to the proportion of the fire-box to the total heating surface, the consumption of fuel in locomotive engines varies from 9·2 to 11·3 and 11·7 pounds per cubic foot of *total* water vaporized: so that it may, on an average, be valued at 10·7 pounds of coke per cubic foot of total vaporization, or its equivalent in other fuel.

Fuel.—To find the quantity of fuel necessary for the engine per ton per mile, the load the engine is to draw must previously be given: in multiplying the given load by the velocity the engine will assume with that load, the product will immediately make known, in tons conveyed one mile per hour, the useful effect of the engine. Dividing then the consumption of fuel of the engine per hour by the useful effect produced in the same time, the quotient will give definitively the quantity of fuel which will be consumed by the engine per ton per mile in drawing the given load.

The principal problems which occur with respect to locomotive engines have reference in the first place to two circumstances, namely: 1. When the engine is already constructed, and the question is to determine the effects that it will produce; 2. When the engine is as yet unbuilt, and the question is to determine the proportions it ought to have in order to produce desired effects. At present we consider only the questions relative to the first case.

When an engine is already constructed, and all its dimensions may be directly measured, the following problems may present themselves:

1. To determine the velocity the engine will assume with a fixed load;
2. To determine the load it will draw at a desired velocity;

3. To determine the useful effect it will produce at a desired velocity, or with a fixed load.

And this last problem may itself be expressed under ten different forms—namely, to find successively

The useful effect of the engine in tons drawn one mile;
The useful effect expressed in horse-power;
The quantity of fuel necessary per ton per mile;
The quantity of water necessary per ton per mile;
The useful effect produced per pound of fuel consumed;
The useful effect produced per cubic foot of water vaporized;
The consumption of fuel which produces one-horse power;
The consumption of water which produces one-horse power;
The horse-power produced per pound of fuel;
The horse-power produced per cubic foot of water vaporized.

Moreover, as two cases are necessarily to be distinguished in the work of the engines, namely, the case in which they work with a load or velocity *indefinite*, and that in which they work with the load or velocity which produces the *maximum of useful effect*, there will yet occur in this respect a new series of questions, namely:

1. To determine the velocity at which the engine will produce its maximum of useful effect;
2. To determine the load corresponding to the production of the maximum of useful effect;
3. To determine the maximum of useful effect that the engine can produce.

And this last problem may be expressed under the ten different forms which we have indicated above.

Of the velocity of the engine with a given load.—Suppose, in effect, that a load of 50 tons gross, tender included, be drawn up a plane inclined $\frac{1}{300}$, by an engine with 2 cylinders 11 inches in diameter, stroke of the piston 16 inches, wheels 5 feet, friction 103 pounds, total pressure of the steam in the boiler 65 pounds, or effective pressure 50 pounds per square inch, and, finally, vaporizing power 60 cubic feet of water per hour, or 1 cubic foot per minute.

The total resistance opposed by that load to the motion of the piston is 48 pounds per square inch, when the velocity is 20 miles per hour. If, then, we admit that the engine will come near enough to that velocity, for the valuation which we have made of the resistance of the air and the pressure caused by the blast-pipe, in the calculation, not to be very far from the truth, we must conclude that, during the uniform or permanent motion of the engine with that load, the pressure of the steam, during its action in the cylinder, will likewise be 48 pounds per square inch.

Now, the quantity of water consumed by the boiler amounts to 60 cubic feet of water per hour, and we have shown in treating of the vaporization that out of that mass of water 75-100ths only, on an average, are really converted into steam, and that the rest is merely carried away with the steam into the cylinders, but in a liquid state. The effective vaporization of the engine is, then, firstly,

$$\cdot 75 \times 60 = 45 \text{ cubic feet per hour, or}$$
$$\cdot 75 \text{ cubic foot per minute.}$$

This water is first transformed, in the boiler, into steam at the total pressure of 65 pounds per square inch; but on passing into the cylinders it acquires the pressure of 48 pounds per square inch, and we know that, in this change, the steam remains always at the maximum density for its temperature. Its volume may then be determined by the table, which we have already given, on the volume of the steam formed under different pressures. According to this table, the volume of the steam formed under the total pressure of 48 pounds per square inch, is 573 times that of the water which produced it. Hence the quantity of water effectively vaporized per minute in the boiler, will form, during its passage through the cylinders, a volume of steam expressed by

$$573 \times \cdot 75 = 430 \text{ cubic feet.}$$

On the other hand, the area of each cylinder is 95 square inches, or in square feet that area is represented by ·66 square foot; and the stroke of the piston is 16 inches, or 1·33 foot. Whence the capacity of each cylinder traversed by the piston is

$$\cdot 88 \text{ cubic foot.}$$

But besides the portion traversed by the piston there still exists, at each end of each cylinder, a vacant space called the *clearance of the cylinder*, which is necessarily filled with steam at each stroke. The capacity of this vacant space, represented by an equivalent portion of the cylinder, and steam-ways included, is usually 1-20th of the part of the cylinder traversed by the piston. The real capacity, therefore, which is filled with steam at each stroke of the piston, is

$$\cdot 88 \times \tfrac{21}{20} = \cdot 924 \text{ cubic foot.}$$

Consequently the number of strokes of the piston which the engine will give per minute, by reason of its effective vaporization, will necessarily be

$$\frac{430}{\cdot 924} = 465.$$

Now, each time the wheel makes one revolution the engine gives two strokes of the piston in each of its two cylinders; and the diameter of the wheel is 5 feet, which makes 15·71 feet in circumference. Therefore, at every four strokes of the piston the engine advances 15·71 feet; that is to say, its velocity, in feet per minute, will be

$$\frac{465}{4} \times 15\cdot 71 = 1822 \text{ feet.}$$

Finally, as one mile contains 5280 feet, and one hour contains 60 minutes, the definitive velocity of the engine, in miles per hour, will be

$$\frac{60}{5280} \times 1822 = 20{\cdot}71 \text{ miles.}$$

Thus we see that the above vaporization will necessarily produce a velocity of 20·7 miles per hour for the engine; that is to say, a locomotive engine with the given proportions may, if in good order, and with a well-stocked fire, draw a load of 50 tons gross, tender included, up a plane inclined $\frac{1}{300}$, at the velocity of 20·7 miles per hour.

With regard to the velocity which we have just obtained, we must add that if the engine suffers besides a loss of steam by the safety-valve, which takes place in a great number of locomotive engines, there will then be a corresponding loss on the effective vaporization; and consequently the definitive velocity of the engine will be reduced in a corresponding proportion. For instance, if the engine be liable to a loss of ·05 of its vaporization in full activity, its definitive velocity, in the case above mentioned, will become

$$\cdot 95 \times 20{\cdot}71 = 19{\cdot}67 \text{ miles per hour.}$$

The calculation will be performed in the same manner for every other load and for every other engine. Thus, in general,

M, Representing the number of tons of the load, tender included;
m, The weight of the engine, in tons;
g, The gravity, in pounds, of one ton on the plane the engine has to traverse; this gravity being null for the case of a horizontal plane;
k, The friction of the wagons per ton, expressed in pounds;
v, The velocity of the engine, in miles per hour;
$u v^2$, The resistance of the air against the train, at the velocity v, resistance expressed in pounds;
$p' v$, The pressure against the piston, arising from the action of the blast-pipe, expressed in pounds per square foot;
F, The friction of the engine, in pounds;
δ, Its additional friction, measured as a fraction of the resistance;
D, The diameter of the propelling wheels of the engine, in feet;
d, The diameter of the cylinder, in feet;
l, The length of the stroke of the piston, in feet;
c, The clearance of the cylinder, represented by an equivalent portion of the stroke of the piston, and consequently in feet;
P, The *total* or *absolute* pressure of the steam in the boiler, in pounds per square foot;
p, The atmospheric pressure, expressed in pounds per square foot; finally,
S, The *effective* vaporization of the engine, in cubic feet of water per hour, at the velocity known or unknown of the motion;

$$R = (1 + \delta)\left[(k \pm g) M \pm g m + u v^2\right] \frac{D}{d^2 l} + \frac{D F}{d^2 l} + p + p' v,$$

will be the pressure of the steam per unit of surface in the cylinder.

On the other hand, if we express by μ the relative volume of the steam generated under the pressure R, a relative volume which will be found in the tables given, p. 230, since S is the volume of water vaporized per hour in the engine, it follows that

$$\mu S$$

will be the corresponding volume of the steam under the pressure R; that is to say, during its action in the cylinders.

But, expressing by π the ratio of the circumference to the diameter, the capacity of each cylinder which is traversed by the piston, has for its measure

$$\tfrac{1}{4} \pi d^2 l;$$

and the clearance of the cylinder offers, besides, a capacity of

$$\tfrac{1}{4} \pi d^2 c.$$

Therefore the totality of the space filled with steam at each stroke, in each cylinder, has for its expression

$$\tfrac{1}{4} \pi d^2 (l + c).$$

Consequently the number of strokes of the piston corresponding to the volume of steam expended μ S, will be

$$\frac{\mu S}{\frac{1}{4} \pi d^2 (l + c)}.$$

But, while each piston performs 2 strokes, that is, at every expenditure of 4 cylinders-full of steam, the engine advances 1 turn of the wheel, that is to say, a space represented by

$$\pi D.$$

Therefore the velocity of the engine, in feet per hour, will be expressed by the above number of strokes, divided by 4 and multiplied by π D; that is to say, the velocity will be

$$V = \frac{\mu S}{d^2} \cdot \frac{D}{l + c}.$$

And finally, as 1 mile contains 5280 feet, the velocity of the engine expressed in miles per hour, will be

$$v = \frac{1}{5280} \cdot \frac{\mu S}{d^2} \cdot \frac{D}{l + c} \cdot \quad \ldots \ldots \quad (1)$$

This expression will make known the velocity required, on substituting, for each of the letters, the value suitable to it in the engine considered.

As it has been shown that the relative volume of the steam under the pressure R, may be expressed by

$$\frac{1}{n+q\,\mathrm{R}},$$

it is plain that, instead of seeking the relative volume μ in the table which we have given, its value may be represented by the expression

$$\mu=\frac{1}{n+q\,\mathrm{R}}=\frac{1}{n+q\left\{(+\delta)\left[(k\pm g)\,\mathrm{M}\pm g\,m+u\,v^2\right]\frac{\mathrm{D}}{d^2\,l}+\frac{\mathrm{D\,F}}{d^2\,l}+p+p'\,v\right\}}$$

and consequently the preceding expression of the velocity of the engine may equally be written under the form

$$v=\frac{1}{5280}\cdot\frac{1}{q}\cdot\frac{l}{l+c}\cdot\frac{\mathrm{S}}{(1+\delta)\left[(k\pm g)\,\mathrm{M}\pm g\,m+u\,v^2\right]+\mathrm{F}+\frac{d^2\,l}{\mathrm{D}}\left(\frac{n}{q}+p+p'\,v\right)}\cdots\cdots(1\text{ bis})$$

Such then will be the general expression of the velocity of the engine, in miles per hour; an expression in which all is known from measures taken on the engine, even the vaporization S, which results from the extent of heating surface.

Making use of this formula to find the velocities corresponding to divers loads of the engine, or to divers values of M, attention must be paid never to suppose, for M, a load capable of producing on the piston a resistance greater than the pressure of the steam in the boiler, because it is evident that the resistance would then exceed the power, and the motion could not take place. Nor can M be supposed of a value less than the weight of the tender, which is the *minimum* load an engine can have to draw. Beyond these two limits the solutions given by the formula would evidently cease to suit the problem.

Practical formulæ for calculating the effects of locomotive engines, and examples of their application.— We have hitherto presented the formulæ proper for calculating the effects of the engines, under a form completely algebraical, that is to say, leaving in them all the quantities represented by letters, without excepting the constant quantities whose values have been already determined in former pages. But we now purpose to reduce these formulæ to their most simple practical form; in order to effect which, it will be proper to replace in them, as far as may be, the letters, by the numerical values which they represent.

The letters which have a constant value in all cases and for all the engines are—

k, Friction of the wagons, which we have found equal to 6 lbs. per ton;
p, Atmospheric pressure, the value of which is 2118 lbs. per square foot;
n, Constant quantity relative to the volume of the steam, its value being ·0001421, when the pressure is measured in pounds per square foot;
q, Factor relative to the volume of the steam, equal to ·00000023 when the pressure is expressed in pounds per square foot;
c, Clearance of the cylinder, which may be taken generally at $\frac{1}{20}$ of the useful stroke of the piston, which gives $\frac{l}{l+c}=\frac{20}{21}$.

These values being constant for all engines, may be introduced permanently into the equations. Substituting them therefore for the respective letters, and effecting the calculation as much as possible, we obtain the following formulæ, which are quite prepared for practical applications.

In order to avoid recurring to another page of the work, we will first repeat here the signification of all the letters which subsist in these formulæ.

M, Load of the engine, in tons gross, tender included;
m, Weight of the engine, in tons;
C, Weight of the tender, in tons;
g, Gravity, in pounds, of 1 ton placed on the inclined plane to be traversed by the engine. If the inclination of the plane be $\frac{1}{e}$, that gravity will have for its value, in pounds, $\frac{2240}{e}$; and if the plane be horizontal, the gravity will be equal to zero;
v, Velocity of the engine, expressed in miles per hour;
$u\,v^2$, Resistance of the air against the train, at the velocity v, a resistance expressed in pounds;
$p'\,v$, Pressure owing to the blast-pipe, expressed in pounds per square foot;
F, Friction of the engine, in pounds;
δ, Additional friction of the engine, measured as a fraction of the resistance, namely: ·14 for engines with uncoupled wheels, and ·22 for those with coupled wheels;
D, Diameter of the propelling wheels, in feet;
d, Diameter of the cylinder, in feet;
l, Stroke of the piston, in feet;
P, *Total* or absolute pressure of the steam in the boiler, in pounds per square foot;
S, Effective vaporization of the engine, in cubic feet of water per hour. It varies according to the engines, but may, on an average, be valued at ·75 of the total or gross vaporization, when there is no blowing of steam at the valves;
S′, Total vaporization of the boiler, at the velocity of the motion, in cubic feet of water per hour·
N, Consumption of coke in the fire-box, in pounds per hour.

PRACTICAL FORMULÆ FOR CALCULATING THE EFFECTS OF LOCOMOTIVE ENGINES.

General case.

$$v = \frac{784\,S}{(1+\delta)\,[(6 \pm g)\,M \pm g\,m + u\,v^2] + F + \frac{d^2\,l}{D}\,(2736 + p'\,v)} =$$

Velocity of the engine, in miles per hour.

$$M = \frac{1}{(1+\delta)\,(6 \pm g)}\left[784\,\frac{S}{v} - \frac{d^2\,l}{D}\,(2736 + p'\,v) - F\right] - \frac{1}{6 \pm g}\,(u\,v^2 \pm g\,m) =$$

Load of the engine, in tons gross, tender included.

$$\text{u. E.} \ldots\ldots\ldots\ldots = M\,v =$$

Useful effect, in tons gross, drawn 1 mile per hour, tender included.

$$\text{u. E. in H P} \ldots\ldots\ldots\ldots = \frac{M\,v}{62{\cdot}5} =$$

Useful effect, in horse-power.

$$\text{Q. co. pr. t. pr. M} \ldots\ldots\ldots\ldots = \frac{N}{M\,v - C\,v} =$$

Quantity of coke in pounds, per ton gross drawn 1 mile, tender *not* included.

$$\text{Q. wa. pr. t. pr. m} \ldots\ldots\ldots\ldots = \frac{S'}{M\,v - C\,v} =$$

Quantity of water, in cubic feet, per ton gross drawn 1 mile, tender *not* included.

$$\text{u. E. 1 lb. co} \ldots\ldots\ldots\ldots = \frac{M\,v}{N} =$$

Useful effect produced per pound of coke, in tons gross drawn 1 mile, tender included.

$$\text{u. E. 1 ft. wa} \ldots\ldots\ldots\ldots = \frac{M\,v}{S'} =$$

Useful effect produced per cubic foot of total vaporization, in tons gross drawn 1 mile, tender included

$$\text{Q. co. fr. 1 H P} \ldots\ldots\ldots\ldots = \frac{62{\cdot}5\,N}{M\,v} =$$

Quantity of coke in pounds, which produces the effect of 1 horse.

$$\text{Q. wa. fr. 1 H P} \ldots\ldots\ldots\ldots = \frac{62{\cdot}5\,S}{M\,v} =$$

Quantity of water, in cubic feet, which produces the effect of 1 horse.

$$\text{u. E. 1 lb. co. in H P} \ldots\ldots\ldots\ldots = \frac{M\,v}{62{\cdot}5\,N} =$$

Useful effect, in horse-power, produced per pound of coke.

$$\text{u. E. 1 ft. wa. in H P} \ldots\ldots\ldots\ldots = \frac{M\,v}{62{\cdot}5\,S'} =$$

Useful effect, in horse-power, produced per cubic foot of *total* vaporization.

Case of maximum useful effect.

$$v' = \frac{1{\cdot}804}{1{\cdot}421 + {\cdot}0023\,P} \cdot \frac{D}{l} \cdot \frac{S}{d^2} =$$

Velocity of maximum useful effect, in miles per hour.

$$M' = \frac{d^2\,l}{(1+\delta)\,(6 \pm g)\,D}\,(P - 2118 - p'\,v') - \frac{1}{6 \pm g}\left(\frac{F}{1+\delta} + u\,v'^2 \pm g\,m\right) =$$

Maximum load of the engine, in tons gross, tender included.

$$\text{M. u. E} \ldots\ldots\ldots\ldots = M'\,v' =$$

Maximum useful effect, in tons gross drawn 1 mile per hour, tender included.

That there may be no misunderstanding as to the manner of expressing the divers quantities contained in the formulæ, nor on the manner of performing the calculation, we will here give an example or two with some detail.

Suppose a locomotive of 65 cubic feet of total vaporization, at the velocity of 20 miles per hour; with cylinders 11 inches or ·917 foot in diameter, stroke of the piston 16 inches or 1·33 foot, wheels 5 feet in diameter, not coupled, friction 103 lbs., weight 8 tons, blast-pipe 2·33 inches in diameter, *total* or absolute pressure in the boiler 65 lbs. per square inch, and consumption of coke per hour 598 lbs. Suppose this engine employed on a level railway, of about 5 feet of width of way, and let it be required tc

know what velocity it will attain with a train of 10 wagons weighing 56 tons, tender included, which is the same as 50 tons without tender.

1st. As the motion takes place on a horizontal plane, we have $g=0$; and since the wheels of the engine are not coupled, we have $\delta = \cdot 14 = \frac{1}{7}$. Moreover, from the ratio which we have found between the total and the effective vaporization of the engine, the value of the latter, at 20 miles per hour, is

$$S = \cdot 75 \times 65 = 48\cdot 75 \text{ cubic feet of water per hour;}$$

and in fine, from the proportions of the engine, we have

$$\frac{d^2 l}{D} = \overline{\cdot 917}^2 \times \frac{1\cdot 33}{5} = \cdot 2237.$$

This done, to find what velocity the engine will acquire in drawing the train of 56 tons, we will first suppose that it may be, approximatively, 23 miles per hour, and we shall then have, for the pressure in the blast-pipe, 4 lbs. per square inch, or $p' v = 576$ lbs. per square foot. As the effective surface presented to the shock of the air, valued according to the mode already explained, is $\Sigma = 70 + 10 \times 12 = 190$ square feet, the resistance of the air at the velocity of 23 miles per hour, will be $u v^2 = 270$.

Thus the value of v, taken without supposing that the vaporization changes with the velocity, will be

$$v = \frac{784 \times 48\cdot 75}{1\cdot 14\,(6 \times 56 + 270) + 103 + \cdot 2237\,(2736 + 576)} = 24\cdot 88.$$

This first essay of calculation gives then 24·88 miles per hour, for the velocity of the engine, and we conclude from it that the two terms $u v^2$ and $p' v$ which we have calculated on the supposition of $v = 23$, have not been valued in a manner sufficiently exact, but that the true velocity is comprised between 24·88 and 23 miles.

Trial then might be made of $v = 24$, and this value would be found to satisfy the problem, when the variation which the vaporization undergoes with the velocity of the motion is neglected. Thus approximatively we might hold to this result; but if it be desired to calculate with greater accuracy, it will be proper to introduce the increase of vaporization due to the velocity.

For this purpose, as the increase of vaporization will have the effect of increasing the result of the calculation, we will try a number greater than 24, as $v = 25$, for instance. Supposing then this datum for the valuation of the variable quantities, we shall have

$$S = 51\cdot 55,$$
$$p' v = 630,$$
$$u v^2 = 319;$$

and resolving the equation with these values we find

$$v = 25\cdot 19.$$

Consequently, in fine, taking a mean between 25 and 25·19, we have, for the definitive velocity sought,

$$v = 25\cdot 10 \text{ miles per hour.}$$

Such then will be the velocity which the engine will assume, when drawing on a level a train of 56 tons, tender included.

2d. To continue this example of the application of the formulæ, let it be required to find what will be the velocity of the maximum useful effect of the engine.

In order to effect this, we will replace in the equation proper to that problem, the pressure P in the boiler by its value $P = 65 \times 144 = 9360$ lbs. per square foot; and supposing first that the vaporization of the engine will undergo no change notwithstanding the reduction of velocity, we obtain the result

$$v' = \frac{1\cdot 804 \times 48\cdot 75}{1\cdot 421 + \cdot 0023 \times 9360} \cdot \frac{1}{\cdot 2237} = 17\cdot 13.$$

This would then be the velocity sought, if the vaporization of the engine were invariable; but as the diminution of velocity will lower the vaporization, which is such as we have supposed it, only at the velocity of 20 miles per hour, we will try whether the velocity of 16 miles will suit the formula. Then the effective vaporization of the engine, reduced in the proportion of the fourth roots of the velocities, will become 46·10 cubic feet of water per hour, and the formula resolved according to this supposition, will give

$$v' = 16\cdot 20 \text{ miles per hour.}$$

This is therefore the velocity suitable to the production of the maximum useful effect required.

3d. In fine, to obtain the load corresponding to the maximum of useful effect, we recur to the proper equation, which is

$$M' = \frac{d^2 l}{D} \cdot \frac{1}{6\,(1+\delta)}\,(P - 2118 - p' v') - \frac{F}{6\,(1+\delta)} - \frac{u v'^2}{6};$$

and first calculating in this all the terms, except the last, we have as a result 208·46.

It remains then to subtract from this number the value of $\frac{u v'^2}{6}$, to conclude from it definitively the required value of the load. As the value of the term $\frac{u v'^2}{6}$ depends on the number of carriages in the train, which will itself be known only by the definitive solution of the problem, we will again in this place follow the method of approximations. Supposing the load to be of about 160 tons, the train will consist of 31 carriages besides the tender; thus the effective surface offered to the shock of the air, will be

$$\Sigma = 70 + 33 \times 10 = 400 \text{ square feet.}$$

Consequently the resistance of the air, at the velocity found, of 16·20 miles per hour, will be $u v'^2 = 282$ lbs., which gives

$$\frac{u v'^2}{6} = 47{\cdot}00\,;$$

substituting then this valuation in the formula, we obtain the result

$$M' = 208{\cdot}46 - 47{\cdot}00 = 161{\cdot}46.$$

Consequently the load of 161·5 tons, forming a train of 31 carriages, besides the tender, will be the maximum load required.

4th. In fine, if it be desired to know the maximum velocity the engine is capable of attaining, when followed by its tender only, and without drawing any train, the proceeding will be as in the first case; but supposing the load to be of 6 tons only, and taking account of the increase of vaporization, according to the velocity, the result will be

$$v = 35{\cdot}03 \text{ miles per hour.}$$

In this last case, the useful effect of the engine, *tender not included*, will be null.

From these detailed examples is seen how the calculation is to be performed in all the cases; but it must be remarked, that with the use of logarithms, these different trials present no sort of difficulty, and that those who have once got the habit of these researches, guess immediately and at a glance, what numbers they ought to employ in the approximations, so that the apparent length of the calculation entirely disappears.

Collecting the results which we have just obtained, calculating moreover the useful effect of the engine, and expressing it under the different forms already indicated, we form the following Table:

Effects of a locomotive of 65 *cubic feet of vaporization, with a load of* 56 *tons gross, on a level, tender included.*

M .... = 56 tons gross, tender included, (10 carriages and the tender;)
v .... = 25·10 miles per hour;
u. E. .... = 1411 tons gross drawn 1 mile per hour, tender included;
u. E. in H P. .... = 23 horses;
Q. co. pr. t. pr. m. .... = ·47 lb. per ton gross per mile, tender *not* included;
Q. wa. pr. t. pr. m. ... = ·052 cubic foot per ton gross per mile, tender *not* included;
u. E. 1 lb. co. .... = 2·36 tons gross drawn 1 mile, tender included;
u. E. 1 ft. wa. .... = 21·70 tons gross drawn 1 mile, tender included·
Q. co. fr. 1 H P. ...... = 26·50 lbs.;
Q. wa. fr. 1 H P. .... = 2·880 cubic feet;
u. E. 1 lb. co. in H P. = ·038 horse;
u. E. 1 ft. wa. in H P. = ·347 horse.

Maxima effects of the same engine.

M′ .... = 161·5 tons gross, tender included, (31 carriages and tender;)
v' .... = 16·20 miles per hour;
u. E. .... = 2616 tons gross drawn 1 mile per hour, tender included;
u. E. in H P. .... = 42 horses;
Q. co. pr. t. pr. m. ... = ·24 lb. per ton gross per mile, tender *not* included;
Q. wa. pr. t. pr. m. ... = ·026 cubic foot per ton gross per mile, tender *not* included;
u. E. 1 lb. co. .... = 4·38 tons gross drawn 1 mile, tender included;
u. E. 1 ft. wa. .... = 40·25 tons gross drawn 1 mile, tender included;
Q. co. fr. 1 H P. ...... = 14·29 lbs.
Q. wa. fr. 1 H P. ...... = 1·553 cubic foot;
u. E. 1 lb. co. in H P. = ·070 horse;
u. E. 1 ft. wa. in H P. = ·644 horse.

To give a second example of this calculation, we will suppose the railway to have 7 feet of width of way, and seek what will be the velocity of the engines of medium force, in use on such a line, under the same circumstances as we have just examined relatively to a railway of about 5 feet of width of way.

We will suppose then a locomotive of 120 cubic feet of vaporization, at the velocity of 25 miles per hour, with the following proportions: cylinders, 14 inches or 1·17 foot in diameter; stroke of the piston, 16 inches or 1·33 foot; wheels, 8 feet in diameter, not coupled; weight, 18 tons; friction, 270 lbs.; blast-pipe, 3·14 inches in diameter; total or absolute pressure in the boiler, 80 lbs. per square inch; and consumption of coke in the same time, 1050 lbs. or 8·75 lbs. per cubic foot of water vaporized. Moreover, by reason of the width of the way, we will take the surface of the largest wagon of the train at 100 square feet, the average surface of a wagon at 56 square feet, and the weight of the tender at 10 tons.

Seeking then by the same calculation as before, what effects this engine is capable of producing, first in drawing a train of 60 tons gross, tender included, which makes 50 tons without the tender and afterwards in drawing its maximum load, we obtain the following results:

Effects of a locomotive of 120 cubic feet of vaporization, with a load of 60 tons gross, tender included

M .... = 60 tons gross, tender included, (7 carriages and the tender;)
v .... = 34·75 miles per hour;
u. E. .... = 2085 tons gross drawn 1 mile per hour, tender included;
u. E. in H P. .... = 33 horses;
Q. co. pr. t. pr. m. ... = ·60 lb. per ton gross per mile, tender *not* included;
Q. wa. pr. t. pr. m. ... = ·069 cubic foot per ton gross per mile, tender *not* included;
u. E. 1 lb. co. .... = 1·99 ton gross drawn 1 mile, tender included;
u. E. 1 ft. wa. .... = 17·38 tons gross drawn 1 mile, tender included;
Q. co. fr. 1 H P. ...... = 31·48 lbs.;
Q. wa. fr. 1 H P. .... = 3·597 cubic feet;
u. E. 1 lb. co. in H P. = ·032 horse;
u. E. 1 ft. wa. in H P. = ·278 horse.

Maxima effects of the same engine.

M′ .... = 147 tons gross, tender included, (20 carriages and the tender;)
v' .... = 25·55 miles per hour;
u. E. .... = 3756 tons gross drawn 1 mile per hour, tender included;
u. E. in H P. .... = 60 horses;
Q. co. pr. t. pr. m. ... = ·30 lb. per ton gross per mile, tender *not* included;
Q. wa. pr. t. pr. m. ... = ·034 cubic foot per ton gross per mile, tender *not* included;
u. E. 1 lb. co. .... = 3·58 tons gross drawn 1 mile, tender included;
u. E. 1 ft. wa. .... = 31·30 tons gross drawn 1 mile, tender included;
Q. co. fr. 1 H P. ...... = 17·47 lbs.;
Q. wa. fr. 1 H P. .... = 1·997 cubic foot;
u. E. 1 lb. co. in H P. = ·057 horse;
u. E. 1 ft. wa. in H P. = ·501 horse.

The velocity of the same engine, drawing its tender alone, would be 43·28 miles per hour; which would be the maximum of velocity that this engine could attain.

It is visible, in these examples, that the above formulæ present no difficulty, and that it is merely necessary to preserve in them the homogeneity of the measures employed.

Practical formulæ, to determine the proportions of locomotive engines, according to given conditions.— We will here give, in their numerical form, all the formulæ which are essential for determining the proportions of the engines, according to given conditions. For the signification of the signs employed, we refer to page 243 of this volume.

PRACTICAL FORMULÆ TO DETERMINE THE PROPORTIONS OF LOCOMOTIVE ENGINES, NECESSARY TO PRODUCE GIVEN EFFECTS.

$$S=\frac{(1+\delta)v}{784}\left[(6\pm g)M\pm gm+uv^2+\frac{F}{1+\delta}+\frac{1}{1+\delta}\cdot\frac{d^2 l}{D}(2736+p'v)\right]=$$

Total vaporization of the boiler, in cubic feet of water per hour.

$$d^2=\frac{D}{l}\cdot\frac{1+\delta}{2736+p'v}\left[\frac{784}{1+\delta}\cdot\frac{S}{v}-(6\pm g)M\mp gm-uv^2-\frac{F}{1+\delta}\right]=$$

Square of the diameter of the cylinder, in feet.

$$l=\frac{D}{d^2}\cdot\frac{1+\delta}{2736+p'v}\left[\frac{784}{1+\delta}\cdot\frac{S}{v}-(6\pm g)M\mp gm-uv^2-\frac{F}{1+\delta}\right]=$$

Stroke of the piston, in feet.

$$D=\frac{d^2 l}{1+\delta}\cdot\frac{2736+p'v}{\frac{784}{1+\delta}\cdot\frac{S}{v}-(6\pm g)M\mp gm-uv^2-\frac{F}{1+\delta}}=$$

Diameter of the wheel, in feet.

$$S=\frac{1}{784}\cdot\frac{d^2 l}{D}\cdot v\,(618+P)=$$

Total vaporization of the boiler, in cubic feet of water per hour.

$$P=(1+\delta)\frac{D}{d^2 l}\left[(6\pm g)M\pm gm+uv'^2+\frac{F}{1+\delta}\right]+2118+p'v'=$$

Total or absolute pressure of the steam in the boiler, in pounds per square foot.

$$P=784\frac{D}{d^2 l}\cdot\frac{S}{v'}-618=$$

Total or absolute pressure of the steam in the boiler, in pounds per square foot.

$$d^2=784\frac{D}{l}\cdot\frac{S}{v'}\cdot\frac{1}{618+P}=$$

Square of the diameter of the cylinder, in feet.

$$l = 784 \frac{D}{d^2} \cdot \frac{S}{v'} \cdot \frac{1}{618 + P} =$$

Stroke of the piston, in feet

$$D = \frac{1}{784} \cdot d^2 l \cdot \frac{v'}{S} (618 + P) =$$

Diameter of the wheel, in feet.

$$d^2 = (1 + \delta) \frac{D}{l} \cdot \frac{(6 \pm g) M' \pm g m + u v'^2 + \frac{F}{1 + \delta}}{P - 2118 - p' v'} =$$

Square of the diameter of the cylinder, in feet.

$$l = (1 + \delta) \frac{D}{d^2} \cdot \frac{(6 \pm g) M' \pm g m + u v'^2 + \frac{F}{1 + \delta}}{P - 2118 - p' v'} =$$

Stroke of the piston, in feet.

$$D = \frac{d^2 l}{1 + \delta} \cdot \frac{P - 2118 - p' v'}{(6 \pm g) M' \pm g m + u v'^2 + \frac{F}{1 + \delta}} =$$

Diameter of the wheel, in feet.

Of adhesion.—It has been observed, in the description of the engine, that the effort of the steam being applied to the wheel, the engine is precisely in the case of a carriage which is made to advance by pushing at the spokes. Thus, as in this action the only fulcrum of the mover is the adhesion of the wheel to the rails, if that adhesion were insufficient, the force of the steam would indeed make the wheels turn; but these, sliding on the rails instead of adhering to them, would turn without advancing, and the engine would remain on the same spot.

The heavier the train to be drawn, the more force the engine must employ, and the more resistance it must consequently meet with at the point on which it strains to effect the motion. It might then be feared that with trains of considerable weight, the engines would be unable to advance; not that force would be wanting in the mover itself, but in the fulcrum of the mover.

Adhesion being indispensable to the creation of the progressive motion, two conditions are requisite for an engine to be capable of drawing a given load: 1st, the dimensions and proportions of the engine and its boiler must enable it to produce, by means of the steam, the necessary pressure on the piston, which constitutes the force applied by the engine; and 2d, the weight of the engine must be such as to cause a sufficient adhesion to the rails. These two conditions of force and weight should accord together; for, were there a great force of steam and a slight adhesion, the latter would limit the effect of the engine, and steam would be lost; and were there too much adhesive weight for the power of the engine, that weight would, during the motion, become a useless burden, since the limit of the load would then be marked by the pressure of the steam.

It is necessary therefore, after having determined the dimensions of the engines from the conditions which they are to fulfil, as has been done in the preceding pages, to seek what ought to be their weight so as to enable them to draw the greatest load intended to be imposed on them during their work. The enormous weight now given to locomotive engines, generally causes this condition to be fulfilled of itself. Six-wheel engines however require, in this respect, more attention than four-wheel engines, because it often happens, on an uneven railway, that a six-wheel engine is wholly supported on its four extreme wheels, whereas the middle ones, which are the propelling wheels, being accidentally situated immediately above a low part of the railway, scarcely touch the rail, and therefore have but a slight adhesion. In the best state of the rails the adhesion which is the limit of the traction of an engine, may be taken at $\frac{1}{6}$ of the weight on the driver, and it is never less than $\frac{1}{20}$ in the worst state of the rails, when they are greasy and dirty from the effect of wet weather.

For the preceding calculations and formulæ we are indebted to M. Pambour, whose works on the steam-engine, both locomotive and stationary, should be in the hands of every engineer and machinist, and to which we refer for a more complete elucidation of the laws which govern the motion of this wonderful machine.

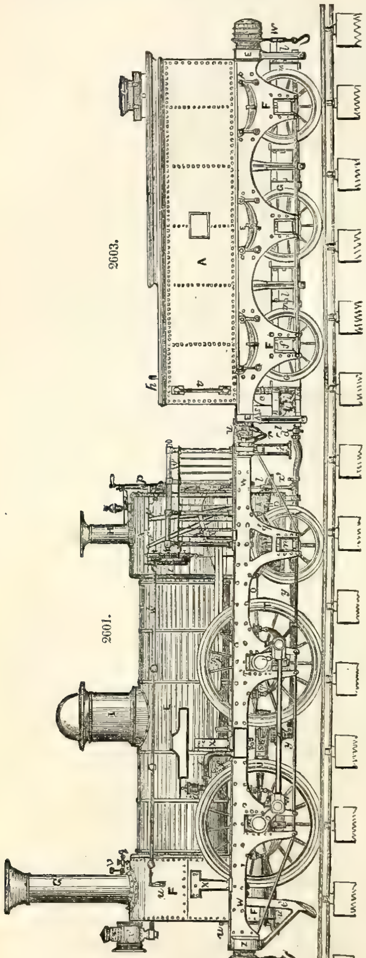
Locomotive engine and tender.—The example which we have chosen for detailed illustration is the form of locomotive engine and tender at present constructed by Messrs. Hawthorn, of Newcastle, England, a firm whose success and extensive employment in this branch of the trade is a sufficient guarantee for the excellence of their arrangements. In these figures are embodied all the most recent improvements which Messrs. Hawthorn have introduced into their engine, including their patent auxiliary expansion-frame, and the mechanism by which it is moved.

The engine is made, according to the method generally adopted by Messrs. Hawthorn, with a cranked axle and outside bearings; it is furnished with six wheels, (designated a six-wheeled engine;) the driving and fore wheels, which are five feet in diameter, are coupled together, and the hind-wheels, three feet diameter, are placed immediately below the fire-box. By this arrangement the greatest safety is insured, and particularly at high speeds; the same amount of stability being given to the engine as if the hind-wheels were placed *behind* the fire-box, with this additional advantage, that the length of coupling between the wheels may by the present disposition, be regulated to any convenient distance. An engine of this description will be found exceedingly useful for general purposes, being adapted both for merchandise and for mixed or passenger trains at ordinary speeds; while for express or special

trains, where a high rate of speed is required, railway travelling would be rendered comparatively safe by employing engines specially made and adapted for such purposes.

Enumeration of the figures.—Fig. 2601, a longitudinal elevation of the locomotive engine.

Fig. 2602, a general plan of the same.



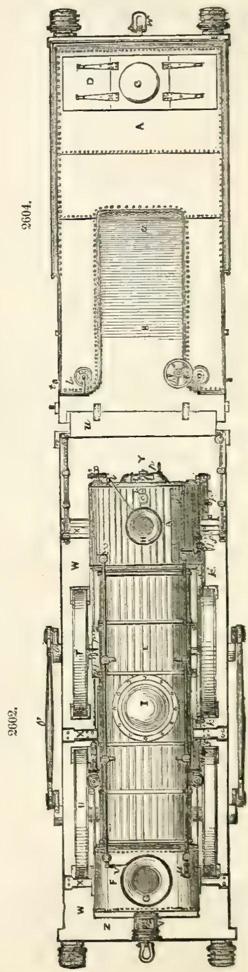


Fig. 2603, a longitudinal elevation of the tender, showing the mode of its connection with the engine.

Fig. 2604, a general plan of the tender, in which are seen the cocks for regulating the supply of water to the boiler, and the hand-wheel for working the brake apparatus.

The following four figures are sectional views.

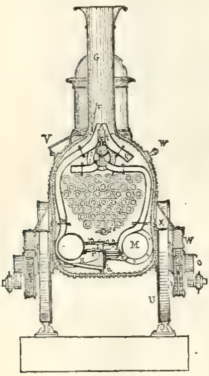
Description of the engine.—The fire-box.—The first part of the engine which claims our attention is the fire-box. The form of fire-box which Messrs. Hawthorn have adopted is clearly shown in the end elevation, Fig. 2609, and transverse section, Fig. 2610. It consists of two parts: the external fire-box A, which in reality forms part of the boiler, being filled with water to about fifteen inches from the top; and the internal fire-box B, placed within the other, and which contains the fuel for generating steam. The internal fire-box is made of copper, and tapered slightly towards the top, for the purpose of allowing the globules of steam which are formed on its sides to ascend more freely. To resist the downward pressure of the steam, the roof is strengthened by the strong malleable-iron stays C C bolted across, and having a bearing against its sides, while both external and internal fire-boxes are secured against the lateral strain by having numerous iron stay-bolts *a a a* screwed through both boxes, and riveted at each end. The fire-door *b* affords access to the internal fire-box for the admission of coke. It is of an oval form, and the latch is provided with a chain for the greater convenience of opening and shutting. The space between the two fire-boxes at that part where the fire-door is situated is filled by an oval-shaped frame, securely riveted through both, and the fire-door itself is furnished with a plate of iron riveted to the inside at some little distance from it, to save it from warping by the intensity of the heat within. The fire-bars *c c* distinctly shown in the section Fig. 2605, and in the plan Fig. 2606, are ranged parallel

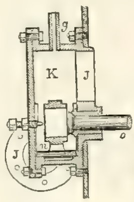
to each other on a wrought-iron frame fixed to the under side of the fire-box, and a portion of them marked *d* in the plan, is so arranged as to admit of their falling at one end on the removal of the pin which supports them. In this case the burning fuel drops into the ash-box D fixed below to receive it and the combustion almost immediately ceases.

The boiler.—As before remarked, the external fire-box A forms part of the boiler, communicating freely with it, and being, like it, filled with water to the proper height when the engine is in operation. The boiler, properly so called, is marked E in the figures, and in the specimen now under notice consists of a cylinder 11 feet 6 inches in length, and 3 feet $6\frac{5}{8}$ inches in diameter outside. It is traversed throughout its length by 107 brass tubes *e e e*, $2\frac{1}{8}$ inches outside diameter, of No. 13 and 14 wire gage.

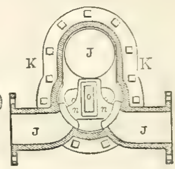
2612.



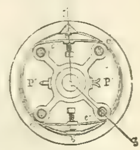
2614.



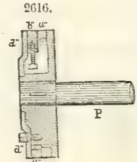
2613.



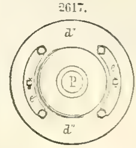
2615.



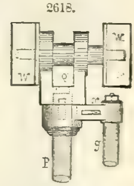
2616.



2617.

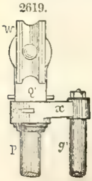


2618.

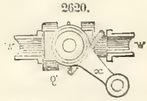


These tubes are inserted into the front plate of the internal fire-box, (called the *tube-plate,*) which is made of a sheet of copper considerably thicker than the other plates of which the fire-box is composed, so as to afford a better bearing for the fixing of the tubes. At the front extremity of the boiler, they pass through a similar plate of iron, which forms the partition between the boiler and the smoke-box. Into these plates the tubes are secured at both ends by riveting, and subsequently by strong steel ferrules accurately turned, and driven firmly into the interior of the tubes, so as to render them perfectly tight and free from leakage. The cylindrical form of the boiler renders lateral staying unnecessary, and the tubes themselves, at that part where they are situated, secure it against the pressure in a longitudinal direction; but for further safety, three strong malleable-iron stay-bolts *f f f* traverse the whole length of the boiler, and are secured to it by round pins passing through brackets riveted to the front tube-plate, and to the back plate of the external fire-box. The whole boiler is covered externally with a coating of thick felt and with strips of wood, called the *lagging*, or *cleading*, to prevent the radiation of heat, as well as to give greater symmetry of appearance.

2619.

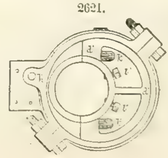


2620.



2622.

2621.



2624.

2623.

The smoke-box.—The tubes *e e e* all open into that part of the boiler called the smoke-box F, the purpose of which is to collect the gases evolved by the combustion of the fuel, and to transmit them through the chimney G into the air. In this compartment of the boiler are also placed the steam cylinders, and other very important parts of the engine, to be hereafter described. The front plate of the smoke-box is furnished with large folding-doors *g g*, fitted air-tight to it, and provided with a handle, by which both doors are simultaneously shut and opened. These doors, which are distinctly shown in the end elevation, Fig. 2611, and in the section, Fig. 2605, serve to afford access for the insertion and cleaning of the tubes, as well as for the examination and repair of the parts of the engine referred to above.

The safety-valves and boiler mountings.—Although the efficient working of the engine requires that the boiler be capable of generating steam of a high elastic force, it is yet essential to safety that the steam pressure be confined within certain limits. In order to insure this, the boiler is provided with

two safety-valves, *h* and *i*, both placed in one chest, (Fig. 2629,) fixed on the summit of the external fire-box, and surrounded by a polished brass chimney H, of a form symmetrical with that of the large chimney G. One of these valves, marked *i*, which is of the kind called the *lever safety-valve*, can be regulated to any required degree of pressure by the engine-driver, being furnished with a *spring-balance*, by which the amount of pressure is distinctly indicated. The other safety-valve *h* is inaccessible, and is loaded by a spiral spring and screws, to such a pressure as may be considered safe, yet higher than the engine is expected, under ordinary circumstances, to require.

2626.

To indicate the height at which the water stands in the boiler, and to enable the driver to keep it always at its proper level, a set of gage-cocks and glass tube *j*, communicating with the water inside, are fixed at a convenient situation near the foot-plate. A graduated scale is fixed behind the glass tube, and the required level may thus be maintained with considerable accuracy.

As a precaution against accidents, and to give notice of the approach of the engine, a steam whistle *k* is attached to the top of the fire-box, and communicates with the steam within by a short pipe, provided with a stop-cock. The internal construction of the whistle is such, that when the stop-cock is opened, the steam rushing out with great force encounters the sharp edges of a species of inverted cup, thereby emitting a shrill and very loud noise, which can be heard at the distance of several miles.

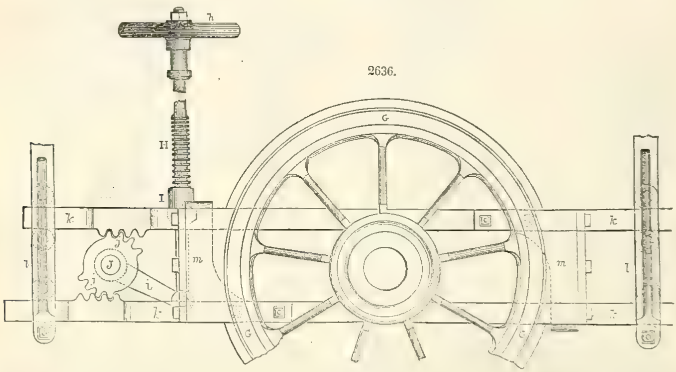
2638.

Behind, and at the lowest extremity of the fire-box, is situated the *blow-off cock l*, by which the boiler may be emptied of water when required; and, for the purpose of cleansing it of the accumulation of sediment which is constantly being formed in it when the engine is in operation, it is provided with *mud-holes* both at fire-box and smoke-box ends. These mud-holes, which are shown in Figs. 2609 and

2612, are secured when the engine is at work, by covers or *doors* bearing against the inside of the boiler and fixed each by a single bolt passing through a strong wrought-iron bridge bearing against the outside

The steam-pipes and regulator-valve.—The steam-chest or receiver I rises from the centre of the cylindrical part of the boiler, and is carried to a considerable height above it, in order that the mouth of the steam-pipe J, which opens into it, may be removed to as great a height as can conveniently be obtained, from the surface of the water in the boiler. The object of thus raising the open orifice of the steam-pipe is to prevent *priming*, that is, the ascent of water along with the steam, and its consequent flow through the steam-pipe into the cylinders, where its presence in any considerable quantity would produce the most serious inconveniences, besides the danger to which the boiler would be exposed by its rapid abstraction. As a further precaution against priming, Messrs. Hawthorn make use of a simple but very ingenious contrivance. This consists of a species of inverted cone *m*, Fig. 2605, made of sheet-iron, and riveted to the interior of the steam-chest, with an aperture in the centre just wide enough to allow the free ascent of the steam between it and the steam-pipe, which passes through it. The water in the boiler tends to prime chiefly where there is a surface of metal to which it may adhere; consequently, when, in rising up the sides of the steam-chest, it encounters the inverted cone *m*, its course is diverted downwards and towards the centre, where being unsupported it falls back into the boiler. Should any priming occur round the sides of the steam-pipe itself, the water is, in a somewhat analogous way, diverted by the bell-shaped mouth of the pipe, and returned into the boiler. The steam-receiver is surrounded by a polished brass dome, which, besides being highly ornamental to the engine, serves the very important purpose of diminishing the radiation of heat, by interposing a stratum of heated air between the steam-chest and the external atmosphere.

2636.



The steam-pipe J is made of copper, and that part of it which is inclosed within the boiler is 5¼ inches internal diameter. It enters an orifice accurately bored and fitted to receive it, in the cast-iron *regulator-valve chest* K, which is bolted steam-tight to the exterior of the front tube-plate of the boiler. The valve-chest K incloses a regulator-valve *n*, of a new and improved form, which, as well as the chest itself, is shown on an enlarged scale in Figs. 2613, 2614. It is formed of cast-iron, and has two projecting faces accurately and smoothly turned, and of such form and dimensions as, when placed in the position shown in Fig. 2613, completely to cover the orifices of the two branch steam-pipes J J, whose faces are bored truly cylindrical, and of the same diameter as that of the faces of the valve. The distance between the contiguous edges of the two branch-pipes is somewhat greater than the breadth of the valve face, so that when turned round in either direction, the orifices of both pipes may be fully opened. In the centre of rotation of the valve is an oblong hole, into which is fixed the correspondingly formed end of a long rod *o o*, traversing the whole length of the boiler, and passing steam-tight through a stuffing-box in the back plate of the fire-box. A long lever-handle *p*, is fixed to the outer extremity of this rod, and the engine-driver is thereby enabled, with the greatest ease and precision, to regulate the supply of steam to the cylinders. A small pipe *q*, screwed into the upper part of the regulator-valve chest, rises through the smoke-box, and is surmounted by a cup, and provided with a stop-cock, by which oil may be admitted into the interior of the valve-chest, for the lubrication of the working parts.

The two branch steam-pipes J J, as will be distinctly seen by reference to the transverse section, Fig. 2612, open a communication for the admission of steam from the regulator-valve chest K, into the valve casing or steam-chest L L. They are each 3¾ inches internal diameter, and they, as well as the discharge-pipes N N, are so disposed within the smoke-box as not to obstruct the cleaning or replacing of the tubes.

The cylinders and valves.—The slide-valves, with their expansion-slide frames, are placed between the cylinders M M, in one steam-chest L, formed by the construction of the cylinders when bolted together, as will be seen by inspection of Fig. 2606. By this arrangement access is afforded to both valves by the removal of only one cover, which seems to be an improvement over the other methods now in use.

The steam cylinders M M are 14 inches diameter, with a stroke of 21 inches. They are placed at a slight angle in the smoke-box, for the purpose of being accommodated to the position of the cranked axle. The form and dimensions of the pistons P′ P′, and the arrangement of the packing-rings $a'' a''$, are clearly indicated in Figs. 2615, 2616, 2617. The packing consists of two cast-iron rings $a'' a''$, turned slightly eccentric, the thick sides in each being set diametrically opposite. At these points they are cut, and wedges $b'' b''$ fitted accurately into the openings. These wedges are pressed outwards by two springs $c'' c''$, which are adjustable by set-screws. The whole is rendered compact and secure by the piston cover, d'', which is bolted to the body of the piston by four bolts, guarded by the pieces $e'' e''$, as shown in Fig. 2617.

The steam-ports *s s*, which communicate between each extremity of the cylinders and the slide-valves *r r*, are formed in the body of the cylinders, as are also the discharge-ports N N, to the point where the blast-pipes are jointed to them. The discharge or blast pipes N N, ascend from each cylinder till they reach the bottom of the chimney, where they are formed into one pipe, in the orifice of which is placed a cone or tapered plug *t*, so disposed and connected by means of a system of rods and levers *u u*, as to be capable of being raised or depressed by the engine-driver. By this means the orifice of the blast-pipe may be enlarged or contracted at pleasure, thereby causing a greater or less draught to the fire. By this simple contrivance, the engine-driver is enabled to adapt the quantity of steam generated in the boiler to the exact amount required for the supply of the engine, and thereby to prevent the waste of fuel indicated by the steam blowing off at the safety-valve. For the further regulation of the draught when the engine is at rest, it is provided with a damper *v*, at the lower end of the chimney, worked, like the blast regulator, by a system of rods and levers, also marked *v v*, and terminating near the foot-plate.

The framing and connections of the engine.—Having described the internal arrangements of the engine, we now proceed to explain the parts by which motion is communicated to the wheels. These are most fully and clearly delineated, in combination, in our sectional elevation, Fig. 2605, and in the plan, Fig. 2606. Between the smoke-box and external fire-box, are bolted the four strong malleable-iron beams O O O, called the *inside framing*, and which, besides imparting great strength and rigidity to the whole structure, serve the purpose of giving fixed points of resistance for the bearings of the working parts. Of these, the first that claim our attention are the piston-rods P P. These are made of steel, turned truly cylindrical and smooth, and of the diameter of $2\frac{1}{4}$ inches; they are fixed into the piston with a cotter in the manner indicated in the detail, Figs. 2615, 2616, and at the opposite extremity they are terminated each by a cross-head Q′, also attached to them by a cotter, Fig. 2618. On these cross-heads are bearings for the small ends of the connecting-rods Q Q; and concentric, and of the same piece with these bearings, are projecting arms into which the cast-iron guide-blocks *w w*, Figs. 2618, 2619, are fitted. The guide-blocks are formed with flanges, and are accurately fitted and ground into steel slide-bars, also marked *w w*, so as to work smoothly and steadily between them. These latter are set truly parallel and in the same inclined plane with the centre of the piston-rods, and are firmly bolted to the framing-plates O O. By this means, the piston-rods are constrained to move in a rectilinear direction, and secured against any deflection, or undue strain arising from the continual change of position of the opposite ends of the connecting-rods, in obedience to the revolution of the cranks to which they are respectively attached.

The feed-pumps S S, for the supply of water to the boiler, are also set in the line of the piston-rods and their plungers partake of their motion, being each fixed to a small arm *x*, firmly secured by a cotter to the cross-head Q′. The pumps, the internal arrangement of which is fully shown in the longitudinal section, Fig. 2627, are formed of cast-iron, and are firmly fastened to the inside framing O, by bolts passing through the projecting flanges $f'' f''$. The plungers g'' are of brass, two inches in diameter, and at each stroke of the engine draw the water from the tender through the feed-pipe *y*, and lower or suction valve h'', forcing it, at the return stroke, through the upper or delivery valve i'', and along the pipe *z*, into the boiler. The valves are prevented from rising out of their seats by the stops $j'' j''$, fixed into the covers of their respective chests, and so adjusted as to admit of their rising only to the proper height for the due ingress and egress of the water. At the point where the water is discharged into the boiler is placed a valve-box a', within which is a valve opening upwards, for the retention of the water within the boiler. A small cock, called the *pet-cock*, b', is fixed to the outside of the feed-pump, and by means of a long slender rod, the handle is brought within reach of the engine-driver, so that he may be enabled to ascertain at any time whether the pump is working efficiently.

The connecting-rods Q Q are jointed, as we have before explained, to the cross-heads of the piston-rods. The coupling is effected in the usual way, by means of straps, gibs, and cotters, properly secured against relaxing or falling out. The opposite ends are attached in the same manner to the cranks R R, upon the axle of the driving-wheels. This cranked axle is made of the best forged iron, the cranks being cut out of the solid mass, and the one formed exactly at right angles to the other. In the earlier stages of the locomotive engine, it was usual to provide bearings for the cranked axle upon each of the frames O O, but this practice is now discontinued, and thereby the machinery is much simplified, and the friction considerably reduced.

The eccentrics and valve geer.—This engine is provided with four eccentrics, two for the forward, and the other two for the backward geer. The form and dimensions of these are shown upon an enlarged scale in Fig. 2621, which gives a view of one of the backward eccentrics, but which, with a slight difference, presents an accurate type of the whole set. Each eccentric is formed in halves, for the purpose of embracing the axle, and these are joined immovably together by the two round pins $k'' k''$, screwed into one half, and secured, after passing through the other, by cotters It is fixed firmly to the axle by the two pointed set-screws, $l'' l''$. The forward eccentrics for both cylinders are fixed upon the axle a little *in advance* of a line at right angles to their respective cranks, for the purpose of giving the required *lead*, and the position of the backward eccentrics is adjusted upon the same principle, though of course in a diametrically opposite direction. The

eccentric-rods $m'' m''$, are bolted firmly to the brass strap surrounding the eccentrics; and their opposite extremities, the form of which is shown in Fig. 2625, are connected together by a double link e' Figs. 2623 and 2624, so formed as to admit of either forward or backward eccentric being thrown into geer with the valve-spindle, as may be required. The link which Messrs. Hawthorn employ for coupling the ends of their eccentric-rods is of a new and improved construction, being so formed as to diminish as much as possible the friction and wear upon the slide-rod pin and the eccentric-rod ends. The *reversing geer*, or mechanism by which the engine-driver is enabled to propel the engine in either direction, consists of a system of rods and levers $f' f' f'$, commencing with a stud upon the lower extremity of the coupling-link e', and terminating in a long handle, placed in a convenient position near the foot-plate. The motion of the eccentrics is communicated *directly* to the slide-valves by means of valve-spindles, working through oblong guides at the one extremity, to insure steadiness, and attached at their opposite ends to the slide-valves by nuts and jam-nuts, for the purpose of adjustment. We may here take occasion to remark, in anticipation of the subject upon which we are now about to enter, that by Messrs. Hawthorn's arrangement the ordinary slide-valves, when once properly adjusted, never require to be varied, to whatever extent the expansion geer may be employed.

Auxiliary expansion slide-frame and geering.—On each of the backward eccentrics is fixed a stud h', Fig. 2621, to which is jointed a rod, the other extremity of which is connected with the upper arm of a double lever, working upon a bearing fixed to one of the framing-beams O O. The lower arm of this lever is grooved throughout its length to receive a sliding-pin, attached by a link to a system of rods and levers, terminating in a long handle, working on the same centre with the reversing handle. The sliding-pin is also connected by the rod to the hollow spindle which works through the stuffing-box of the valve-chest L, and incloses the spindle g of the ordinary slide-valve. It may here be remarked, as objections may be urged on the ground of expense, that the hollow spindle is not essentially requisite in this arrangement of valves; the spindle may be made solid, similar to the rod of the ordinary slide, and worked through a separate stuffing-box, either above or on one side of it; the mode represented is, however, the neatest and most compact arrangement.

The expansion slide-frame is worked by the hollow spindle, being attached to it by means of a slender malleable iron frame, embracing it on all sides, and screwed to the end of the hollow spindle. It is fitted to and works upon the same face as the ordinary slide-valve, but is of such a form as, when the frame is in motion, to overlap alternately the ends of the latter, (the back of the slide-valve being accurately planed and fitted for that purpose,) according to the amount of expansion required. This can be varied at pleasure by the mechanism above described; for when the sliding-pin which works in the grooved arm is brought into the centre of motion of that lever, it is obvious that no motion of the slide frame will ensue, and in this position, when it is not required to work expansively, the geering may be secured so as to obviate all unnecessary wear and tear. If, however, the handle be advanced into the position represented in the general elevation, Fig. 2601, the sliding-pin and rod l', which is attached to it, will then be forced downwards, as shown in Fig. 2605, and the slide-frame will partake of the motion communicated to the lever i' by the backward eccentric, and the amount of this travel will obviously be in proportion to the distance at which the sliding-pin is set from the centre of motion. A graduated sector is placed at the foot-plate in view of the engine-driver, as shown in the general elevation, for the purpose of indicating minutely the amount of expansion, or at what part of the stroke the steam is cut off.

We may remark that Messrs. Hawthorn's expansion geer appears to possess advantages over many of the other methods hitherto employed. The first and perhaps the most important of these we have before adverted to, namely, the complete independence of the motion of the ordinary slide-valve from that of the expansion-frame, rendering any alteration of the latter, after it has been once properly adjusted, unnecessary, whatever amount of expansion may be employed. The admission and discharge of the steam are thus, in all cases, regular, and take place under the most advantageous circumstances attainable by the ordinary valve. Again, the movement communicated by the backward eccentric to the expansion-slide is so regulated, in relation to that of the ordinary valve, as to produce a very peculiar and advantageous effect in cutting off the steam quickly. Thus, the expansive principle may be employed to any extent, between that due to the cutting off of the steam at $\frac{1}{8}$ of the stroke of the piston, to that which would be produced by the action of the ordinary slide alone, without throttling, or what is technically called *wire-drawing* the steam, a defect so much complained of in most of the other modes of expansion hitherto in use. These theoretical advantages have been fully corroborated by the results of experience. Messrs. Hawthorn have successfully applied their expansion geering to the locomotives which they have supplied to ten different railways in England, and the saving of fuel effected by the use of it, in many cases, amounts to 30 per cent.

The wheels and outside framing.—The driving-wheels T T are firmly fixed to the cranked axle, the ends of which, produced beyond the bearings, carry the cranks and coupling-rods $o' o'$. The other extremities of these rods are connected by cranks of exactly the same dimensions with the axle of the fore-wheels U U. By thus connecting the driving and fore wheels, the amount of *traction*, or the surface upon the rails available for the propulsion of the engine, is greatly increased, which renders this species of engine peculiarly suitable for drawing merchandise or other heavy trains, at moderate speeds. The hind or trailing wheels V V, are situated under the fire-box, and the advantages of this disposition have been already pointed out. The dimensions of all these wheels have also been already given, and the mode of their construction will be clearly understood by reference to Fig. 2631, which shows both external and sectional views of one of the driving-wheels, but which, as far as regards construction, may be taken as a type of the whole. The nave is of cast-iron, moulded and poured round the arms, which have been previously prepared with a dove-tail at their inner ends, for the purpose of giving additional security. The arms and rim are of the best forged iron, and the latter is accurately turned in the lathe

after being welded together. The tyre, which is also of the best forged scrap-iron, is bored internally to a slightly smaller diameter than the rim, and shrunk on. It is then secured to the rim by a few rivets, and the whole turned accurately to the proper form and diameter.

As the whole weight of the engine rests upon the wheels, it may be expected to suffer from jolting in passing over the irregularities of the rails. To obviate this as far as possible, the springs $p' p' p'$ and $q' q' q'$ are interposed, the former upon bearings in the outermost of the internal framings O O, and the latter under the axle-boxes $r' r' r'$, of the main external bearings. The springs marked $q' q'$, and the mode in which they are attached to the axle-boxes and to the framing, are clearly represented in Figs 2634 and 2635. They are composed of thin layers of steel, gradually diminishing in length from the centre to the extremities, and bound together by the connecting-hoop o'', secured in its place by a small round pin passing through it and the steel plates. The connecting-hoop is formed with a tail projecting upwards into the lower portion of the axle-box, where it is fixed by a round pin p'' passing through it. The axle-box r', which is of cast-iron, fitted with bearings composed of a metallic alloy favorable for the reduction of friction, slides up and down as the springs bend with the weight of the engine, between the cast-iron axle-guides $q'' q''$, which are accurately planed and fitted to receive it, and bolted firmly to the plates of the external framing. The axle-boxes are formed with a sort of reservoir for oil or tallow, which is constantly supplied to the rubbing surfaces by two small tubes and siphon-wicks. It may here be remarked, that the other rubbing parts of the engine are lubricated in the same manner. The mechanism by which the springs are attached to the external framing is shown in Figs. 2634, 2635. These parts are called the *spring-links*, and consist of a species of small cross-head r'', fitted with round pins for passing through the plates of the external framing, and with screwed studs attached by similar round pins to the ends of the springs $q' q'$. The nut s'' works into these screws, and by means of it the weight which it may be thought expedient to throw upon each spring may be accurately adjusted.

The external framing consists of two strong parallel beams W W, extending somewhat beyond the engine at both ends, and connected in front by the wooden cross-beam or *buffer-bar* Z, and behind by a similar beam, on which rests the foot-plate Y. These beams are firmly bound together at the corners by angular plates of iron bolted through each, and the weight of the boiler is supported upon them by the strong malleable iron brackets or stays X X X, riveted to the boiler, and bolted through the beams W W. These latter are formed each of two parallel plates of iron, cut out into the form shown in the general elevation, with *horns* projecting downwards for the bearings of the wheels. Between each pair of plates a beam of well-seasoned oak is interposed, and the whole firmly bolted together.

To deaden the shocks to which the engine is exposed, it is provided with *buffers*, $s' s'$, fixed to and projecting in front of the buffer-bar Z. These buffers are a species of elastic cushions, formed of horse-hair, surrounded by strong leather, and further strengthened by slender malleable iron hoops. To secure the engine against the effects of the wheels coming in contact with stones or other obstacles which may happen to be lying on the rails, it is furnished with strong malleable iron *safe-guards* $t' t'$, descending from the external framing to within a short distance of each rail, and so formed at the points as to turn aside any object with which they may come into collision.

Any water which may happen to accumulate in the cylinders, whether from the priming of the boiler or the condensation of the steam, and which, unless removed from time to time, would be very detrimental to the working of the engine, is let off by means of the pipe and stop-cock u', communicating with the discharge passage of each cylinder.

Upon the front of the smoke-box, and towards the top, is fixed a small bracket for supporting the *signal-lamp* v', by which notice is given at night of the approach of the engine and train.

As a precaution against accident to the engine-driver and his assistant, hand-rails $w' w'$ are erected on each side of the foot-plate Y, and these are continued along the whole length of the boiler, so that they may be enabled with comparative safety to walk round the engine, even when it is in rapid motion. The rods forming this latter part of the hand-rail are made hollow, and thus afford a neat and compact guide and protection for the slender rods by which the blast regulator on one side, and the damper on the other, are worked.

When the engine is at rest, the steam which would otherwise escape at the safety-valve and be thrown to waste, is made available for the heating of the water in the tender. This is accomplished by means of the bent pipe x', by which a communication is made between the steam within the fire-box and the feed-pipe y, and thereby a considerable saving of fuel is found to be effected.

The connection of the engine and tender is made by means of the strong double link or drag-bar y', one end of which is secured by a strong pin to a bracket fixed under the foot-plate of the engine, while the other is in a similar manner jointed to the drag-springs of the tender.

To assist the engine-driver in rising into his place on the foot-plate, the foot-steps $z' z'$ depend on each side of it to within an easy distance from the ground.

Having thus minutely described the parts of which this engine is composed, and explained their several uses as we went along, we consider it unnecessary to occupy more space with an account of its mode of action. This is in every respect identical with that of the ordinary high-pressure engine, and to those who have followed us in our previous descriptions will be perfectly intelligible.

Description of the tender.—The tender is an invariable concomitant of the locomotive engine, and as in it, as well as in the engine, there is considerable room for the display of tasteful design and judicious arrangement, we have thought that we should render our engravings more interesting and more acceptable by giving representations of both. The water-tank A A forms the principal part of the tender, and consists of a rectangular sheet-iron cistern, capable of containing 1200 gallons of water for the supply of the boiler. It is made with a long recess B for the reception of the fuel. The floor a of this recess is made with a slope downwards from the front of the tender, by

which arrangement the fuel is prevented from being thrown out by any jolting or shaking to which it may be subjected.

Towards the back of the tank it is surmounted by a pipe or opening C, by which water is introduced from the water-crane or other contrivance for that purpose. A wooden cover is fitted over this opening when not in use. At the same point are fixed the wooden tool-boxes D D for containing spanners and other implements which may be required for the engine. At the front of the tank, and on each side, are situated the cocks *b b* for regulating the supply of water to the suction-pipes *c c* communicating between the feed-pumps and the tender. These are connected to the feed-pipes *y y* by means of leather hose screwed on to each by the union-joints *d d*, thus admitting of a considerable amount of vibration or change of position of the pipes, without breaking the connection. The tank is secured to a strong wooden frame E E, forming the body of the tender, and strengthened by numerous cross-beams. Beyond this wooden framing, and on each side of it, the external iron framing-plates F F are fixed by bolts passing through short cross-beams of timber *e e e* abutting against both. The external framing-plates are made of a form symmetrical with those of the engine, as seen in the general elevations, Figs. 2601 and 2603, and their purpose is to afford bearings for the reception of the axle-boxes *f f f*, which slide up and down in them in obedience to the action of the springs *g g g*.

The tender is supported upon six wheels G G G, of the same diameter as the trailing or hind wheels of the engine, and constructed in the manner already described in treating of the latter. The brake apparatus, which is shown on an enlarged scale in Fig. 2636, consists of a train of mechanism by which a great amount of friction can be simultaneously produced upon the peripheries of the tender-wheels, for the purpose of reducing the momentum of the engine and train, when it is required to arrest the motion of the train. The hand-wheel *h* is fixed to the upper extremity of the vertical spindle H, working in a strong bearing attached to the tank. The lower portion of the spindle is formed into a screw, and works through the wrought-iron nut I, on which is forged a double link, jointed at its lower end to the brake-lever *i*. The latter has its centre of motion in the short shaft J, which works in strong bearings attached to the wooden frame, and carries the double-toothed sector *j*. Two longitudinal iron rods *k k* extend the whole length of the tender, and a small portion of each towards the front extremity is formed into a rack, so adjusted as to work into the teeth of the sector *j*. The rods *k k* are supported and guided in their motion by small rollers working in the wrought-iron guides *l l l*, and upon them are bolted the wooden brake-blocks *m m m*, by the contact of which with the exterior surface of the wheels the friction is produced. By this arrangement it is obvious that by screwing the vertical spindle H into the nut I, the latter will be drawn upwards, and carrying with it the lever *i*, the toothed sector *j* will be made to revolve upon its axis J, and consequently the rods *k k* will be drawn each in the opposite direction to the other. Each wheel will therefore be forcibly compressed between the brake-blocks *m m*, and the engine and train be proportionally retarded.

At the point where the engine is connected to the tender, the latter is provided with a system of springs, to deaden the effects of shocks from either direction. This consists of two springs set back to back, and connected together by a socket *n*, which receives the end of the drag-bar. The fore spring *p* comes into action when any force is applied tending to *separate* the engine from the tender, as in starting a train, and the hinder spring *o* when the force is applied in the opposite direction. Both springs are supported upon pieces of thin iron bolted between the beams of the wooden frame, and the extremities of the spring *o* bear upon the two guide-pins *q q*.

For further security, in case of the ordinary connections failing, the safety-chains *r r* are attached between the engine and tender.

For the accommodation of the engine-man and fireman, or stoker, the tender is furnished with footsteps *s s*, placed at an easy distance above the steps of the engine. By these arrangements, and with the assistance of the handles *t t*, the foot-plate is rendered easily accessible.

At the front of the tender a piece of boiler-plate *u* is fixed by hinges, for the purpose of forming a floor where the engine and tender are connected. At the other extremity of the tender the buffers *v v*, similar in construction and in situation to those formerly described, are fixed to the cross-beam of the wooden framing, for the purpose of deadening the shocks produced by the occasional irregularities of motion between the engine and the train. The drag-chain *w*, which is firmly secured to the same beam, forms the connecting link between the tender and the train.

Literal References to the Engine.

A, the external fire-box.
B, the internal fire-box.
C C, stays for strengthening the roof of the internal fire-box.
a a a, stays between the external and internal fire-boxes.
b, the fire-door.
c c, the fire-bars.
d, the movable portion of the fire-bars.
D, the ash-box.
E, the cylindrical part of the boiler.
e e e, the tubes.
f f, longitudinal stays from the back of the fire-box to the front of the boiler
F, the smoke-box.
g g, the smoke-box doors.
G, the chimney.
H, a brass funnel for inclosing the safety-valves.
h, the spring safety-valve.
i, the lever safety-valve and spring-balance.
j, the water-gage, and gage-cocks.
k, the steam-whistle.
l, the blow-off cock.
I, the steam-receiver.
m, the inverted cone for preventing priming.
J J, the steam-pipes.
K, the regulator valve-chest.
n, the regulator valve.
o, a rod connecting the regulator valve with
p, the handle for working it.
q, the oil-cup and pipe for lubricating the regulator valve.

L, the steam-chest of the cylinders.
r r, the slide-valves.
M M, the steam-cylinders.
s s, the steam-ports.
N N, the discharge-ports and blast-pipes.
t, the blast-regulator.
u u, handle, rods, and levers for working the blast-regulator.
v v, the damper, with the handle, rods, and levers for working it.
O O, the inside framing of the engine.
P′, the steam-piston.
a″ a″, the packing-rings of the piston.
b″ b″, wedges for tightening the packing.
c″ c″, springs bearing on the back of the wedges *b″ b″*.
d″, the piston-cover.
e″, guards for the bolts of the piston-cover.
P P, the piston-rods.
Q′ Q′, cross-heads for the piston-rods.
w w, the cross-head slides.
x x, projecting-arms for working the feed-pumps.
Q Q, the connecting-rods.
R, the cranked axle.
S S, the feed-pumps.
f″ f″, flanges for bolting the feed-pumps to the inside framing.
g″ g″, the plungers of the feed-pumps.
h″, lower or suction valve of the feed-pump.
i″, upper or delivery valve.
j″ j″, stops for regulating the lift of the valves.
y y, the feed-pipes from the tender to the feed-pumps.
z z, branch-pipes from the feed-pumps to the boiler.
a′ a′, valve-boxes at the boiler.
b′ b′, the pet-cocks and their handles.
c′ c′, the forward eccentrics.
d′ d′, the backward eccentrics.
k″ k″, bolts for connecting the halves of each eccentric.
l″ l″, steel pinching-screws for fixing the eccentrics to the axle.
m″ m″, the eccentric-rods.
e′ e′, coupling links for the ends of the eccentric-rods.
f′ f′ f′, levers, shafts, and rods for working the reversing-geer.
g′ g′, the main steam-valve spindles.
h′ h′, studs on the backward eccentrics for working the expansion slide-frames.
n″ n″, connecting-rods between the studs *h′ h′* and
i′ i′, the grooved arms for the variable expansion.
j′ j′, links between the grooved arms and the levers *k′ k′*.
k′ k′ k′, levers, shafts, and rods for regulating the expansion-geer.
l′ l′, connecting-rods between the grooved arms *i′ i′*, and
m′ m′, the hollow spindles attached to
n′ n′, the expansion slide-frames.
T T, the driving-wheels.
o′ o′, the outside cranks and coupling-rods.
U U, the fore-wheels coupled to the driving-wheels.
V V, the hind-wheels under the fire-box.
p′ p′, springs for the inside bearings of the cranked axle.
q′ q′, springs for the outside bearings of all the axles.
o″ o″, connecting-hoop for the outside springs of the cranked axle.
r′ r′, the axle-boxes.
p″ p″, pins for attaching the springs to the axle-boxes.
q″ q″, cast-iron guides for the axle-boxes.
r″ r″, the spring-links.
s″ s″, the nuts for adjusting the weight upon the springs.
W W, the external frame of the engine.
X X, stays from the external frame to the boiler.
Y, the foot-plate.
Z, the buffer-beam.
s′ s′, the buffers.
t′ t′, the safeguards.
u′ u′, a cock and pipe for letting off water from the cylinders.
v′, the signal-lamp.
w′ w′, the hand-railing.
x′, a pipe from the boiler for heating the water in the tender.
y′, the drag-bar.
z′ z′, the foot-steps.

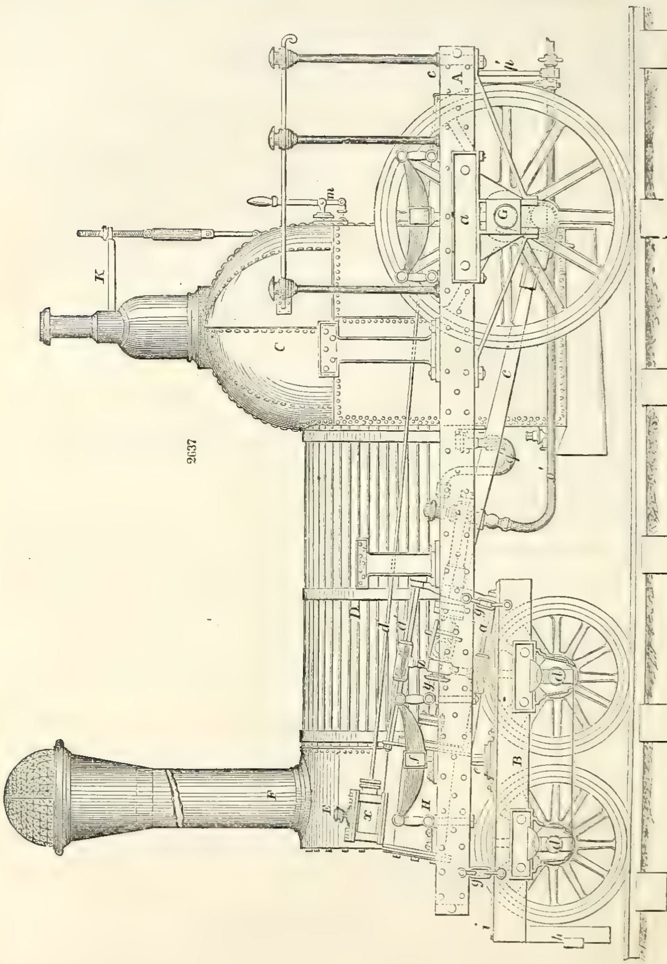
Literal References to the Tender.

A, The water-tank.
B, the recess for containing the coke.
a a, the floor of the coke-box.
C, the opening into the tank.
D D, the tool-boxes.
b b, the cocks for regulating the supply of water to the feed-pumps.
c c, water or suction pipes to the engine.
d d, union-joints for connecting the feed-pipes.
E E, wooden frame of the tender.
e e, stays between the wooden and iron frames.
F F, the iron frame for receiving the axle-boxes.
f f f, the axle-boxes.
g g g, the springs.
G G G, the wheels.
H, the vertical spindle and screw for working the brake.
h, the hand-wheel for the brake-screw.
I, the nut and link for connecting the screw with
i, the brake-lever.
J, the short shaft carrying the brake-lever, and
j, the double-toothed sector, working into
k k, the longitudinal rods carrying the brake-blocks.
l l, supports fitted with rollers for guiding the rods *k k*.
m m, the wooden brake-blocks.
n, socket for connecting the drag-springs to the drag-bars.
o p, the springs for buffing and drawing.
q q, bearings for the spring *o*.
r r, the safety-chains.
s s, the foot-steps.
t t, handles to assist in rising to the foot-plate.
u, a hinged plate between the engine and tender.
v v, buffers for the tender.
w, drag-chain of the tender.

Fig. 2637 is an elevation of a small American locomotive built by H. R. Dunham & Co., New York The distinctive part of the engine and of American locomotives in general, is the forward truck consist-

ing of two sets of wheels on one frame, the frame revolving on a centre-pin, which enables the machine to move more easily around corners; this form of engine is called the *bogey* in England.

The locomotive here shown is one of the earlier kind, with inside connection, and but one pair of drivers. At present in this country, engines with outside connections are thought to be safer, steadier and cheaper than inside, and are very generally adopted. The number of driving wheels is seldom less than two pairs. Fig. 2638 is the side elevation of a locomotive as built by Rogers, Ketchum & Gros



2637

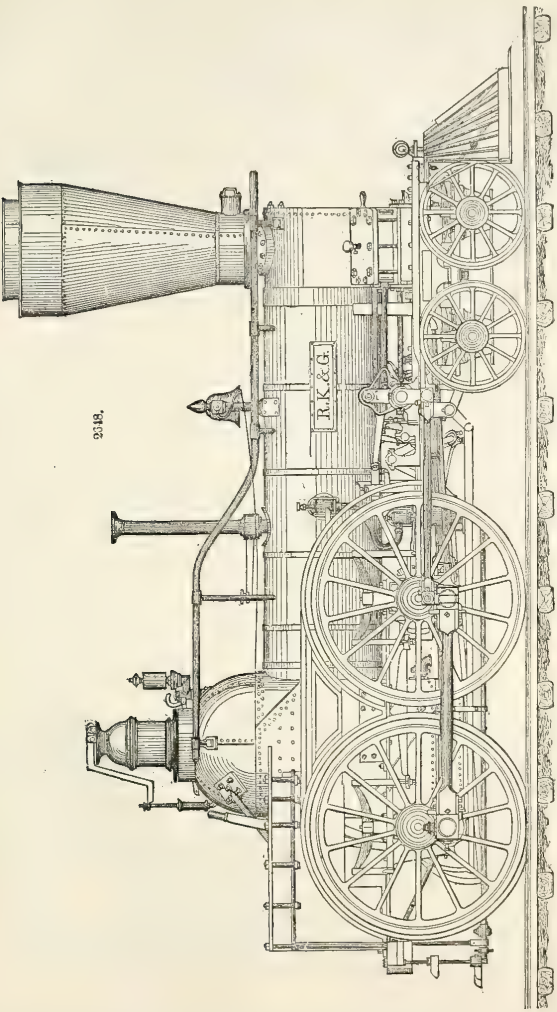
vner of Paterson, and may be taken as the type of the American locomotive. The earliest American locomotives were but copies of the English with slight adaptations, for the service required and fuel used, but the later engines, as will be seen, are distinctive.

The valve-geer now mostly used is the link-motion, for description of which see LINK-MOTION.

The coal locomotives as built by Ross & Winans of Baltimore, differ essentially from those of other

makers. The freight engines are usually eight-wheeled engines, all connected; the fire-box is extremely long and capacious. The fuel is let down through a hopper above the fire-box, the tender being two-storied, and the engineer is placed on the top of the engine, immediately back of the smoke-stack. For the results of experiments on these engines on the Reading Railroad see BOILER.

2348.



Coal engines, as built by Perkins of Alexandria, have three pairs of connected drivers and a forward truck. The coal engines of other makers are in general appearance similar to the wood engine, the difference being almost entirely in the form of the boiler.

LOGARITHM. The logarithm of a number is the exponent of a power to which another given invariable number must be raised in order to produce the first number. Thus, in the common system of logarithms, in which the invariable number is 10, the logarithm of 1000 is 3, because 10 raised to the third power is 1000. In general, if $a^x = y$, in which equation a is a given invariable number, then x is the logarithm of y. All absolute numbers, whether positive or negative, whole or fractional, may be produced by raising an invariable number to suitable powers. The invariable number is called the *base* of the system of logarithms: it may be any number whatever greater or less than unity; but having been once chosen, it must remain the same for the formation of all numbers in the same system. Whatever number may be selected for the base, the logarithm of the base is 1, and the logarithm of 1 is 0. In fact, if in the equation $a^x = y$ we make $x=1$, we shall have $a^1 = a$, whence, by the definition, log. $a=1$; and if we make $x=0$, we shall have $a^0 = 1$, whence log. $1=0$.

These properties of logarithms are of very great importance in facilitating the arithmetical operations of multiplication and division. For if a multiplication is to be effected, it is only necessary to take from the logarithmic tables the logarithms of the factors, and add them into one sum, which gives the logarithm of the required product; and on finding in the table the number corresponding to this new logarithm, the product itself is obtained. Thus by means of a table of logarithms the operation of multiplication is performed by simple addition. In like manner, if one number is to be divided by another, it is only necessary to subtract the logarithm of the divisor from that of the dividend, and to find in the table the number corresponding to this difference, which number is the quotient required. Thus, the quotient of a division is obtained by simple subtraction.

Logarithms apply with equal advantage to the formation of powers and extraction of roots. Let y be a number to be raised to the power m, (m being any number, whole or fractional, positive or negative.) As before, we have $y = a^x$; and, on raising both sides of the equation to the power m, $y^m = a^m x$: whence, by the definition, log. $y^m = m\,x = m$ log. y; that is, the logarithm of the power of a number is equal to the product of the logarithm of the number by the exponent of the power.

If in the equation of log. $y^m = m$ log. y we make $m = \frac{1}{n}$, we shall have log. $y^{\frac{1}{n}}$ (or log. $\sqrt[n]{y}$) $= \frac{1}{n}$ log. y; that is to say, the logarithm of any root of a number is equal to the logarithm of the number divided by the index of the root.

From these two last results it is obvious that by means of a table of logarithms numbers may be raised to any power by simple multiplication, and that the roots of numbers may be extracted by simple division.

When a table of logarithms has been calculated for any given base, it is easy to find by means of it any other system of logarithms corresponding to a different base. Thus, supposing a system of logarithms has been calculated of which the base is a, or, which is the same thing, that the value of x has been found for every different value of y in the equation $a^x = y$, and that it is required to construct another table, of which the base is b, or to find the values of v corresponding to every different value of y in the equation $b^v = y$, we may proceed as follows: Taking the logarithms of both members of this last equation from the table supposed already calculated, of which the base is a, and recollecting that log. $b^v = v$ log. b, we have v log. $b =$ log. y; whence $v = \frac{\text{log. } y}{\text{log. } b}$. But because $b^v = y$, it follows that v is the logarithm of y in the system of which the base is b; therefore, denoting the logarithms in this new system by L, we have L $y = \frac{\text{log. } y}{\text{log. } b}$. Hence it appears that, in order to find the logarithm of any given number y in the new system, it is only necessary to multiply its logarithm in the system already calculated by the constant number $\frac{1}{\text{log. } b}$. This constant number, by means of which we pass from the one table to the other, is called the *modulus* of the new table with reference to the old.

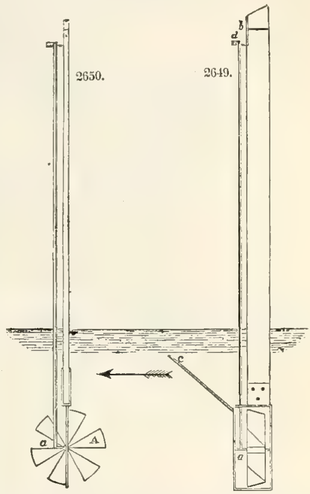
The logarithms of the particular system of which the modulus is 1, is called the *Napierian system*. But, as has been shown, when the logarithms have been found in any one system, they may be transferred into those of any other system by means of a constant factor. In the common system the base is 10, and the Napierian logarithm of any number is consequently transformed into the common logarithm of the same number by multiplying by the modulus $\frac{1}{\text{L}10}$. This number, which is of great importance in the computation of the logarithmic tables, is found to be 0·4342944819, &c., the Napierian logarithm of 10 being 2·30258509, &c. It may also be remarked that this modulus 0·4342944819 is the ordinary logarithm of the base of the Napierian system; for, calling e this base, we shall have $e^{\text{L}10} = 10$, whence, taking the ordinary logarithm of both sides of the equation L10 $\times$ log. $e =$ log. $10 = 1$; therefore, log. $e = \frac{1}{\text{L}10} = 0{\cdot}4342944819$. On passing to numbers, we find $e = 2{\cdot}7182818284$.

The Napierian logarithms are sometimes called the *natural logarithms*, on account of the modulus of the system being unity; and, more frequently, *hyperbolic logarithms*, because they represent the area of a rectangular hyperbola between its asymptotes, and on this account are of immense use in calculations connected with the steam-engine.

Logarithms being of constant use in calculations, the tables which have been published are very numerous. The most complete are those of Vlacq, to ten decimals; but they are very scarce, and can with difficulty be procured. There is an edition of them by Vega, in 1797, also scarce. *Gardiner's Logarithms*, printed in 1742, in 4to, and another edition of them at Avignon, in France, in 1770, are to seven decimals. *Callet's Logarithms*, in 8vo, like Gardiner's, contain the logarithmic sines, &c., for

every 10 seconds. *Taylor's Logarithms*, in 4to, and also *Baguay's*, have them to every second. *Hutton's Logarithms*, and *Babbage's Logarithms of Numbers*, are well known. The latter was carefully collated, and is very accurate and convenient. *Hulsse's Sämmlung Mathematischer Tafeln* (8vo. Leipsig, 1840) deserves to be mentioned as a very useful collection. The above (excepting Vlacq's and Vega's) are all to seven decimal figures; but for many purposes, logarithms to a less number of decimals are sufficiently accurate. For navigation and surveying, tables to six fixgures are the most convenient, as they give, in general, the trigonometrical lines correct to single seconds. The best tables of this kind are *Farley's Tables of Six-figure Logarithms*, (12mo, 1840.) For many auxiliary computations in astronomy it is sufficient to have the logarithms to five places. The reprint of *Lalande's Five-figure Table* by the Useful Knowledge Society (18mo, 1839) is convenient, and may be relied on for accuracy.

LOG, *for steam-vessels.* Fig. 2649 is a side view, and Fig. 2650 an end view of this instrument. A is a small wheel, 1 foot diameter, having vanes set at such an angle that, when let into the water, the action upon their inclined surfaces would cause the wheel to revolve once in passing the distance of two feet through the water. Upon the axis of the wheel is an endless screw *a*, into which works a small toothed wheel, having 51 teeth. The instrument should be mounted on the low end of a stiff bar of wood, or other material, of such length as that the top end could be fastened by a joint or hinge *b*, to the side of a vessel, in convenient proximity to a cabin window, or to the deck. To the low end of the rod or bar a small line should be attached, *c*, the other end of which to be secured on the deck of the vessel. The use of this line would be to withdraw the instrument from the water when not required for observation, and to lash it horizontally out of the reach of the waves. When the line was released, the instrument should be so suspended as to fall perpendicularly into the water, and the bar sufficiently stiff to remain perpendicular, and resist the pressure of the water against its front edges, which, however, would be but trifling. The axis of the small toothed wheel should be inclosed in a tube in front of the bar on which the wheel is suspended, and prolonged to a short distance below the hinged joint; and upon the top end of it should be fixed an index *d*, to revolve on a dial-plate decimally divided. The wheel being constructed as before described, this index would make one revolution round the dial-plate in the time that the vessel passed 102 feet through the water, which is about the one-sixtieth part of a knot, or nautical mile. If, therefore, an observer stood with a minute-glass, (or seconds watch,) and turned the glass the moment the index was at zero upon the dial-plate, and noted the number of revolutions and parts made by the index during the time the sand was running out, he would have the rate at which the vessel passed through the water, in knots and decimals, per hour.



LOGWOOD. A hard, compact wood, so heavy as to sink in water, of a fine grain, capable of being polished, and so durable as to be scarcely susceptible of decay. Its predominant color is red, tinged with orange, yellow, and black. It yields its color both to spirituous and watery menstrua. Alcohol extracts it more readily and copiously than water. The color of its dye is a fine red, inclined a little to violet or purple, which left to itself, becomes yellowish, purple, and at length black. Acids turn it yellow, alkalies deepen the color, and give it a purple or violet hue. A blue color is obtained from logwood, by mixing verdigris with it in the dye-bath. The great consumption of logwood is for blacks, to which it gives a lustre and velvety cast; it is also extensively used as a red, purple, or black dye to beech, and various white woods. See WOODS, VARIETIES OF.

LOOM, POWER. Fig. 2651 is a front elevation of a power-loom for weaving printing goods, as built in the Lowell Machine Shop, Lowell, Mass.

Fig. 2652 is the driving-end, showing pulleys, geers, shipper, &c.

Fig. 2653 is a view of the other end, showing the take-up motion.

A denotes the cast-iron ends, which, with the iron girts that are bolted between, constitute the frame-work to which all other parts are attached.

B is a cast-iron arch, which supports the roll over which the harnesses hang.

C C are the driving-pulleys, one loose, the other fast.

D, large geer or cam shaft, driven by a geer on the crank-shaft.

E, cams for working the harnesses; F, cam for throwing shuttle.

G, lever for taking up the cloth by operating on the ratchet-wheel H. This lever is worked by a crank-motion attached to the end of cam-shaft.

H, ratchet-wheel, operated by lever G.

I, emery-roll; J, binder-roll; K, cloth-roll. The cloth, after passing between the rolls I and J, winds up on this roll. This roll is driven from I by a belt.

L, Fig. 2652, is a view of the filling stop-motion.

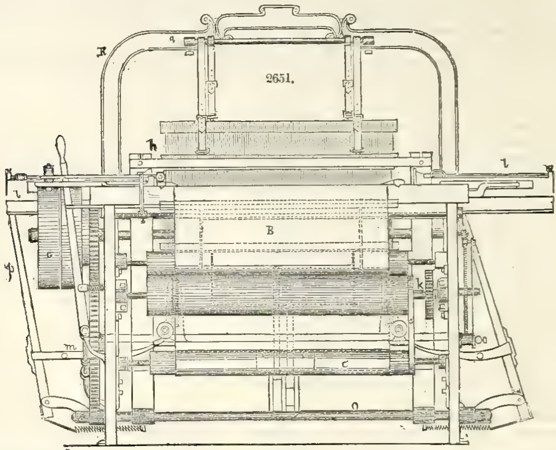
M, head on yarn-beam, with a groove for a strap.

N, strap and spring for friction on yarn-beam.

O, lever, operated by cam, on cam-shaft.

P, lever attached to O, which comes in contact with catch L, (when the filling breaks,) and throws the shipper-handle Q out of the notch in which it is held, and stops the loom.

Q, shipper-handle for stopping and starting the loom.

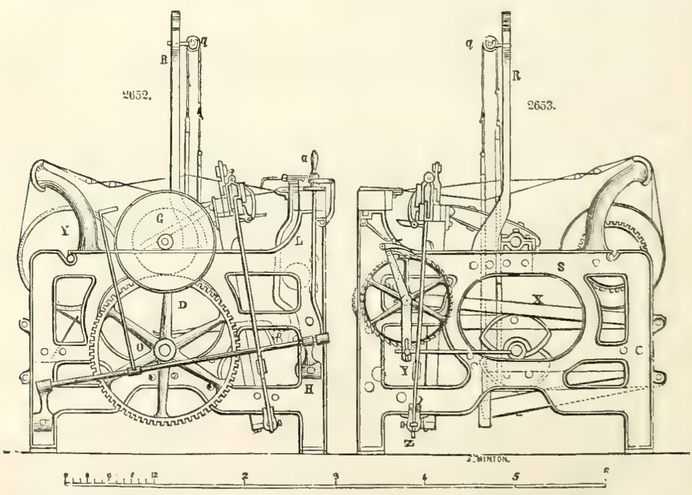


2651.

R, piece attached to the protecting-rod, that strikes a lever under the breast-beam, (whenever the shuttle fails of performing its duty,) and stops the loom.

S, picker-staff for throwing the shuttle, which receives its motion from a cam on cam-shaft, communicated by a treadle and strap T.

T, strap for picker-motion.



2652. 2653.

U, harness-treadles, operated by the cams E E.

V, crank-shaft, which gives motion to the lathe or sley. X, sley or lathe, which contains the reed.

Y, harnesses for separating the warps while the filling passes through, which are operated by the harness-cam E alternately.

Z Z are the swords that support the lathe, and are attached to the rocking-shaft at the bottom.

&, rocking-shaft on which the lathe swings.

a' is a geer attached to the yarn-beam, used only when dressing the yarn. *b'*, reed. *c'*, friction roll for picker-lever strap. *d'*, picker-levers or treadles. *e'*, race-rods, on which the pickers slide. *f'*, pickers, made of green hide, dried and pressed. *g'*, temples for holding the cloth in its place and keeping it stretched in width. *h'* is the cloth, as it passes over the breast-beam down between the two rolls on to the cloth-roll.

LOOM, BIGELOW'S COUNTERPANE. This improvement consists principally in the manner in which the shuttles are thrown; the manner of raising and depressing the shuttle-boxes; and the manner in which the picker is relieved from the shuttle.

We copy from the specification of the patentee:

In throwing the shuttles, I cause the two picker-staves to operate simultaneously, so that the shuttle may be thrown from whichever of the boxes is presented to their action. This I effect by the use of one picker-treadle only, which is acted upon by a cam-ball, in the usual way of working such treadles. From this treadle two bands are extended, and pass around the two picker-pulleys in such manner that when the treadle is depressed both the picker-staves will be set in action at the same moment. By this arrangement, two or more shuttles may be successively thrown from the same end of the loom by the action of one treadle.

The shuttle-boxes are raised and lowered in the following manner: a shaft extends along under the race-beam, from one shuttle-box to the other, and carries pinions, which take into racks attached to the shuttle-boxes; it will be manifest, therefore, that by causing this shaft to revolve, the shuttle-boxes may be raised. The revolving of this shaft is effected by the action of a spiral or other spring, one end of which is attached to the frame of the loom at its back, and said spring extends forwards towards the lathe; from this forward end a band attached to it passes round guide-pulleys, the situation of which will be shown in the accompanying drawing, and also round a pulley upon the above-named shaft, to which latter said band is attached. The action of the spring, by its drawing upon the band, will cause the pinion-shaft to revolve, and will consequently raise the shuttle-boxes. Should this spring be thrown out of action, and the band by which the shuttle-boxes are raised be relaxed, they will then descend by their own gravity. To take off the tension of the spring, there is a cam upon the main shaft of the loom, which cam, as the shaft revolves, depresses a treadle, to the end of which a band is attached, which operates in such a way as to relieve the shuttle-boxes from the action of the spring, and they then descend. In relieving the picker from the point of the shuttle, I make use of the protection-rod constituting a part of the apparatus employed in the ordinary power-loom, for stopping the loom when the shuttle does not arrive home in the shuttle-box. From the protection-rod, which extends along below the shuttle-boxes, I allow a small arm or finger to descend, which finger, as the lathe comes up towards the breast-beam, strikes against a stop or pin, attached, for that purpose, to the frame of the loom, causing the protection-rod to rock or revolve to a short distance. This gives motion to two arms which extend out from the extreme ends of the protection-rod, opposite to the outer ends of each of the shuttle-boxes; from these arms motion is communicated to a lever which works on a fulcrum over the outer ends of each of the shuttle-boxes, said arms being connected to the levers by rods or wires. By depressing the outer ends of these levers their inner ends are raised, and to these ends are appended rods which carry pieces of wood or metal, which, when down, rest on and embrace the picker-rod, and in that position they serve to hold the picker at a short distance from the end of the shuttle-box, and to stop the shuttle; the picker is then removed from the point of the shuttle by the raising of the lever, the picker being made to pass home to the end of the box, thus leaving the shuttle and shuttle-box free to be raised or lowered without obstruction, the picker being also ready again to act on a shuttle.

Having thus given a general description of my improvements, I now proceed to exemplify the same by references to the accompanying drawings.

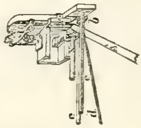
Fig. 2654 is a front view, in perspective, of my improved counterpane power-loom, and Fig. 2655 a back view of one end of one of the shuttle-boxes, this being drawn for the purpose of showing the particular construction and arrangement of this part of the machinery, which could not be exhibited in the front view. In Fig. 2654 the breast-beam is not represented, it being removed for the purpose of showing the lathe, and the parts connected therewith, the more distinctly. The jacquard apparatus, which is employed to regulate the figure, and is perfectly well known, being in general use, I also use as heretofore constructed. It is not represented in the drawing, it not being deemed necessary to describe it; but I have fully shown those parts which constitute my improvements.

A A are the picker-staves, and B the picker-treadle; D is the cam-ball for working this treadle, operating in the usual manner. E E are two straps which are attached to the picker-treadle; these straps pass over the pulleys F F, and are attached by their outer ends to the pulleys G G, which carry the staves A A, and these are consequently acted upon simultaneously. The rods or staves A' A' serve to cause the pickers to pass home when the pieces of wood, &c., above referred to, are raised; these rods are drawn towards the outer ends of the shuttle-boxes by the action of the spiral springs C C, the use of which will more fully appear when describing the parts shown in Fig. 2655.

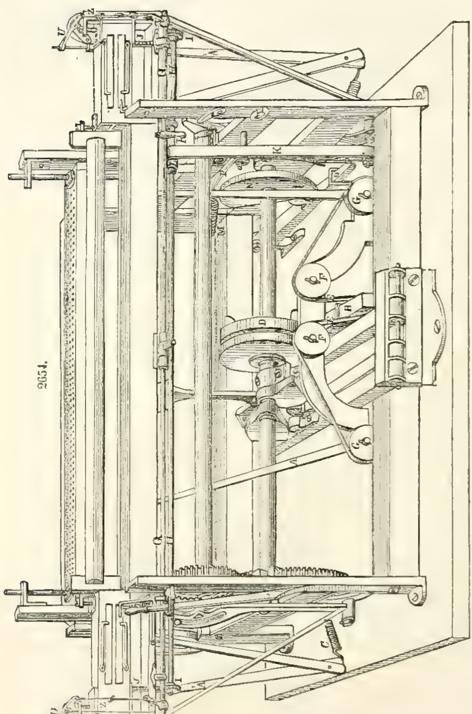
The following is the arrangement devised by me for raising and depressing the shuttle-boxes: a shaft H H is made to extend along under the race-beam, and this shaft carries the pinions I I, which take into vertical racks J J attached to the shuttle-boxes. I sometimes use a single rack affixed at the middle of each box; but I prefer the placing of a rack and pinion at each end of each box, as shown in the drawing. There is a pulley L on the shaft H, and this shaft is made to revolve by means of a band K, one end of which is attached to and laps around the said pulley. The band K passes thence around pulleys *a a'*, the pulley *a* being attached to the frame, and the pulley *a'* either to the frame or to the floor. The spiral spring M affixed to the back of the loom draws on the band K attached to its fore end, so as to cause the pulley L and the shaft H to revolve and raise the shuttle-boxes. When the spiral spring M is relieved from its action on the band K, the shuttle-boxes will descend by their own gravity When

this is to take place, the tension of the spring is taken off by the action of the cam N, placed on the main shaft of the loom, which cam is so formed as to depress the treadle O, which, drawing on the part P of the band K, takes off the action of the spiral spring therefrom, and the shuttle-boxes descend.

The protection-rod Q Q and its appendages, used for stopping the loom when the shuttle does not arrive home, are employed by me in the ordinary way; but I also make use of this protection-rod for the purpose of relieving the shuttle from the picker, in the following manner: R is an arm or finger which is affixed to and descends from the protection-rod, and this, as the lathe approaches the breast-beam, strikes against the stop S attached to the frame of the loom, and causes a partial revolution of the protection-rod. T T are arms on its extreme ends, which arms are connected to two vibrating levers U U, by a rod *z z*, which work on fulcra on the ends of the lathe, above the shuttle-box.



2655.

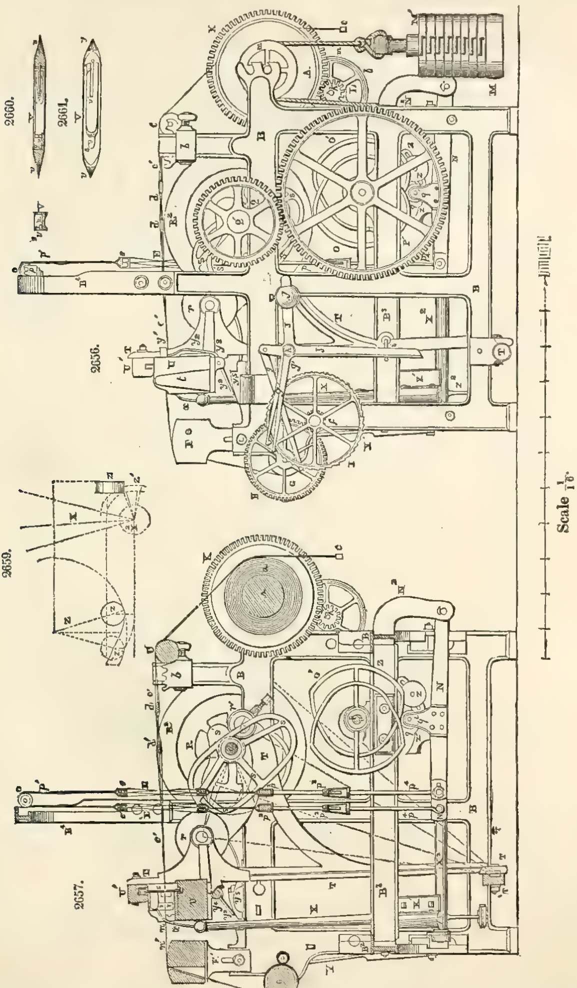


2654.

Fig. 2655 is a back view of the outer end of one of the shuttle-boxes, showing the manner in which the lever U and its appendages operate. The piece of wood or metal V which is raised and lowered by the action of the lever U, and which is represented as resting on the picker W, will, when the inner end of the lever U is down, rest upon the picker-rod X, where it serves to arrest the picker and stop the shuttle. When the lever U is raised, the picker is thereby allowed to pass home, and is consequently removed from the point of the shuttle, and this and the shuttle-box are left free to be raised or lowered. The rod A′ bears against the pin *b* projecting from the picker, and serves to remove it from

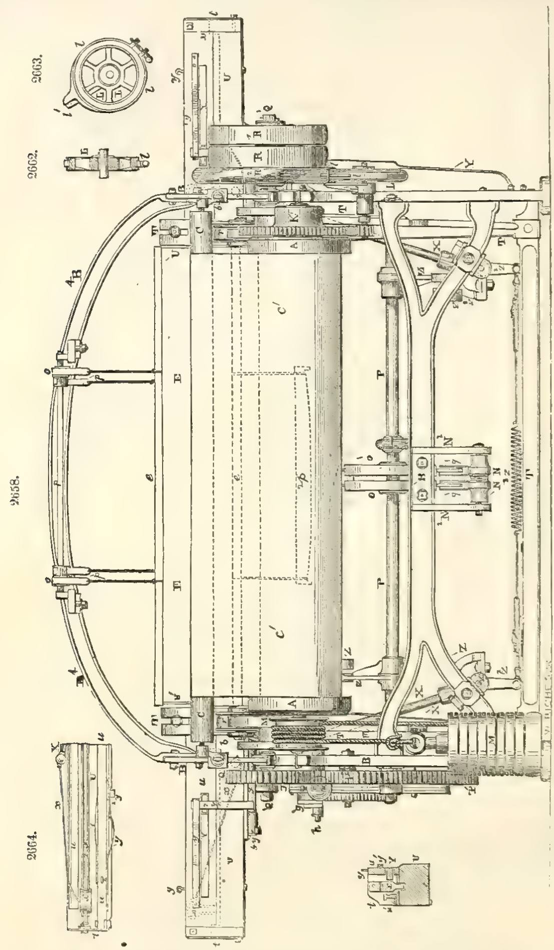
the shuttle when the piece V is raised. The rods *c c* support the pin *b*, and serve as guides to the rod A′; the cord *d* connects the upper end of the rod A′ to the upper end of the stave A, in order that the stave may by its motion move the rod also.

I will here remark, that a weight may be substituted for the spiral or other spring M; that the shuttle-boxes may be raised by springs placed immediately under them, and that the tension of such springs may be taken off by means analogous to those described; but it will be manifest to every competent machinist that any such variation of the respective parts will not substantially change the character of my invention. The manner of constructing and arranging the apparatus as set forth by me, is that which I have deemed the best in practice.



LOOM, DOUBLE-STROKE, *for weaving stuffs of linen, silk, or wool.* Fig. 2656, side elevation of the loom. Fig. 2658, elevation of the loom. Fig. 2657, section.

Fig. 2659, illustration of the movement which operates the picker-staff.
Figs. 2660 and 2661, shuttle. Fig. 2658, elevation of the loom on the side of the warp.
Figs. 2662 and 2663, plan and section of the brake.
Fig. 2664, plan of one of the shuttle-boxes.
A, warp-beam. $B\ B^1\ B^2\ B^3\ B^4$, frame of the loom. $b\ b$, supports of the shaft of the drum C, fastened to the uprights of the frame by set-screws. C, wooden drum. $d\ d'$, blocks to preserve separate the



2658. 2662. 2663. 2664.

threads of the warp. E E′, harness for raising and lowering the threads of the warp for the passage of the shuttle. F, breast-beam. G, cloth-beam. H, spur-wheel on the shaft of the cloth-beam. *f*, pinion working into the wheel H. I, ratchet-wheel, which works with the pinion. J, bell-crank, moving on the centre *n*, and carrying the clicks $g\ g'$ and the counterpoise *j*. *g*, lay-click, serving to give motion to the ratchet-wheel. $g'\ g'$, stop-clicks, to arrest the movements of the ratchet-wheel. *i*, pin on one of the swords of the lay, to give motion to the bell-crank J. K, spur-wheel on the shaft of the drum A, working with the pinion *k*. *k* pinion of 12 teeth, fixed to the shaft which carries the brake-pulley L, Fig.

2658, and also Figs. 2662 and 2663. *m*, cord, fastened at one end to a spiral spring, and passing over the pulley M, supports the counterpoises M', formed of iron rings. N N', needles, which give movement to the harness of the treadles, one shorter than the other. O O', two eccentrics, cast in the same piece, serving to give motion to the treadles, and consequently to raise and lower the harness. P, shaft carrying the eccentrics of the treadles, and also the cranks Z, which give motion to the picker-staff. P', spur-wheel on the shaft P. Q, pinion, of half the diameter of the wheel P, and giving motion to it. Q', a driving-shaft of the machine. R R', fast and loose pulleys on the shaft Q, for the working of the machine. S S', eccentrics, by means of which a double beat is given to the lay V at each revolution of the main shaft. *t t'*, friction-rollers at the ends of the swords of the lay, to receive the action of the eccentrics S S'. T, two swords of the lay. U, lay or batten, on which traverse the shuttles. V, shuttles; X, picker-staff; *x*, picker strings. *x'*, pickers of hide, serving to throw the shuttle. x^2, guide-rods to the pickers. Y, wooden levers, sunk in the substance of the cheeks of the lay, and turning on the pin *y*. $y' y^2 y^3 y^4 y^5$, details of the stop-motion by which the loom is thrown out of geer by a failure of the proper motion of the shuttle. Z, two cranks on the shaft P, giving motion to the picker-staff by means of friction-rollers *z* on the ends of the crank, working upon inclines *z'*. Z^2. two levers, connected with the axes of the picker-staffs, and united by means of straps to a spiral spring Z^3.

LOOM, POWER CARPET, *for weaving two or three ply ingrain or Kidderminster carpets, by* E. B. Bigelow. It gives peculiar interest to the description of a valuable and meritorious invention, to precede it by some account of the life and character of the inventor. The mind loves to contemplate the early struggles of genius, to perceive and comprehend its first inspirations, and step by step to trace the development of its powers.

Erastus B. Bigelow was born at West Boylston, Massachusetts, in April, 1814. His father was a cotton manufacturer, which circumstance, we have a right to assume, gave to the son's mind its first tendency towards that peculiar branch of mechanical pursuits in which he has now attained an enviable and undisputed eminence. His parents, however, designed him for the medical profession; but such a misdirection of faculties was not predestined by the " Divinity that shapes our ends." Before he had completed his medical education, his father, in common with many others engaged in manufactures at that time, failed in business, and was unable to complete the education of his son. What appeared at first a severe private calamity, has, under a wise Providence, resulted in great public good.

Finding himself without means to prosecute his medical studies, young Bigelow yielded to that necessity which has so often proved the benign mother of early invention, and determined to direct his ingenuity to the contrivance of some piece of mechanism, from which he might obtain some pecuniary benefit. Whilst his thoughts were directed to that object, he happened one day to be lying on a bed covered with a knotted counterpane, a species of fabric in which the figure on the surface appears as if made by tying into knots the threads of the woof; and as, some years before, an attempt had been made in West Boylston (where he was still living) to manufacture such counterpanes on hand-looms, and abandoned on account of the great labor and expense involved, three or four days being required to make one counterpane, it became evident to his mind that if he could succeed in producing a power-loom for this purpose, it would be highly valuable as a labor-saving machine, and that he could derive from it the pecuniary assistance for the want of which his medical studies had been suspended. It was a bold undertaking for one wholly uninitiated in the mysteries of the mechanic art, but his very inexperience was to him a great benefit, by concealing from his sight the enormous mechanical difficulties he would have to encounter, and which, if then fully known, might have deterred him from ever carrying his purpose into execution. We may here notice this remarkable fact, that the most original and important inventions the world has ever seen, were the productions of men who had received little or no previous training in the particular art which they sought to improve. Jacquard, the inventor of the beautiful mechanism which bears his name, for weaving figured fabrics, is the only exception with which we are acquainted. It would seem that in pursuing any avocation steadily, the mind becomes so habituated to a certain practical *routine*, as to make it distrustful of any other; whilst, on the other hand, a mere novice, from the fact of his approaching the subject untrammelled by habit or prejudice, will be better fitted to detect existing errors, and suggest bold and original improvements.

But to return. This new idea, forced by circumstances upon Mr. Bigelow's mind, he prosecuted so vigorously, that in the course of one year he had an automatic loom for weaving knotted counterpanes in successful operation, doing the work in one-fourth of the time required by the hand-loom.

The loom was arranged with every fourth dent of the reed adapted to slide vertically in the lathe, and with a hook on the front edge. To the lower end of each of these hooked dents was suspended a wire, attached at its lower end to one end of a lever, and the series of levers were acted upon at the other end by tappets, arranged in a helical line on a barrel or cylinder, for the purpose of depressing the hooked dents in succession from one side of the lathe to the other. The levers and dents were so weighted as to remain in a depressed position, with the hooks below the race-beam, to permit the passage of the shuttle, and when elevated they were held up by the pressure of a spring on each one. For the production of the figure, the hooks, or rather that portion of them required each time, were operated every fourth pick or throw of the shuttle, and after the fourth throw of the shuttle, the required portion of hooked dents were elevated above the weft-thread, the upper part of the hooks being curved, to admit of its passing by the weft-thread; and then, when drawn down, each hook in succession caught the weft and drew it down below the line of the bottom warps, to form the loop, so that when the weft-thread was beaten up by the reed, and the warps crossed, each loop would project to the required distance above the face of the cloth. To insure the proper action of the hooks on the weft-thread, there was a plate imbedded in the race-board, and adapted to slide up and down, and having a notch corresponding with each hooked dent. This plate was brought up under the warps just before the hooked dents were depressed, and formed a bed for the hooks to draw the weft-thread down. The selection of the hooked

dents required to be elevated and depressed, for each operation to determine the figure was effected by a series of needles, on the principle of the jacquard, and governed by punched cards; but these needles, instead of being used to operate knotted cards, were, at their outer ends, joined to wire hooks connected with the levers of the hooked dents, and when the needles were acted upon by the cards, the hooked wires of such of the levers as were to be operated to lift the dents were brought within the range of motion of a lifting-bar, which carried them up where they were held by the spring before described; the lifting-bar was then depressed, and then, as the tappets on the barrel passed around, the lifted hooked dents were each in succession drawn down to form the series of loops.

This loom was so ingenious, and worked so well, that our young inventor soon found capitalists able and willing to furnish the means necessary for the enterprise, and a patent was secured for the invention in the United States, on the 6th day of January, 1838, and in England the same year.

He contracted with parties to build three looms, they to pay a certain price for the invention, but before this contract was fulfilled on either side, he visited New York, and there saw for the first time a new and different species of counterpanes, then just introduced from England, which, from the superiority of the fabric, he perceived must soon supersede the knotted counterpanes. Although being at that time in great pecuniary want, and surrounded by all its attendant privations and temptations, instead of proceeding to the enforcement of his contract, which would have at once relieved his wants, he immediately returned to Boston, and communicated to the parties what he had seen and believed, and advised them to abandon the enterprise, as, in his judgment, the new kind of fabric would be preferred in the market, and that he could produce a loom which would weave it with greater facility than the knotted counterpanes could be woven. His success in his first effort of invention, and the honesty of purpose manifested in this his first business transaction, could not fail to inspire a degree of confidence in his ability and integrity which proved of great advantage throughout his subsequent life, in bringing all his enterprises to a successful issue.

He now entered into an agreement with the same parties to invent an automatic loom for weaving this new species of counterpanes, which was afterwards produced, and patented on the 24th of April, 1840, and put in successful operation. There are now 36 of these looms in operation at Clinton, Massachusetts, which supply the principal demands of our markets.

Before he had completed the counterpane-loom above described, he had incidentally seen in New Jersey the operation of weaving coach-lace in hand-looms, and not having as yet realized any pecuniary advantage from his efforts, he determined, while progressing with the new counterpane-loom, to direct his attention to the subject of weaving *coach-lace*. With this view, he made inquiries of persons engaged in vending this kind of fabric, as to the extent of the consumption and the cost of production, as well as the difficulties of weaving it by hand. The result of his investigation determined him to make the attempt, and, with the pecuniary assistance of an elder brother, he proceeded to the construction of a loom which was completely successful. So urgent were his necessities at this time, and such was the ardor with which he pursued the subject, that he labored day and night, scarcely taking time for food and rest, and in the short space of six weeks from the time that he made the inquiries above referred to, he had the first loom in operation, and in three months after that, another and more perfect one, and the requisite capital under his control for putting up a large establishment. This result, when we consider the youth and inexperience of the inventor, and the peculiar difficulties of the subject, seems to us to have no parallel in the history of inventions.

The figure on coach-lace is produced by raising on the surface of the ground-cloth a pile similar to the Brussels carpet, formed by looping the warps over fine wires, which are inserted under such of the warps as have been selected by the jacquard to determine the figure. The warps are then woven into the body of the cloth, to tie and fix the loops. The wires are then withdrawn and re-inserted. Automatic pincers, as if instinct with life, grasp the end of the wire, draw it out from under the forward loops, carry it back towards the lathe, where the warps are spread apart, forming what is called the open shed, and there introduce and drop it, that the shed may be closed and opened, that by the throw of the shuttle, the weft-threads, which are to tie and weave the warp-threads into the cloth, may be beaten up by the reeds. The pincers then move back to draw another wire from under the formed loops, and repeat the same operation, several such wires being used at the same time in the cloth, to prevent the loops from being drawn out by the tension which is given to the warps to insure an even and regular surface to the fabric; but as there are a number of these wires woven into the cloth, nearly touching one another, it became a matter of great difficulty to contrive a mechanism which would insure the taking of only one of these wires to draw it out, and select the proper one at each operation. The pincers could not practically be made so narrow, and work so accurately, as to insure this. This difficulty was overcome by an ingenious mechanism placed on the opposite side of the loom, which at each operation selects the required wire, and pushes it out sufficiently far beyond the ends of the others to be gripped by the fingers, which then draw it out to carry it back and introduce it in the open shed of the warps.

Some notion can be formed of the difficulties which this subject presented, by taking into consideration that the mechanism which works the wires must operate in connection with the mechanism which weaves the cloth, and the jacquard which produces the figure.

The cost of weaving coach-lace was very much reduced by this invention, and there are now in one establishment in Clinton, Massachusetts, 96 of these looms in successful operation.

Soon after this was in successful operation, Mr. Bigelow completed his second counterpane-loom, to which we have before referred, and he had then accomplished the first purpose which impelled him to exercise his ingenuity—he had acquired the means of completing his medical studies. But by this time he had found much greater attractions in the new career which circumstances had opened before him—it was one for which nature had manifestly intended him, and therefore invention was an occupa-

tion no longer ancillary, but paramount, and the success with which he has pursued it up to this day is now distinctly marked upon the pages of our industrial history.*

The coach-lace loom was merely the basis of a series of improvements then contemplated, but which have since been completed, and are now in successful use; these improvements are in looms for weaving Brussels and tapestry carpeting.

The weaving of Brussels and tapestry carpets by automatic machinery was considered by many, a few years back, to be a mechanical impossibility, and, indeed, there were few subjects that presented such formidable difficulties. After constant and laborious exertions, at times snatched from other pressing engagements, Mr. Bigelow succeeded also in this undertaking. There are now 28 Brussels looms in operation in one establishment in Clinton, producing carpets which are pronounced by the ablest judges to be the best Brussels carpets manufactured in any part of the world, and 50 tapestry looms in the establishment of Messrs. Higgins & Co., New York; and when those now in contemplation shall have been completed, there will be 225 looms in operation on his plan, weaving each, on the average, from 18 to 20 yards per day, while from 3 to 4 yards per day is the average product of hand-looms.

The surface of the carpets woven by these looms is more perfect and regular than when woven by hand, the texture of the cloth more regular, and, what is of the greatest importance, the figures are so regularly measured that, when put together, they make a perfect match. This perfection in the quality of the cloth and the regularity of the figure is in part due to improvements which will be described in connection with the ingrain-loom, as they are applicable to the weaving of all kinds of figured fabrics that require regularity in the figure.

Shortly after the completion of his coach-lace loom, Mr. Bigelow called on Mr. Alexander Wright, the agent of the Lowell Manufacturing Company, who was not only a man of great experience in manufactures generally, but possessed an intimate knowledge of the manufacture of coach-lace. From him he obtained valuable information, and in the course of their conversation, Mr. Wright called his attention to ingrain carpets, and suggested to him the importance, as well as the difficulty, of producing a power-loom for weaving that kind of fabric. The hint was not thrown away, for as soon as he had completed his second counterpane-loom, he bent his mind to improving the ingrain manufacture, and in the year 1839, through the instrumentality of Mr. Wright, entered into an agreement with the Lowell Manufacturing Company to accomplish this purpose, and before the close of that year had completed the first power-loom for weaving two-ply ingrain carpets. This loom produced from 10 to 12 yards per day—the hand-loom produced only 8 yards per day.

When his mind was first turned to this subject, it presented these leading difficulties. The mere weaving of the fabric by an automatic loom was easily effected, but to invent a loom which should make carpet fast enough to be economical, one which should make the figures match, and to have a good and regular selvage and a smooth, even face, were very serious practical difficulties. The hand-weaver, by the exercise of his judgment, can, to a certain extent, meet these contingencies; if the weft-thread is too loose after the shuttle has been thrown, he can give it a pull with the fingers to make the selvage regular; if he finds by measurement that by reason of the irregularity of the weft-threads or the ingraining, the figure is being produced too long or too short, he gives more or less force to the lathe in beating-up; and if he finds that the surface of the cloth is getting rough, he regulates the tension of the warps. In this way, by observation and the exercise of skill and judgment, he can approximate, and only approximate, to the production of a good and regular fabric. But to invent an organization of matter which should itself observe, and think, and judge, and do it all with more unerring accuracy than man himself—this was a result almost absurd to contemplate, but which it was reserved for Mr. Bigelow to attain.

In the first loom produced, he approximated more nearly than the hand-weaver to a perfect match in the figure, and this he effected by taking up the woven cloth by a regular and positive motion which was unerring, the same amount for every throw of the shuttle and beat of the lathe, and as the weft-threads are not spun regularly, and the weaving in of the warp-threads and passing the different colors from the upper to the lower ply or cloth, (as ingrain carpets are composed of two or three cloths woven and connected together,) to produce the figures, requiring sometimes more and sometimes less to make a given length, he determined to regulate the delivery of the warps as required by their tension, thereby throwing the irregularities into the thickness, where it cannot be noticed, instead of in the length, where it would destroy the match of the figures. And he accomplished this by suspending a roller on the woven cloth, between the lathe and the rollers that take up the woven cloth, so that when the cloth was being woven too short, which indicates a deficient supply of warps, the roller would be elevated, and by its connection increase the delivery motion to give out more warps; and when the cloth was being woven too long, which indicated too great a supply of warps, the roller was let down to decrease the delivery motion, and thus reduce the supply of warps. In this way the roller was made to act as a measurer and feeler of the quantity of warp demanded, and to direct the supply. But this contrivance, like the mind of the hand-weaver, only came in play to prevent the progress of an evil after it had been observed. If he had applied this yielding roller to the unwoven warps to feel and ascertain the demand of warp beforehand, he could have prevented the evil. He did not then perceive that this could be done, for the reason that this roller must be sensitive to detect and indicate the amount, and at the time the lathe beats up the weft, the warps must be rigid to resist the beat, or else a good fabric cannot be produced. This was, however, accomplished by a subsequent improvement, which will be hereafter described.

* In addition to the establishments at Lowell, Thompsonville, and other places which have been built solely for the use of his improvements, the new town of Clinton, Massachusetts, (which we have mentioned before,) situated twelve miles north of Worcester, and now containing a population of nearly 3000, is virtually the creation of Mr. Bigelow's own mind, it having been built up by business consequent upon his inventions.

A smooth and even surface for the cloth he obtained in the following manner. We have already pointed out that the passage of the warp-threads from one ply or cloth to the other, called *ingraining*, must necessarily be unequal and depending on the figure to be produced, and that in consequence of this the warp-threads that are the most ingrained will be taken up faster than those less ingrained, and as all the warps are of necessity rolled up on the warp-beam with equal tension, they can only be given out equally.

This seeming impossibility he did effectually overcome in the following manner. Each warp-thread in the usual way passes through a loop called a mail, attached to a card suspended from the jacquard, and each card has suspended to it a weight, all the weights being equal. The two trap-boards of the jacquard move simultaneously, one up and the other down, and in these movements they catch or trap such of the cords (determined by the combination of cards) as are required to bring up the proper warp-threads at each operation to produce the figure, leaving down such of them as are not required at that particular operation; and when the two trap-boards are on a level, and all the warp-threads connected with them in a horizontal line, and those not connected with them hanging down with the weights suspended to them, the lathe beats up the weft-thread which lies between the warps that are in a horizontal line, at the same time exerting a force on the weft-threads previously thrown, and beating them up more closely.

Now, as the warp-threads are all connected at one end to the woven cloth, and at the other with the beam, it follows that those which are hanging down in a bent line with the weights suspended to them, will receive a greater proportion of the force of the beat of the lathe than those which are in a straight line; and as all the warp-threads in succession take this hanging-down position, and all of them have an equal weight, it follows necessarily that each warp-thread in succession receives the same pull at the time the lathe beats up, and that therefore all tendency to irregularity in the length of the warp-threads taken up by the ingraining will not tend to produce an irregular surface, but, on the contrary, the surface of the cloth will be as smooth and even as if all the warp-threads were equally taken up in the weaving of the cloth, and were under a constant and equal tension.

At the same time he accomplished the making of a good selvage by a mechanism which handed instead of throwing the shuttle across—an arm carried the shuttle half way across, and another there took it and carried it entirely across. By this means any required degree of tension could be given to the weft to make a smooth and even selvage. But although it accomplished this desirable object, it failed to work with sufficient velocity, and thereupon Mr. Bigelow, nothing daunted, renewed his efforts, and produced another loom with the fly-shuttle, in which he was enabled to make a good selvage by a mechanism which gives a pull to the weft-thread after the shuttle has been thrown, and as the lathe beats up. He also introduced other improvements, which will be hereafter described. This loom, although it produced about 18 yards per day, did not satisfy the inventor, and he again applied himself with renewed energy until he made a third loom, which averages from 25 to 27 yards per day of two-ply, and from 17 to 18 of three-ply carpets. There are now in operation at Lowell, Thompsonville, and Tariffville, 450 of these improved looms.

This brings us to our main purpose, the description of the loom as it is now worked, with all the improvements which have been made in succession from the commencement to the date of the last patent, the 23d day of October, 1849. But before proceeding to the detailed description of this loom, it may be well to state that the improved method of producing figures that will match, which makes part of this loom, was invented in 1844, and patented on the 10th of April, 1845, in connection with a loom for weaving plaids and ginghams, which has gone into extensive use at Clinton, there being now 580 of them in one mill, and 120 in another.

In addition to the various important inventions which have been enumerated, many others have been made by Mr. Bigelow connected with the details of various kinds of looms, and for drying and stretching fabrics and printing warps, some of which have been, and others are to be, patented both in England and in this country, and which are nearly all of decided practical utility. No one man within our knowledge, either in Europe or in this country, has given to the world so large a number of valuable inventions as Mr. Bigelow, and inventions, too, evincing not only great ingenuity, but sound inductive powers of the highest order.

This invention for weaving ingrain carpets, taking it from the commencement, through all its stages, to the date of the last patent, consists:

1. In operating the trap-boards of the jacquard in a power-loom simultaneously, one up and the other down, instead of moving them alternately as in the hand-jacquard, whereby either the time required for the movements of the jacquard, or the velocity of their motion is reduced, the former admitting of more expeditious weaving (if the other operations be accelerated in the same ratio), and the latter reducing the liability to wear and tear. But there are other and important advantages incident to this change, such as balancing the weight of the harness, which in a jacquard is considerable, for that part of the harness suspended to the descending trap-board balances the corresponding harness suspended to the ascending trap-board, thus equalizing the resistance to the moving power, and rendering the operations easier and more regular. And still another change is, that the beat of the lathe takes place after the warps connected with the two trap-boards have passed and are a little crossed, and whilst the remaining warps are in their lowest position, that is, bent down by the weights suspended to their trap-cords, so that these, which like the others are held at both ends and bent down, will receive a greater portion of the force of the beat of the lathe; and as all the warps in turn take this position, and each warp-thread, when in this position, is held down by the weights—all of them equal—suspended to its trap-cord, it follows that all the warp-threads, as before stated, receive an equal tension in beating-up the weft-threads, no matter what may be the variation in their lengths between the woven cloth and the yarn-beam, occasioned by the irregularity of the ingraining. The practical weaver will appreciate this as one of the most important advantages in weaving ingrain carpets, for it presents a principle of compensation and self-adaptation to the irregularity of the ingraining due to the figure never before

attained, and by which alone such fabrics have been made with a regular and measured figure, having a face or surface as smooth and even as a plain fabric.

2d. In taking up the woven cloth by a regular and positive motion, which measures the length of cloth to be produced at each beat of the lathe when employed in connection or combination with a method of regulating the delivering out of the warps by their tension in proportion to the quantity required, and taken up in the process of weaving, and also with the holding of the warps rigid at the time the lathe beats up the weft to prevent them from yielding to the force of the beat. It will be seen that in this way the irregularities of the ingraining and of the weft-threads will be thrown into the thickness instead of the length of the cloth, for as the lathe beats up the weft-threads to the same distance each time, and a given and measured length of cloth is taken up, the same length of cloth will be woven; but if the warp-threads were free to yield at the time the lathe beats up instead of forcing up the weft-threads to the required position, the whole cloth and warp would be forced forward, and produce what is called a sleazy fabric; and this, from its loose texture, would soon accumulate to such an extent as to stop the further progress of weaving. But to prevent this, the moment the lathe begins to beat up the weft-thread, the warps are held firm to resist the force of the beat, and thus insure the carrying of the weft-thread up to the required line. In this way the two opposing or antagonistic conditions—sensitiveness to deliver out the quantity required, whatever may be the irregularity of the demand, and non-yielding to resist the beat of the lathe—are reconciled to produce the important result of weaving ingrained fabrics with a regular and measured figure; a result never before attained, even with the hand-loom.

3d. In mounting the shuttle-boxes in independent frames at the sides of the lathe, which in this way becomes a mere guide to the shuttles as they are thrown from one side to the other. The advantages of this arrangement are, first, the weight of the lathe (which must have a considerable range of motion and a high velocity) is greatly reduced, and will not, therefore, require so much power to operate it; for in weaving two and three ply carpets, particularly such as have a variety of colors, the shuttle-boxes are numerous and heavy, and in proportion to the number and weight would be wasteful of power and liable to derangement if carried by the lathe. Secondly, it affords a surer, easier, and more durable mode of operating the shuttle-boxes to shift the shuttles for the changes in the colors of the pattern, and, lastly, it is very efficient in producing a good selvage, for the moment the shuttle is thrown the weft-thread is held on a permanent bed by fingers, so that as the lathe beats it up, the pressure of the fingers affords the required friction to pull the weft-thread to make a tight and regular selvage; and the shuttle-boxes being in independent frames, the weft-thread is not drawn out of its position in the cloth by the back movement of the lathe, as in the ordinary loom. Thus, the weft-threads, when once beaten up, are retained in that position, and their parallelism in the cloth is insured.

4th. In connection with the mounting of the shuttle-boxes in independent frames by the side of the lathe, using one cam and roller to work the lathe, and another to hold it in a fixed position during the throw of the shuttle, one of the said cams being on the lathe-shaft, and the roller which works in connection with it on the lathe, and the other cam on the lathe, and its roller or wrist attached to the first cam; one of the cams being concentric to hold the lathe in a fixed position during a part of the rotation, and whilst the shuttle is being thrown, with its ends eccentric, that the roller may enter and leave it as the lathe is either gradually started or gradually arrested, and the other cam being of any form suitable for giving the lathe the required varying motions.

By this means the cam and roller, which operate the lathe, and which are, in consequence, exposed to all the strain and wear and tear, are not used to hold the lathe in a fixed position during the throw of the shuttle.

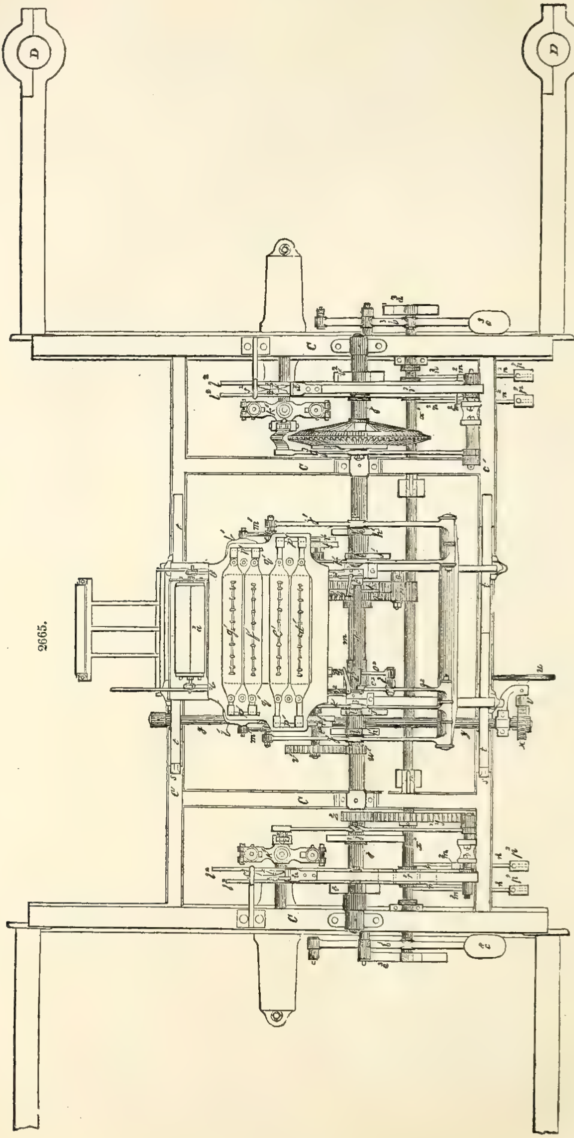
5th. In combining with a power or automatic loom four series of shuttle-boxes, two on each side in separate frames at the sides of, and independent of the lathe, the said four series of shuttle-boxes receiving motion from the loom or from some first mover in connection with, or operating in unison with the loom; one series of these shuttle-boxes on one side being for the purpose of holding all the shuttles of the various colors required for one ply of the carpet, and the corresponding series on the other side to contain the shuttles of the various colors for the other ply, so that by the up and down motions of these boxes, the various changes of colors can be effected, the other two series of shuttle-boxes being merely to receive and return the shuttle from and to the first series. In view of this, for some patterns the second or receiving shuttle-boxes may be single; but for others they are required to be double, as the colors are required to be alternated.

6th. In combining with the lathe and the shuttle-boxes in separate and independent frames by the sides thereof, hinged guides to guide the shuttles from the one to the other, and to yield and thereby prevent breaking whenever a shuttle, or any part of it, fails to enter the shuttle-boxes.

7th. In giving to the jacquard, which determines the figure, a separate organization independent of the loom which forms the cloth, that the various motions of the jacquard may be taken from or given by a shaft or shafts within it, and simply deriving its or their motions from some part of the loom, or from some first mover corresponding with or regulated by the motion of the loom or part thereof, that the motions of the jacquard may correspond with those of the loom. In this way the motions of the jacquard are rendered more accurate and steady, and the weight of the moving parts is greatly reduced.

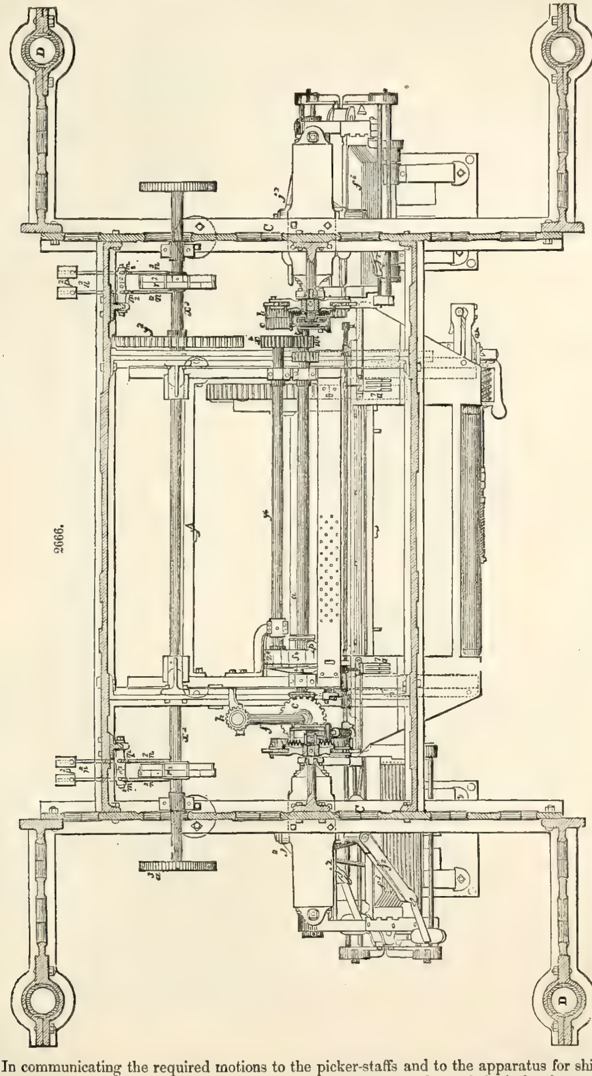
Prior to this invention, in all looms for weaving by power in connection with the jacquard, all the motions of the jacquard were derived directly from some part of the loom and communicated by connecting-rods, which were necessarily of great length. The principal difficulties attending this old mode of construction and organization were the inaccuracy of the motions by reason of the great length of the connecting-rods, the liability to derangement, and the labor and difficulty of adjusting the connections to the varying lengths of the cords of the harness as they are affected by atmospheric changes. All of which difficulties are avoided or greatly reduced by this separate organization.

8th. In making the whole frame of the jacquard adjustable at one operation relatively to the frame of the loom, that the distance between the two may be adjusted to the varying lengths of the cords of



2665.

the harness, whereby the utmost nicety in the adjustment can be obtained, and at the same time, in connection with the separate organization, avoiding the necessity of adjusting the connections when it becomes necessary to adjust the jacquard to the varying lengths of the cords of the harness, for the jacquard, having a separate organization, no change becomes necessary in its own connections.

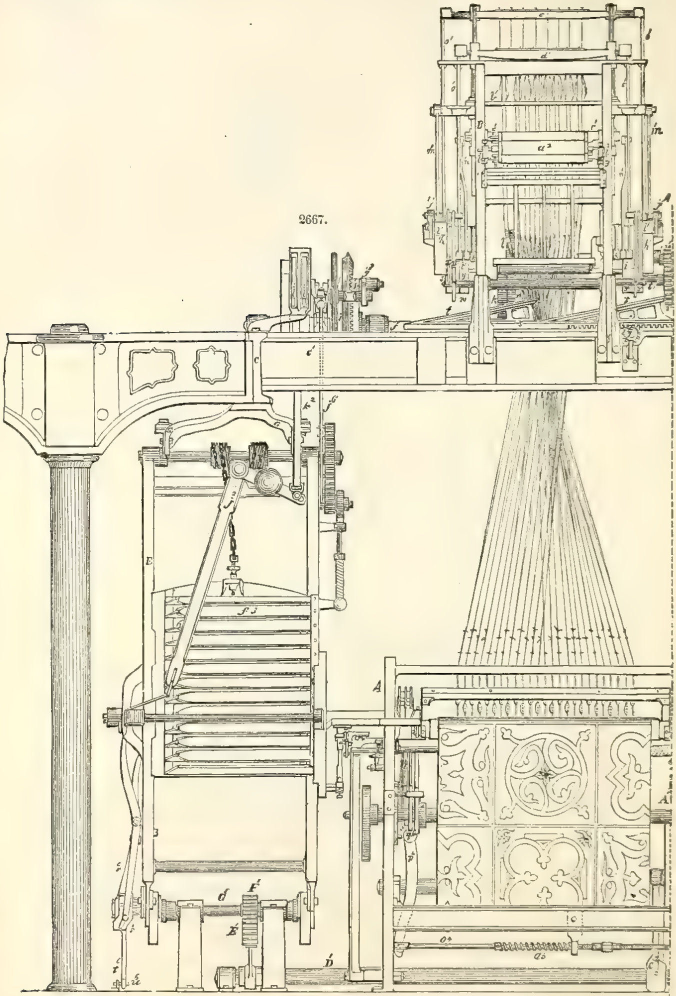


2666.

9th. In communicating the required motions to the picker-staffs and to the apparatus for shifting the shuttle-boxes hung in pendulous frames at the sides of and independent of the lathe, from a shaft or shafts above, whereby is avoided the serious difficulty before experienced of communicating the motions

from a shaft or shafts below to the picker-staff and the apparatus for shifting the shuttle-boxes which must be attached to or connected with the shuttle-box frames that vibrate on axes above. By this improved arrangement the motions are derived from a shaft or shafts coincident with or near to the axis of motion of the pendulous frames that carry the shuttle-boxes, instead of being below, where the frames have the greatest motion.

2667.



10th. In introducing in power-looms a reversing motion. Before this, power-looms were simply provided with the means of disconnecting the motive power, and arresting the momentum of the moving parts to enable the attendant to piece the threads, or to do what might be necessary preparatory to re-starting; but as the loom cannot always be stopped with the parts in the positions required, the

attendant has to reverse the motion of the loom by the application of hand-power to the driving-pulley, a mode of procedure attended with waste of time and great inconvenience, for the attendant must leave his usual position to go to the driving-pulley, and in heavy looms, such as are used for weaving carpets, much strength is required to set the machinery in motion. But by the use of a reversing motion, the attendant, without leaving his place, and by the simple motion of a lever, can operate the mechanism in either direction and to any extent desirable to bring the parts to a proper position for piecing the threads, &c., and re-starting.

In the accompanying drawings, Fig. 2665 is a plan of the loom in the present improved form.

Fig. 2666, a plan of the loom below the jacquard.

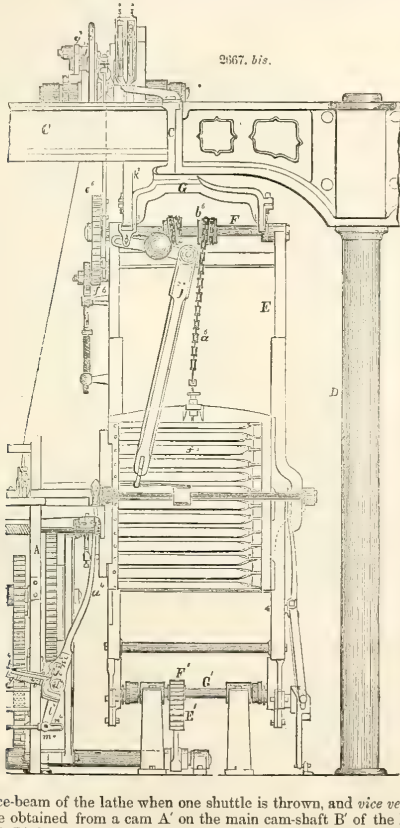
Fig. 2667, a front elevation; Fig. 2668, a back elevation.

Fig. 2669, an elevation of the left-hand side, without the jacquard; Fig. 2670, a vertical section, with the jacquard; and Fig. 2671 another section.

In the said drawings, A represents the power-loom, and B the jacquard-frame resting on beams C C C′ C′, supported on columns D from the main floor.

The pendulous frames E E, which carry the series of shuttle-boxes, are arranged on each side of the lathe, and independent thereof, and are hung on arbors F F, at the top, on which they vibrate. These frames are vibrated back and forth simultaneously, in opposite directions, at each throw of the shuttle, so that the first series of shuttle-boxes on one side, and the second or receiving boxes on the other, shall

2667. *bis.*

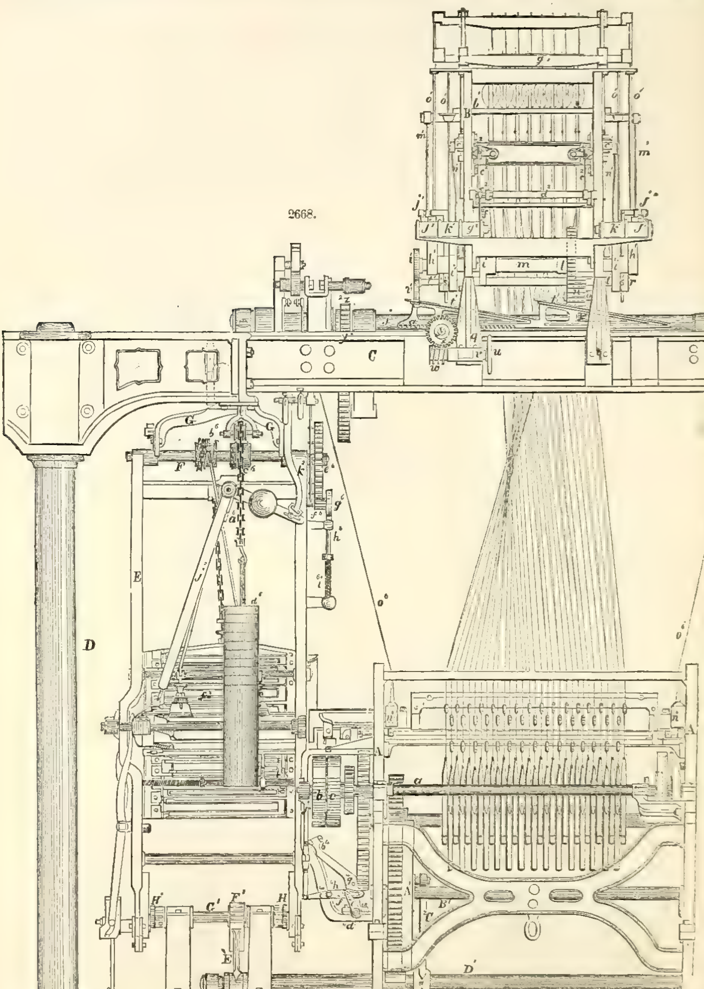


be in line with the race-beam of the lathe when one shuttle is thrown, and *vice versa* for the next throw And these motions are obtained from a cam A′ on the main cam-shaft B′ of the loom, which acts on an arm C^2 of a rock-shaft D′ that extends across the loom. This rock-shaft carries at each end a cogged sector E′, which engages a pinion F′ on a short arbor G′ (one on each side) which carries two cranks H′, one at each end, the wrists of which are fitted to grooves I′ I′ in the pendulous frames, so that as the

arbors G′ G′ are vibrated by the rotation and peculiar form of the cam A′ and the connections, the pendulous frames are vibrated in opposite directions, and there held during the throw of the shuttle, and then back again.

The driving-shaft *a* of the loom has a fast and loose pulley *b c* on one end, which receives the driving-belt from any first mover in the usual way; and on the other end the said shaft has a bevel-pinion *d*.

2668.



which takes into and drives a bevel-wheel *e* on the lower end of a line-shaft *f*, which extends up to and has its upper bearing in a box *g* attached to one of the beams C′, the upper end of the said shaft having a bevel-pinion *h*, which engages and carries a bevel-wheel *i* on one end of a horizontal shaft *j*, which has its bearings in boxes attached to the tops of the beams C. It is from this horizontal shaft that all the jacquard and shuttle motions are taken.

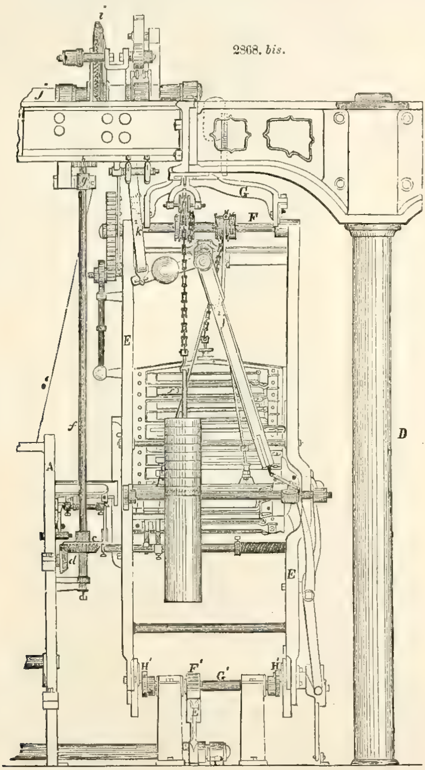
On this shaft *j* there is a cogged wheel R which communicates motion to a cog-wheel *i* on the jacquard-shaft *m*, by the medium of a connecting pinion *n*, which turns on a stud-pin *o* adjustable in a sector-mortice *p*, the curve of which is struck from the centre of the shaft *m*, that the pitch-line of the said connecting pinion may be always at the same distance from the axis of the wheel *i*, when its stud-pin is shifted. By this means, when the jacquard-frame is adjusted, the connecting pinion can also be shifted and adjusted relatively to the pinion *k* on the shaft *j*.

The frame B of the jacquard, as already intimated, instead of being permanently attached to the beams C′ C′, is free to slide vertically, for the purpose of vertical adjustment, to suit any change in the length of the harness. The side-pieces *q q* of the frame of the jacquard embrace the transverse beams C′ C′, and slide in them accurately, but freely.

The jacquard-frame rests on two horizontal slides S S, which are adapted to slide on the transverse beams C′ C′, the upper surfaces of each being formed with two inclined planes *t t*, one for each of the sides of the jacquard-frame to rest on, so that when these two slides are moved to the one side or the other, the entire jacquard-frame will be elevated or depressed relatively to the loom below, the stud-pin of the connecting pinion *n* being at the same time adjusted in its sector-mortice to adjust the pitch-line of the cogged geering. The slides S S are operated simultaneously by a hand-wheel *u* on a short arbor *v* in front, which carries a worm *w* that engages the cogs of a wheel *x* on a shaft *y* that carries two pinions *z* (only one shown in the figures) that engage the cogs of a rack *a′* on each of the slides.

For the purpose of adjustment, it is only necessary to turn the hand-wheel until the jacquard is

2868. *bis.*

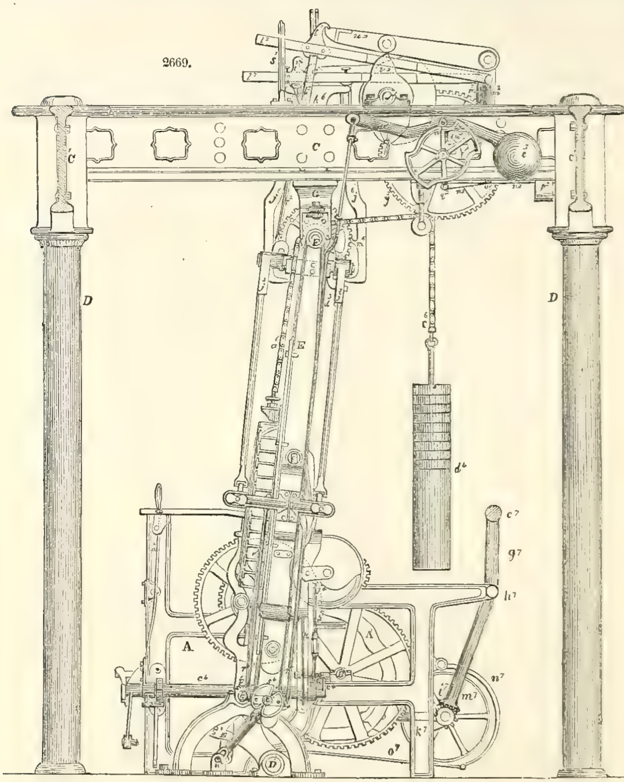


brought to the required position, and then to adjust the geering by shifting the stud-pin of the connecting pinion, the thread of the worm on the hand-wheel arbor and the inclination of the wedges being sufficient to retain the parts in a permanent position.

The required motions of the trap-boards *b′* and *c′*, and the journals *d′ e′ f′ g′*, are derived from the jacquard-shafts *m*, which, as described above, receive a continuous rotary motion from the driving-shaft

of the loom below, and the proportions of the geering, as represented in the figures, should be such as to give to the jacquard-shaft one revolution for every two of the lathe-shaft of the loom. On each end of the jacquard-shaft m there are two cams $h' h'$ and $i' i'$, which are all of the same form as represented in the figures. The cams $h' h'$ are placed on opposite ends of the shaft, and in corresponding positions to work the trap-board b', and the other two cams $i' i'$ are arranged in the same manner, but on the opposite side of the axes of the shaft m, to operate the other trap-board c', as one trap-board descends whilst the other ascends; and the form and position of the cams should be such that one trap-board shall begin to ascend as the other begins to descend. There are four levers $j' j' k' k'$ placed above the cams and operated by them, each lever being hung on a fulcrum-pin at the rear of the frame, and having a roller m which bears on the cam. The two levers $j' j'$ are connected with the ends of the trap-board b' by connecting-rods $m' m'$, that the cams $h' h'$ may communicate the required motions to it; and the

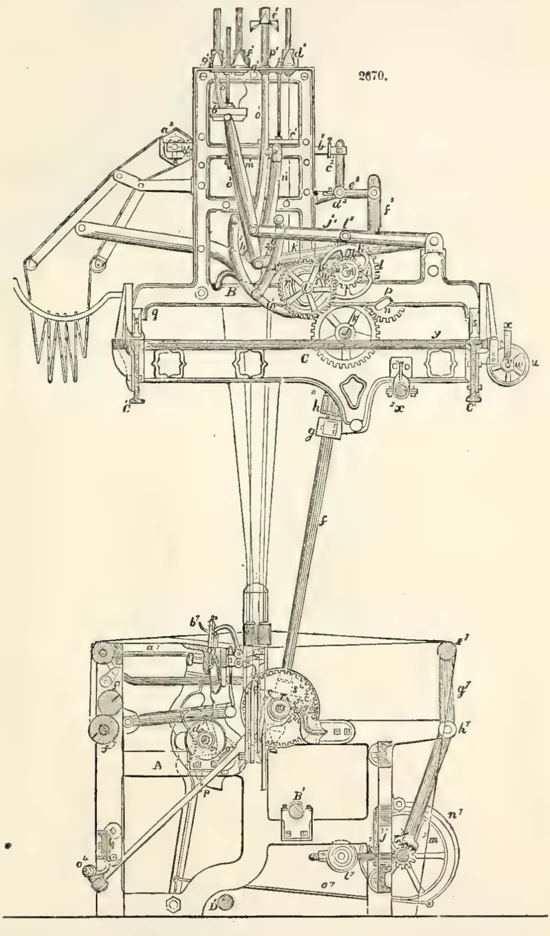
2669.



other levers $k' k'$ are in like manner and for the same purpose connected to the other trap-board c', by similar rods $n' n'$. In this way it will be perceived that the required alternate up and down motions are given to the two trap-boards. The same cams and levers are employed for operating the four journals $d' e' f' g'$. The two journals are alternately elevated with the trap-board b', and the other two $f' g'$ are in like manner operated with the other trap-board c', which is effected in the following manner: To the ends of the four levers j' and k' are jointed four rods $o' o' o' o'$, (one to the end of each,) the upper ends of which play in slots $p' p' p' p'$ in the top plate q' of the jacquard-frame—these slots being of such length that the rods can vibrate sufficiently to pass from one journal to the other. The upper ends of these rods are rounded, and enter sockets in the under face of the ends of the journals, so that when brought under either of the journals, when the levers are raised by the cams, the journals will be elevated. As there are two journals for each trap-board, and these are alternately elevated with the corresponding trap-board, the lifting-rods must be alternately shifted from the one to the other. As the

rods are so jointed as to incline outwards, when vibrated they will fall, by gravity, against the outer ends of the slots p', which are so located as to hold the rods in a position to catch under the two outer journals d' ang q'.

In this position, when either of the trap-boards are elevated, one of the journals will be carried up with it; but when the other journals are to be lifted, the rods o' are to be shifted from the outside journals to the inside ones, and this is effected by cams r' r' s' s', two on each side of the frame, and on one

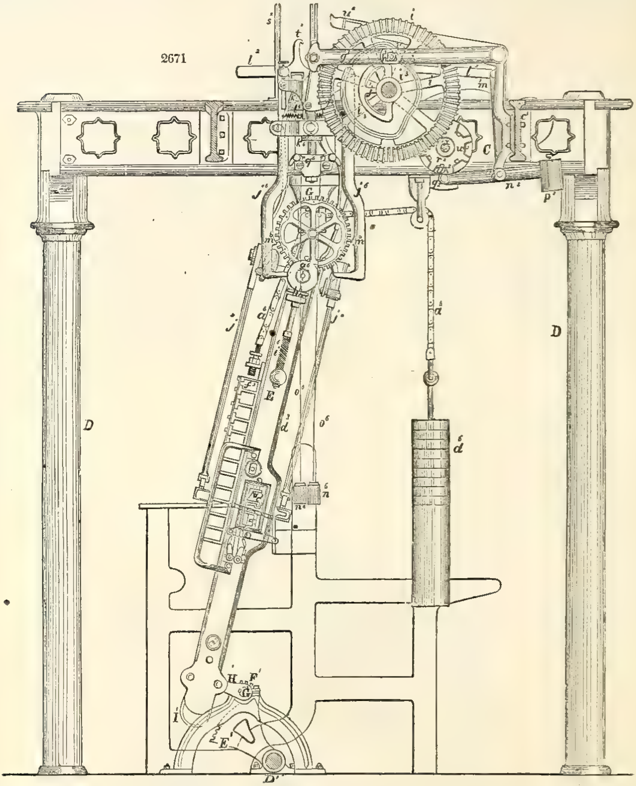


and the same shaft t', receiving motion from the shaft m' by two cog-wheels, u' v'. These four cams are all of the same form as represented in the plates, and arranged in two sets, one of each set being on each end of the shaft, and the position of the two sets relatively to each other will depend upon the form and position of the levers which they operate. On each side of the frame there are two levers, w' x', (the two sets corresponding in every particular,) that vibrate at y' on the same arbor, the one w' of which bears by the disposition of its weight on the periphery of one of the cams r', and the other x' on one of the cams s'. The arm of each of these levers acts against one of the rods o', so that there is one such lever and cam for each rod o'; and as the shaft t' of these cams makes but one rotation for every

two of the jacquard-shaft, the levers w' and x' will act upon the corresponding rods o' at every alternate descending motion of each trap-board.

The form of the cams r' and s' is such that during one rotation of the jacquard-shaft m', they elevate one set of levers w' w', to shift the two corresponding rods o' o' from one journal to the other, and during the next rotation of the jacquard-shaft they recede to permit these rods to fall back, whilst the other set of levers x' x' shift the other two rods o' o' from one to the other of the other set of journals, the next rotation liberating these and shifting the first set. In this way it will be seen that during one operation, when the trap-board c' descends, the journal g descends with it, the trap-board b' at the same time being carried up and down with the journal e'. At the end of this motion the cams r' r' throw out the levers w' w', which shift the rods o' o' to the journal f'; at the next operation the trap-board c' is

2671



elevated, and with it the journal f', the trap-board b' at the same time descending, and with it the journal e', and when this has reached the end of its down motion, the rods o' o' continue the motion down sufficiently to clear the sockets of the journals, and then by their own weight the rods fall back to the journal d', to be ready to carry it up at the next upward motion of the trap-board b'; and when this takes place the trap-board c' descends, and with it the journal f', at the end of the down motion of which the rods o' o' fall, to come under the journal g', so that at the next upward motion of the trap-board c', this journal may be elevated, during which the trap-board b' descends, and with it the journal d', and when this is entirely down, the cams s' s' act upon the levers x' x', which shift the rods o' o' to the journal e'. Thus the journals d' and e' are alternately carried up and down with the trab-board b' and the other two journals f and g' with the trap-board c'.

The journals of the card-prism a^2 (of the usual construction) are hung in the rods b^2 b^2, which slide horizontally on the sides of the jacquard-frame, and which at the back are jointed to two arms c^2 c^2 in a rock-shaft d^2, from which projects another arm e^2, connected by a rod f^2 with a treadle g^2 that vibrates

on a fulcrum-pin at the back, its front end being provided with a weight h^2 of sufficient gravity to push out the prism, the levers being elevated to draw in the prism by a cam i^2 on the jacquard-shaft m. The form of the cam i^2, and its position relatively to the trap-board cams, must be such as to bring the prism into action while the trap-boards are at rest.

The straps $k^2\,k^2\,k^2\,k^2$ of the picker-staffs $j^2 j^2$ extend up to, and are secured each to a picker-lever l^2, there being two such levers on each side, which are jointed at their back end to the upper arm m^2 of two levers $n^2\,n^2$ that vibrate on a stud-pin o^2 attached to one of the beams C.

The levers $n^2\,n^2$ constitute each two arms, at right angles with the arm m^2, the back one carrying a weight p^2 which must be sufficient to carry back the picker-lever l^2, and the forward end carries a roller q^2 which bears up against the periphery of a cam-wheel r^2, so that when the roller bears on the periphery of this wheel, the picker-lever is pushed and held forward to the full length of its longitudinal motion; but when, by the rotation of the wheel, the roller is permitted to enter a depression in its periphery, the picker-lever is drawn back. As stated above, and as represented in the plates, there are two picker-levers on each side, one for each picker-staff, and, therefore, two inverted T levers $m^2\,n^2$, and one cam-wheel r^2, for each lever $m^2\,n^2$. The forward ends of the picker-levers l^2 work between vertical guides s^2, to prevent lateral play, and they are each provided with a hook t^2, which, when the lever is drawn back, hooks into the end of the picker-treadle u^2, which is made of sufficient breadth to receive and operate the two, there being one treadle on each side, and operated at the proper periods of time by two cams $v^2\,v^2$, one for each treadle, and placed on opposite ends of the shaft j, as before described.

Each cam has two projections opposite to each other, so as to operate the treadle twice for each rotation, and the projections of the two cams are placed in the same line, so that the two treadles are operated at the same time, and the shaft makes one rotation for every two beats of the lathe of the loom; hence the treadles are both worked once for each beat. This simultaneous working of the treadles is rendered necessary, because two shuttles have frequently to be thrown in succession from the same side. As both treadles are operated for each beat of the lathe, and there are two picker-staffs on each side, at each beat of the lathe one of the picker-levers l^2 must be put in connection with one of the treadles, whilst the other remains disconnected. This is effected by drawing back the picker-lever which is to be operated, until its hook catches into one of the treadles, and this must be done whilst the treadle is down, and at rest. The manner in which the picker-treadles are drawn back to effect the hooking on to the treadle has already been described, as also the manner of pushing them forward to carry their hooks beyond the range of motion of the treadles, and it only remains to explain how the succession is determined. This is done by means of four cam-wheels r^2, which act on the four levers $n^2\,m^2$, as described above. These cam-wheels are formed with a series of cam-like depressions u^2 made at equal distances around the periphery, into each of which the rollers of the levers n^2 enter; and when this takes place, the weights on the levers n^2 draw the picker-levers so far back that the treadles in rising catch under the hooks and elevate the picker-levers, and the further rotation forces out the rollers from the cam-like depression on to the periphery of the circle of the wheels, which forces the picker-levers so far forward as to disengage the hooks. There must be as many of these cam-like depressions in each cam-wheel as the number of changes of shuttle required in the kind of fabric to be woven; eight being the number represented in the plates for eight changes of shuttle. To each of these depressions is fitted a block, which when put in renders the periphery of the wheel cylindrical; and when all are in, the picker-levers will not be engaged or hooked by the treadle, and hence no shuttle will be thrown; and, therefore, in setting the loom for any particular kind of fabric, the operator will leave out of each of the cam-wheels as many of these blocks, and in the order required, as may be necessary for operating the picker-staffs in the order required for the succession of the shuttles. The four cam-wheels r^2 are on a shaft x^2, parallel with, and receiving motion from the shaft j, by a cog-wheel and pinion $y^2\,z^2$, the shaft x^2 making one rotation for four of the shaft j. The plates represent the back, or receiving shuttle-boxes $c^3\,c^3$, as consisting of two on each side, although for some kinds of fabrics but one is required, in which case they are not required to be operated in the pendulous frames. When the two are used on each side, they are adapted to slide in the back of the pendulous frames, and are suspended each to one end of a lever b^3, by a connecting-rod d^3, the rear end of the said levers being provided with a sufficient weight e^3 to lift the boxes, in order to bring the lower box of the series in line with the race-beam of the lathe; and when the upper box is to be let down to receive a shuttle, the weighted end of the lever is elevated by a cam a^5 on the end of the shaft x^2, before described as carrying the cams to determine the succession of the motions of the picker-staffs. The form of the cams a^3 will of course depend on the pattern to be woven, and as they are on the ends of the shaft, they can be removed and other cams of different forms substituted. The front series of shuttle-boxes $f^3\,f^3$ are represented as consisting of twelve shuttle-boxes on each side, adapted to work patterns requiring twenty-four shuttles. As the two series are operated in like manner, it is only necessary to describe one series.

These shuttle-boxes f^3 are all connected together, and slide in the front of the pendulous frame, and are suspended to a chain a^6 that is attached to and winds on a barrel b^6 on the arbor F of the pendulous frame; and this arbor carries another barrel, on which winds another chain c^6 that passes over a guide-pulley, and has a counter-weight d^6 suspended to it to counterbalance the shuttle-boxes, the weight being made in sections, that it may be regulated to suit the number of shuttles employed. As the shuttle-boxes are connected with the arbor F, it will be obvious that their weight will carry them down, when permitted so to do by the turning of the arbor in one direction, and that they will be lifted when the arbor is turned in the reverse direction. On the inner end of the said arbor there is a cog-wheel e^6, the cogs of which engage a pinion f^6 of one-sixth its diameter, which has attached to its face a wheel g^6 with a portion of its periphery cut off, against which bears a stop h^6 on the end of a rod surrounded by a helical spring i^6, which forces the stop against the periphery of the wheel cut out, so that when the wheel is turned, the pressure of the stop shall have the effect to stop the wheel, to aid in bringing the parts to a state of rest in the proper position, and there hold them. The wheel e^6 has six

pins projecting from its inner face, at equal distances apart, and so proportioned that the turning of the wheel the distance of one of these pins shall shift the shuttle-boxes to a distance required for one change. There are two rods $j^6 j^6$, one on each side of the axis of the wheel e^6, and so far apart that when thrown out they will not touch the pins on the wheel. These rods are jointed to a sliding-frame k^6 above, adapted to work on a guide-rod, and suspended to a lever g^3 that carries a roller h^3 working in a cam-groove i^3 on the shaft j^2, which makes two revolutions to each beat of the lathe, so that the lever and rods j^6 will be carried up and down every alternate beat of the lathe; and there being a similar arrangement on each side of the loom, with the cams placed on opposite sides of the axis, one set will be worked for each beat of the lathe. The rods $j^6 j^6$ before described, are drawn together by a helical spring l^6 to bring their inner edges against the pins of the wheel e^6. Their inner edges are formed each with a hook m^6, so that when drawn up the hooks catch under the pins to turn the wheel; and as the two rods are on opposite sides of the axis of the wheel, the wheel can be turned in either direction if the appropriate hook be brought in the required position. The manner in which the rods are drawn inwards has been pointed out. They are kept out so that their hooks shall not engage the pins as they are moved up and down at each operation, by means of weights $n^6 n^6$ (represented by dotted lines) suspended to cards $o^6 o^6$ attached to levers $q^6 q^6$, which by the force of the weights are made to bear against the inner faces of the said rods j^6, and to overcome the tension of the spring which tends to draw them in. The weights $n^6 n^6$ are connected each to one of the cards (not represented) of the jacquard, so that when either weight is lifted by the jacquard, the corresponding rod j^6 will be drawn inwards by its spring, and hence, when drawn up by the rotation of the cam, as before described, its hook will catch under one of the pins and turn the wheel, and hence shift the shuttle-boxes. As these movements are very quick, and it is important that the shifting motion be accurate, the two rods are bent in at their lower ends to such an extent, that when drawn up, with the hook of one turning the wheel at the required extent of motion, the said bent projection of the other comes in contact with another one of the pins on the wheel, and thus effectually stops the movements. In this way it will be seen that by the punching of the cards that operate the needles connected with the cards that control the weights to disengage the hooks, the shuttles can be shifted to suit any variety of changes of color in the pattern.

The connection between the frames that carry the hook-rods $j^6 j^6$ and the levers operated by the cams to give the shuttle-motions, is by means of spring-gripes, which hold by friction surface, so that in case of an imperfect throw of a shuttle, or any other impediment, the connections will yield instead of breaking. This is effected in the rear or receiving shuttle-boxes by the weighted lever, which is sufficient to move the boxes, but not to strain the parts in case of any impediment.

When a shuttle enters either of the boxes, it is arrested in part by its point striking against the picker, which soon becomes so indented as to permit the point of the shuttle to lodge therein, and therefore it will be seen that in this condition of the parts the shuttle-boxes could not be shifted, or rather would be seriously impeded, for the shuttle being in the box which is to rise, and its point imbedded in the picker, which does not move up, the parts would thus be held or strained. To prevent this, at the time the shuttle enters a box the picker is forced inwards by a lever r^6, which is afterwards drawn back to permit the picker to be drawn back clear of the point of the shuttle by the spring of the picker-staff. There are four such levers r^4, one for each series of shuttle-boxes; they turn on fulcrum-pins on the pendulous frames, and at their lower ends carry wrist-pins that work in cam-grooves on wheels s that turn on stud-pins on the lower ends of the pendulous frames, and from each of these wheels extends an arm t^6 with a slot near the end, playing on a pin u^6 attached to the floor, so that as the pendulous frame vibrates, the required vibratory motion shall be given to the cam-groove wheels One such cam-groove wheel answers for two levers, as shown in the plates.

The warps pass from the warp-beam below the floor, and pass over a roller e^7 above the warp-beam, and thence through the mails of the trap-cards in the usual manner of mounting a jacquard loom. The woven cloth from the breast-beam passes between two rollers $f^7 f^7$, one of which is weighted to make pressure against the other, that the cloth may be gripped between the two with sufficient force to prevent it from slipping. And thence the cloth is wound upon the cloth-beam, (not represented,) which is driven by a friction-strap with sufficient velocity to take up the slack, the band slipping on the pulley when the diameter of the beam becomes so large as to tend to wind on the cloth faster than it is carried forward by the two rollers $f^7 f^7$, which constitute what is called a positive take-up motion, and which receive the same motion for each beat of the lathe, that the same length of cloth may be taken up for each operation of the loom, and thus measure the figure to be produced on the cloth. As the mechanism for giving this regular and positive take-up motion to the rollers was not invented by Mr. Bigelow, but was previously well known to weavers, it is deemed unnecessary to give a description of it here.

The mode of operating the yarn-beam is not represented, but it will be understood with sufficient clearness from the description alone.

On the shaft of the yarn-beam there is a cog-wheel operated by a worm on a vertical shaft, which carries a crown ratchet-wheel, the teeth of which are engaged by a pall, or ratchet-hand, on the end of a rod jointed to the sword of the lathe, so that as the lathe beats back, by the connections described, the ratchet-wheel is turned a given portion of a revolution, which shall be sufficient to give out the required quantity of warp-threads for any one operation of the loom. But as the diameter of the beam is constantly varying, beginning with a large diameter, and gradually diminishing as the warps are given out, and the demand for warps is constantly varying, by reason of the irregularities of the weft-threads and the ingraining of the fabric, the regular and positive motion of the warp-beam given by the mechanism requires to be varied to suit the varying conditions above described. This, as before intimated, is governed by the tension of the warps between the beam and the woven cloth. The roller e^7 over which the warps pass from the warp-beam is hung in the upper ends of two levers $g^7 g^7$ which have their fulcra at h^7; and the lower arms of these levers are formed in sector-racks i^7, the cogs of

which engage pinions j^7 on the ends of a shaft, and this shaft is provided with an arm which carries a weight l^7, which, by the connections of the pinions and sector-racks, tends always to force back the roller e^7 to keep the warps under the same, or nearly the same tension. This weight is adjustable on the arm by a set-screw, to regulate the degree of tension, to suit the quality of the warps and the fabric to be produced. From this it will be seen not only that the warps will be always kept under the same degree of tension during the operation of weaving, a condition very essential to the production of a fabric of regular texture, but if the quantity of warps given out by the warp-beam be greater than the quantity taken up in weaving, the roller will be carried back by the weight, and that when the quantity is less than enough, the roller will be drawn forward. This motion of the roller is made use of to regulate the motion of the warp-beam in the following manner: On the shaft before described there is another arm, to which is jointed one end of a connecting-rod, the other end of which is in turn jointed to an arm which turns on the arbor just above the ratchet-wheel, and this arm carries a plate that rests on the face of the ratchet-wheel, so that when the roller is carried back by the action of the weight when the supply of warps is too great, the shaft is turned in one direction, which, by the connection described, carries the plate so far over the surface of the ratchet-wheel as to cover all, or only a portion of the teeth which would otherwise have been engaged by the band, and hence the let-off motion of the warp-beam is either entirely or partly prevented; and when, on the other hand, the roller is drawn forward by the amount of warps given being insufficient, the plate is drawn back, which permits the band to engage the teeth of the ratchet, and to operate the warp-beam, to give out the required quantity of warps. In this way the supply of warps is proportioned to the demand, and the cloth being taken up by a positive and measured quantity at each operation, it follows that the irregularities will be thrown into the thickness instead of the length of the cloth, and hence the figures will be produced of a regular and measured length, whatever may be the irregularities of the weft-threads and the ingraining.

But there is still another condition which is important to be observed. The roller e^7 must be sufficiently sensitive to yield to the tension of the warps under the force of the weight suspended to the arm of the shaft connected with the levers that carry the roller; and hence, when the lathe beats up the weft-threads, it would yield to the force of the beat, particularly in weaving fabrics of a close texture, which motion would have the effect to prevent the full action of the reed, and cause the cloth of loose texture to lay up in front of the reed, and in a short time impede the proper working of the loom. To prevent this, the shaft carries a wheel m^7, and around a portion of its circumference passes a friction-brake, n^7; that is, a metal strap jointed to the frame and to a connecting-rod o^7, attached to the sward of the lathe, so that when the lathe beats up, this metal strap is drawn in contact with the periphery of the wheel, and thus by friction holds it firmly so that it cannot turn, by the connections holding the roller firmly, that the warps may be prevented from yielding to the force of the beat of the lathe. In this way the desired effect is produced; viz., that of producing a close fabric of regular texture and measured figure, with the irregularities thrown into the thickness instead of the length of the cloth.

So soon as the shuttle has been thrown the weft-thread lies between the warps in a diagonal line from the selvage on one side to the shuttle-box on the other, and this diagonal line being longer than the breadth of the cloth, it is evident that if the weft-thread were beaten up freely, it would become loose and produce a bad selvage. To prevent this, the sides of the frame at a^7 constitute a bed on each side, grooved to receive a series of fingers b^7, jointed to the frame, and the moment the shuttle has passed a cam d^7, on the lathe-shaft, permits the fingers to fall on to, and gripe the weft-thread, so that when it is carried forward by the reed it is resisted by the pressure of the fingers, which gives the required pull to insure a good selvage. The cam then passes around to lift the fingers, that the shuttle may pass. These fingers are made to answer the purpose also of stopping the loom when the weft-thread has not been carried across; for then, as the fingers descend, not being held up by the weft-thread, they enter the grooves, and the arm at the back acts as catch-levers connected with the shipper to stop the loom.

The manner of operating the lathe has been described with sufficient clearness in pointing out the characteristics of this invention, and it is therefore unnecessary to give a more detailed description of it.

The belt is shifted from the loose to the fast pulley, and *vice versa*, by the belt shipper a^4, and belt-guide b^4, in the usual way; but to adapt this to the introduction of a reversing motion, the shipper and the guide are differently arranged. The shipper a^4, and the belt-guide b^4, are on opposite ends of a shaft c^9, hung in appropriate boxes, and this shaft is hollow, and within it there is an arbor d^4, which extends out at each end. From the rear end of this inner arbor projects an arm e^4, which carries a wrist-pin f^4, that fits and slides freely but accurately in a curved mortise g^4, in one arm of a lever h^4, that turns on a fulcrum-pin i^4, its other arm being jointed to the connecting-rod of the brake j^4, that works against the inner periphery of the fast pulley b, in the usual way of arranging the brake for arresting the operation of the loom when the belt is shifted from the fast to the loose pulley. When the inner arbor d^4 is therefore connected with the shaft of the shipper, the brake is operated to make friction on the fast pulley when the belt is shifted to the loose pulley, and liberated to relieve the friction when the belt is shifted to the fast pulley, the motion of the shipper to shift the belt from the one to the other of the pulleys being sufficient to move the arm e^4, so that its wrist f^4 shall move over a distance equal to half the length of the curved mortise in the lever of the brakes, the curve and the length of this mortise being such that moving the wrist-pin from either end of the mortise to the middle will force the brake against the pulley to make friction, and moving it from the middle towards either end will remove the brake. As I employ the loose pulley for the purpose of giving the reverse motion, it becomes necessary in the first place to stop the loom, and then to start it in the reverse direction, and therefore in shifting the belt from the fast to the loose pulley, the brake at first must be operated to make friction to arrest the parts, and then liberated whilst the mechanism of the reversed motion is brought into action. This is effected in the following manner: on the front end of the arbor d^4, when it projects beyond the hollow shipper-shaft, there is an arm g^4, which projects out towards the middle

of the loom, nearly in a horizontal direction and at a convenient height to be reached by the attendant's foot. On this arm is journalled a treadle h^4, and so connected with the arm g^4, by means of a helical spring i^4, that when no force is applied to it, an arm j^4, which projects upward from its inner end, is held against a projection k^4 of the shipper, so that the arbor of the brake and the shaft of the shipper are kept in a locked condition by the helical spring i^4 to be operated together; but when pressure is applied on the top of the treadle, then the brake is operated separately to remove the friction from the pulley. When the attendant moves the shipper towards him, the belt is shifted from the fast to the loose pulley, the brake at the same time being drawn down to make friction for arresting the momentum of the moving parts, and then the attendant with his foot forces down the treadle which relieves the brake, thereby liberating the parts preparatory to the reversing motion which is brought into action by the same motion. From the bottom of the treadle projects an arm l^4, that carries a pin m^4, that plays freely in a mortise n^4, in the end of a sliding-rod o^4, and the length of this mortise is such that the motions given to the arm l^4 by the ordinary motions of the shipper will not communicate motion to the sliding-rod, but when the treadle is borne down to relieve the brake after the shifting of the belt into the loose pulley, the sliding-rod is drawn in the direction of the arrow.

The sliding-rod o^4 is jointed to the lower arm of a lever p^4, which turns on a fulcrum-pin q^4, its upper arm being forked and made to embrace the collar r^4 of a wheel s^4, which slides freely on the main driving-shaft a of the loom. When the sliding-rod o^4 is drawn in the direction of the arrow, it forces the wheel s^4 against the face of a friction-plate u^4, which is fast on the main shaft, and this friction-plate has the effect of locking it with the main shaft, so that any motion given to this wheel s^4 will drive the main shaft. The hub v^4 of the loose pulley carries a pinion w^4, which engages another pinion x^4, on a parallel shaft y^4, the other end of which has a pinion z^4, which engages cogs on the inner periphery of the wheel s^4, so that the motion of the loose pulley communicates a reversed motion to this wheel, which drives the main shaft in the reversed direction whenever they are locked together by the friction-plate.

The moment the attendant removes his foot from the treadle, the wheel is withdrawn from the friction-plate by the tension of a helical spring a^5, on the slide-rod o^4, and the parts are then in a condition for starting the loom by the shifting of the belt on to the fast pulley.*

MACHINES are instruments employed to regulate motion, so as to save either time or force.

The maximum effect of machines is the greatest effect which can be produced by them. In all machines that work with a uniform motion there is a certain velocity, and a certain load of resistance, that yields the greatest effect, and which are therefore more advantageous than any other. A machine may be so heavily charged that the motion resulting from the application of any given power will be but just sufficient to overcome it, and if any motion ensue it will be very trifling, and therefore the whole effect very small. And if the machine is very lightly loaded, it may give great velocity to the load; but from the smallness of its quantity the effect may still be very inconsiderable, consequently between these two loads there must be some intermediate one that will render the effect the greatest possible. This is equally true in the application of animal strength as in machines.†

1. The maximum effect of a machine is produced when the weight or resistance to be overcome is four-ninths of that which the power, when fully exerted, is able to balance, or of that resistance which is necessary to reduce the machine to rest; and the velocity of the part of the machine to which the power is applied should be one-third of the greatest velocity of the power.

2. The moving power and the resistance being both given, if the machine be so constructed that the velocity of the point to which the power is applied be to the velocity of the point to which the resistance is applied, as four times the resistance to nine times the power, the machine will work to the greatest possible advantage.

3. This is equally true when applied to the strength of animals; that is, a man, horse, or other animal will do the greatest quantity of work, by continued labor, when his strength is opposed to a resistance equal to four-ninths of his natural strength, and his velocity equal to one-third of his greatest velocity when not impeded.

Now, according to the best observations, the force of a man at rest is, on an average, about 70 lbs.; and his greatest velocity, when not impeded, is about 6 feet per second, taken at a medium. Hence the greatest effect will be produced when the resistance is equal to about 31 1-9th pounds, and his uniform motion 2 feet per second.

The strength of a horse at a dead pull is generally estimated at about 420 pounds, and his greatest

* The history of the invention of this machine is so full of instruction to the young mechanic, and the facts of the case coming entirely within our own knowledge, we have been induced to dwell upon them, although by so doing we have departed somewhat from the original plan of the Dictionary, which would confine all description to the machines themselves.

† These conditions are deduced from the following empirical expression, which is adopted by Euler and other writers, to represent the law of the moving power: Let $P =$ the power applied, (or weight which the power, when fully exerted, is just able to overcome;) $R =$ the resistance, or load, or weight to be overcome; c the greatest velocity, or that at which the power ceases to act; $v =$ any other velocity: then the law of the moving power is

$$R = P\left(1 - \frac{v}{c}\right)^2$$

The variables in this expression are R and v, and the effect is represented by the product Rv; on making which a maximum, the rules of the differential calculus give $v = \frac{1}{3}c$; whence the formula becomes $R = \frac{4}{9}P$.

From these expressions it follows, that when the moving power and the resistance are both given, if a machine be so constructed that the velocity of the part to which the power is applied is to the velocity of the part to which the resistance is applied in the ratio of 9 R to 4 P, the effect of the machine will be a maximum, or it will work to the greatest possible advantage. The above conditions apply equally to machines impelled by animal force and the agents of nature, as running water, steam, the force of gravity, &c. An animal exerts itself to the greatest advantage, or performs the greatest quantity of work in the least time, when it moves with about one-third of the utmost speed with which it is capable of moving, and is loaded with four-ninths of the greatest load which it is capable of putting in motion.

rate of walking 10 feet per second; therefore the greatest effect is produced when the load $= 186\frac{2}{3}$ pounds, and the velocity $\frac{10}{3}$, or $3\frac{1}{3}$ feet per second.

4. A machine driven by the impulse of a stream produces the greatest effect when the wheel moves with one-third of the velocity of the water.

The following may be taken as a general arrangement of machines:

Class I.—*Machines for overcoming inertia.*

Machines for raising weights.	Blowing machines.
Machines for transporting weights on land.	Machinery for ascending and descending in fluids.
Machines for raising water.	Machines for navigation, &c.

Class II.—*Machines for overcoming cohesion.*

Ploughs.	Cutting machines.
Drilling machines.	Machines for cleaning, or removing impurities.
Reaping machines.	Grinding machines.
Threshing machines.	Machines for turning.
Mills.	Machines which act by compression.
Boring machines.	Pile engines, &c.

Class III.—*Machines for combining materials.*

Machines for weaving cloths, carpets, nets, stockings.	Machine for combining materials in brewing, &c.

Class IV.—*Machines for measuring forces.*

Anemometers.	Machines for measuring the elasticity and strength of materials.
Torsion machines.	Dynamometers for measuring the force of men, animals, and other agents.
Balances and steelyards.	Machines for measuring the force of projectiles.
Barometers.	Machines for measuring the force of running water.
Thermometers.	
Hygrometers.	

Class V.—*Machines for measuring and dividing space.*

Quadrants.	Goniometers.
Circles.	Dividing machines.
Theodolites.	Odometers.
Levels.	Drawing and copying instruments.
Micrometers.	

Class VI.—*Machines for measuring time.*

Machinery.—The utility of machinery, in its application to manufactures, consists in the addition which it makes to human power, the economy of human time, and in the conversion of substances apparently worthless into valuable products. The forces derived from wind, from water, and from steam, are so many additions to human power. The difference between a tool and a machine is not capable of very precise distinction, nor is it necessary, in a popular examination of them, to make any distinction. A tool is usually a more simple machine, and generally used by the hand; a machine is a complex tool, a collection of tools, and frequently put in action by inanimate force. All machines are intended to transmit power. Of the class of mechanical agents by which motion is transmitted—the lever, the pulley, the wedge—it has been demonstrated that no power is gained by their use, however combined. Whatever force is applied at one part can only be exerted at some other, diminished by friction and other incidental causes; and whatever is gained in the rapidity of execution, is compensated by the necessity of exerting additional force. These two principles should be constantly borne in mind, and teach us to limit our attempts to things which are possible.

1. *Accumulating power.*—When the work to be done requires more force for its execution than can be generated in the time necessary for its completion, recourse must be had to some mechanical method of preserving and condensing a part of the power exerted previously to the commencement of the process. This is most frequently accomplished by a fly-wheel, which is a wheel having a heavy rim, so that the greater part of the weight is near the circumference. It requires great power, applied for some time, to set this in rapid motion; and when moving with considerable velocity, if its force is concentrated on a point, its effects are exceedingly powerful.

2. *Regulating power.*—Uniformity and steadiness in the motion of the machinery are essential both to its success and its duration. The governor, in the steam-engine, is a contrivance for this purpose. A vane or fly, of little weight, but large surface, is also used. It revolves rapidly, and soon acquires a uniform rate, which it cannot much exceed; because any addition to its velocity produces a greater addition to the resistance of the air. This kind of fly is generally used in small pieces of mechanism, and, unlike the heavy fly, it serves to destroy instead of to preserve force.

3. *Increase of velocity.*—Operations requiring a trifling exertion of force may become fatiguing by the rapidity of motion necessary, or a degree of rapidity may be desirable beyond the power of muscular action. Whenever the work itself is light, it becomes necessary to increase the velocity in order to economize time. Thus, twisting the fibres of wool by the fingers would be a most tedious operation. In the common spinning-wheel, the velocity of the foot is moderate, but, by a simple contrivance, that of the thread is most rapid.

4. *Diminution of velocity.*—This is commonly required for the purpose of overcoming great resistances with small power. Systems of pulleys afford an example of this.

5. *Spreading the action of a force exerted for a few minutes over a large time.*—This is one of the most common and useful employments of machinery. The half-minute which we spend daily in winding up our watches is an exertion of force which, by the aid of a few wheels, is spread over 24 hours.

6. *Saving time in natural operations.*—The process of tanning consists in combining the tanning principle with every particle of the skin, which, by the ordinary process of soaking it in a solution of the tanning matter, requires from six months to two years. By inclosing the solution, with the hide, in a close vessel, and exhausting the air, the pores of the hide being deprived of air, exert a capillary attraction on the tan, which may be aided by pressure, so that the thickest hides may be tanned in six weeks. The operation of bleaching affords another example.

7. *Exerting forces too large for human power.*—When the force of large bodies of men or animals is applied, it becomes difficult to concentrate it simultaneously at a given point. The power of steam, air, or water, is employed to overcome resistances which would require a great expense to surmount by animal labor. The twisting of the largest cables, the rolling, hammering, and cutting of large masses of iron, the draining of mines, require enormous exertions of physical force, continued for considerable periods.

8. *Executing operations too delicate for human touch.*—The same power which twists the stoutest cable and weaves the coarsest canvas may be employed, to more advantage than human hands, in spinning the gossamer thread of the cotton, and entwining the meshes of the most delicate fabric.

9. *Registering operations.*—Machinery affords a sure means of remedying the inattention of human agents, by instruments, for instance, for counting the strokes of an engine, or the number of coins struck in a press.

10. *Economy of materials.*—The precision with which all operations are executed by machinery, and the exact similarity of the articles made, produce a degree of economy in the consumption of the raw material which is sometimes of great importance.

11. *The identity of the result.*—Nothing is more remarkable than the perfect similarity of things manufactured by the same tool. This result appears in all the arts of printing: the impressions from the same block, or the same copper-plate, have a similarity which no labor of the hand could produce.

12. *Accuracy of the work.*—The accuracy with which machinery executes its work is, perhaps, one of its most important advantages. It would hardly be possible for a very skilful workman, with files and polishing substances, to form a perfect cylinder out of a piece of steel. This process, by the aid of the lathe and the sliding-rest, is the every-day employment of hundreds of workmen.

Machines are classed under different denominations, according to the agents by which they are put in motion, the purposes they are intended to effect, or the art in which they are employed.

The reader is referred to the various machines, under their respective heads.

MAGNET—MAGNETISM. The magnesian stone, or *native* magnet, abounds in various parts of the earth, especially in iron mines, where it is found massive, frequently crystallized, and occasionally in beds of considerable thickness. Its constituents are, for the most part, oxygen and iron under the form of two oxides, the black and red. In 100 parts, we have about 73 parts iron and 27 oxygen: it has been termed *magnetic iron ore*. Its color varies from a reddish black to a deep gray. Native magnets from Arabia, China, and Bengal are commonly of a reddish color, and are powerfully attractive Those found in Germany and England have the color of unwrought iron.

The specific gravity of magnetic iron ore is about 4½ times that of water, and affords, when worked, excellent bar-iron.

This remarkable substance has not only the power of drawing apparently towards itself small particles of iron, but it has also the important property of communicating or propagating, as it were, its own attractive power through a series of masses, so as to cause them to hang one on another in a sort of linked chain.

If the magnet be suspended by a delicate silk line from some point between the surfaces of attraction, so as to admit of its turning freely on that point, the mass will rest only in one position: this position will be such as to place its poles either in the line of the meridian, or very near it; one of the surfaces of the mass will have turned towards the north, and the opposite surface towards the south, and, if drawn aside from this position, will continue to vibrate backwards and forwards until it again rests in the same position.

The attractive force of the loadstone or natural magnet cannot generally be considered as of any great amount. Native magnets in their rude state will seldom lift their own weight, and, with some rare exceptions, their power is limited to a few pounds.

The effective power of the loadstone may be considerably improved by means of what is termed an *armature*, which consists of small pieces of very soft iron applied to the opposite polar surfaces of the stone, and projecting a little below it on each side. The attractive force is thus transmitted to the small projecting or artificial poles of iron; this is found not only to augment the power, but also to enable the experimentalist to bring both the poles to bear upon any given mass at the same instant.

The pieces intended for the armature should be made of very soft iron, and each formed with a vertical face about ⅛th to ¼th of an inch thick, with a projecting solid foot below, as at $a\,p$ and $b\,n$, Fig. 2672; the vertical face being closely applied to the polar surfaces, and the mass allowed to rest on the projecting feet $p\,n$, forming the artificial poles. Things being thus arranged, the whole is bound firmly together by a cap of silver or brass, or by plain metallic bands, as represented in A B and C D, Fig. 2673. A ring R is usually fixed in the upper part of the cap for the convenience of raising the whole mass, and a transverse piece of soft iron K, termed a keeper or lifter, furnished with a central hook G, is placed across the artificial poles $p\,n$, so as to unite them. This keeper is found to preserve and increase the attractive force of the poles, especially if the magnet be suspended by its upper ring R, and weights be attached to the hook G, and by which its power may be roughly estimated.

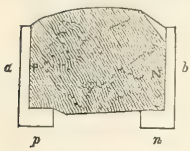
If the armed magnet be thus suspended, and a small scale-pan attached to the keeper K, an additional

weight may be added daily for a considerable time: the loadstone thus armed may be caused to sustain from twenty to thirty times its own weight.

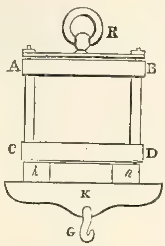
When an armed loadstone is employed for particular experimental inquiries or other purposes, the keeper K may be removed, but it should be replaced when the magnet is not in use.

If we suspend a magnet by a fine silk fibre over another magnet, or near another magnet also suspended, the poles of these magnets will arrange themselves in such a way as to bring the opposite poles together; the similar poles are found so powerfully and reciprocally repulsive, as not to allow the masses to rest with their similar poles in juxtaposition.

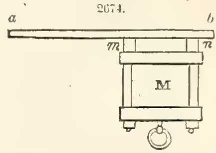
2672.



2673.



2674.



Pieces of common iron, which have been for a great length of time in one fixed position, or underground, acquire considerable polarity—in fact, become magnets. In the "Memoirs of the Academy of Sciences" for 1731, we find an account of a large bell at Marseilles having an axis of iron: this axis rested on stone blocks, and threw off from time to time great quantities of rust, which, mixing with the particles of stone and the oil used to facilitate the motion, became conglomerated into a hardened mass: this mass had all the properties of the native magnet. The bell is supposed to have been in the same position for 400 years.

The artificial magnet.—To make an artificial magnet, procure a small bar of steel about 8 inches in length, ¼th of an inch wide, and ⅛th of an inch thick, or a piece of common steel wire of about the same length, and from ⅛th to ¼th of an inch in diameter. Let the steel be well hardened and tempered by plunging it at a cherry-red heat into cold water; when cold and polished, apply each extremity in succession to the opposite poles of an armed magnet, Fig. 2672, first touching with gentle friction one extremity of the bar, or one of the poles and the opposite extremity on the other pole, or, which is better, draw the bar *a b*, Fig. 2674, a few times, in the direction of its length, across the two poles *m n* of the magnet M, as represented in the figure, and in such a way as not to pass either extremity, *a b*, beyond or off the opposite poles *m n*; finally, bring the bar *a b* so as to rest with its extremity *a b* equally distant from each pole *m n*; that is to say, bring the poles *m n* at the centre of the bar, or as nearly as may be. In this position remove the bar from the poles. The bar will now be found attractive of particles of iron, common steel needles, and other ferruginous matter: when suspended it will arrange itself in the direction of the magnetic meridian, and will, in fact, have all the properties of the loadstone, including the important property of imparting or exciting a magnetic condition in tempered steel.

Take a small bar of steel which has been rendered magnetic by the process just described, apply it with slight friction to a piece of hard steel wire or a similar bar, and in such way that the opposite extremities of each bar may have contact attended by a slight degree of friction: this second bar or wire will be found also to have acquired a similar magnetic condition to the first; and this process may be continued from the second to a third wire of steel, and so on without limit.

The propagation of magnetism from one bar of steel to another, as illustrated in this experiment, enables the experimentalist to obtain artificial magnets to any given amount; and since the form and magnitude of the steel has not been found to interfere with the generality of the result, we are further enabled to obtain magnets of any required figure or magnitude.

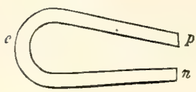
It is to be especially observed that the polarities excited in the opposite portions of a steel bar by this artificial process of magnetizing are the reverse of those of the magnetic poles to which these portions have been applied. Thus in Fig. 2674, if the extremity *b* of the steel *a b* rest on the north, or positive pole *n* of the magnet M, the polarity induced in that extremity *b* will be a south or negative polarity. Reciprocally, if the extremity *n* be brought to rest on the negative or south pole *m*, then the polarity induced in that point of the steel will be a positive or north polarity.

Artificial magnets may be of any required form, or of almost any dimensions, according to the particular views of the experimentalist: for general purposes they are limited to straight bars, such as represented in Fig. 2675, or otherwise to bars bent into a curvilinear form, resembling a horse-shoe, as in Fig. 2676; the branches *c p* and *c n* being longer, and the extremities *p n* nearer than in the common horse-shoe. Many such bars, either straight or curved, form, when combined, what is termed a *compound magnet*, such, for example, as that represented in Figs. 2677 and 2678. The combination of several compound magnets with projecting armatures constitutes a *magnetic battery* or *machine*. The dimensions well adapted to magnetic bars, either straight or curved, are such as to give the breadth about $\frac{1}{14}$th or $\frac{1}{15}$th of the length, and the thickness something less, or not exceeding one-half of the breadth.

To magnetize a bar of tempered steel, Fig. 2676, curved into the horse-shoe form, fix the bar, Fig 2679, on a flat board, with its extremities, *p s*, against a straight piece of soft iron, *p s*, of the same thickness and width as the bar. Having secured the whole in this position, place a compound magnet M, or an armed native magnet, on one of the extremities *s*, of the curved bar, taking care that the opposite or marked and unmarked ends are in contact with each other. Continue as before to glide the magnet M several times round the whole series, and in the same direction, *s c p*, finally stopping in the

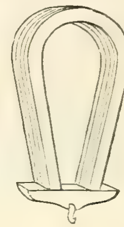
2675.

2676.



2677.

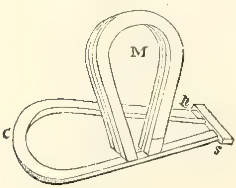
2678.



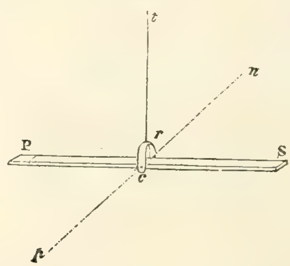
centre, *c*. Repeat this process on each face of the bar, when a high degree of power will have become developed; so much so, that the iron or keeper *p s* cannot be directly pulled away without considerable force, and in some instances cannot be conveniently removed except by sliding it off.

In order to preserve effectually the magnetism thus excited in bars of steel, it is requisite, when not in use, to keep their opposite poles united by means of pieces of soft iron.

2679.



2680.



Take a perfectly straight and even bar of steel, P S, Fig. 2680, sufficiently hard to retain a magnetic state. It may be 7 inches long, $\frac{1}{8}$th of an inch wide, and $\frac{1}{10}$th of an inch thick. Drill a clean hole through the centre of the wide surface, and then pass an extremely fine drill also through the centre transversely to this hole, across the thickness of the bar, edgewise, and so accurately as to pass through the centre of gravity of the mass, or as nearly as possible; proceed now to complete the equilibrium of the bar upon a fine needle as an axis, and in such a way as to render it indifferent as to position in a vertical plane or nearly so, and that whether it be placed with one or the other face uppermost. Let the bar be now magnetized, and then mounted on its central axis; run the axis through a small silver stirrup *c r*, and suspend the whole by a fine silk fibre *r t*, attached to a fixed point *t*; the bar P S will be observed gradually to assume a definite and oblique position, *p n*, inclining in these latitudes its north pole, P, nearly 70 degrees below the horizontal line, turning at the same time into a plane deviating from the plane of the meridian by a given angular quantity, called "the dip," the lower extremity having turned towards the north, and the other extremity towards the south; and it may be likewise observed, on the principle already stated, that the extremities which have thus turned, the one towards the north and the other towards the south, will have been derived from the opposite poles of the loadstone or magnet by which it has been magnetized.

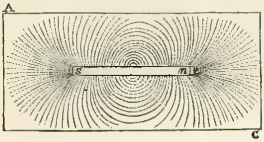
The position of the magnetic centre and poles of each surface, together with the general magnetic condition of the bar, and the reciprocal attractions, repulsions, and neutralization of the opposite forces, may be shown in the following way.

Strain a piece of common drawing-paper on an open frame, A C, Fig. 2681, and place it over a hard steel bar S N, regularly and powerfully magnetic; project on the paper over the bar, through a small muslin or lawn sieve, some fine iron dust or filings; the particles will arrange themselves in a series of

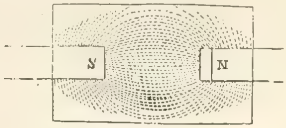
curved lines of magnetic force proceeding from homologous or similar points on each side of the middle of the bar, some uniting about the magnetic centre, others standing out at the extremities as if repelled from the poles N S, and tending to turn at considerable distances into other curved lines of force, to unite their branches between the opposite poles. This experiment may be rendered more decisive by slightly tapping the finger on the paper, so as to give the particles a little vibration.

Oppose the dissimilar poles S N, Fig. 2681½, of two powerful bars to each other at about two inches

2681.



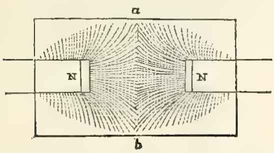
2681½.



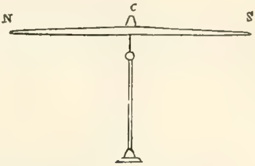
distance, and project over them fine iron filings as before; similar results ensue. Magnetic lines of force, both straight and curved, and proceeding from similar points of each bar, will be apparent, uniting the two poles by chains of reciprocal attraction.

Change the position of one of the bars, so as to oppose two similar poles N N, Fig. 2682; the lines of force will then appear to be conflicting lines; the repulsive forces will cause a straight line *a b* to appear on the open space or field between the poles, from which the iron dust stands out transversely. At this line, the opposed forces on either side are apparently struggling with each other, being exerted in repulsive directions from the opposed poles.

2682.



2683.

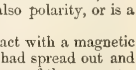


We have in these phenomena satisfactory visual evidence of the existence of two distinct forces—of their reciprocal attractions and repulsions, and their mutual neutralization.

A light magnetic bar N S, Fig. 2683, or a small magnetic steel cylinder, of great comparative length, has been termed a *magnetic needle.* When delicately poised on a central point *c*, so as to retain a horizontal position, and move freely in a horizontal plane, it has been termed the *horizontal needle.* When poised on a fine central axis, so as to move freely in a vertical plane, it has been termed a *vertical* or *dipping needle.* If suspended as in Fig. 2683, so as to have motion in both a horizontal and vertical plane, it has been termed the *horizontal and vertical needle.*

Instruments for ascertaining whether a substance has polarity or not, and for detecting the presence and kind of force in operation, have been termed *magnetoscopes.* The most simple kind of magnetoscope is a small horizontal needle, about an inch in length, delicately suspended by a fine silk fibre, or otherwise set upon a fine point and agate centre, within a small wood or glass case, as represented in Fig. 2684, and so set as to admit of some degree of dip or depression of either pole, as well as a perfect motion in a horizontal plane. From the attractive and repulsive forces of similar and dissimilar poles it is evident, from the kind of effect produced on the poles of the magnetoscope, we may always determine the presence or kind of polarity acting on it. Thus, if such an instrument as that just described, be glided along the surface of any given substance without any attractive or repulsive effect being apparent, such a substance may be considered as non-magnetic. If, on the contrary, we find both poles of the instrument everywhere attracted indifferently, then we may infer that the substance is a magnetic substance: such would be the case with a piece of common soft iron. Should we find certain points attractive of one of the poles of the small needle, and repulsive of the other, then we may infer that not only is the substance a magnetic substance, but that it has also polarity, or is a magnet.

2684.



Magnetic influence or induction.—When a piece of soft iron is brought into contact with a magnetic pole, it immediately acquires an attractive power, as if the magnetism of the pole had spread out and pervaded the iron. In fact, if we examine a piece of iron thus circumstanced by means of the magnetoscope, we find the same polarity continued throughout the iron; it will everywhere attract one pole of the magnetoscope, and repulse the opposite pole. If, however, we separate the iron from the magnet, and retain it at a short distance from the magnetic pole, then a new case appears to arise: that portion of the iron next the magnet will have an opposite polarity to that of the pole to which it is opposed; the two magnetic elements resident in the iron will, in fact, become separated; one of them will be sensible at the extremity next the magnet, and the other at its distant extremity: a result which we

might expect to follow from the repulsion of the similar elements and the attraction of the opposite elements. This separation of the latent magnetism of the iron into its constituent elements has been termed *magnetic induction.* It is altogether a temporary state or condition of the iron sustained by the influence of a magnetic pole, and vanishes so soon as that influence is withdrawn.

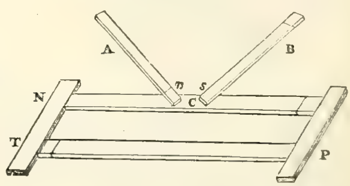
In the communication of magnetism by the loadstone to hardened steel, and from one piece of steel to another without limit, neither the loadstone nor the artificial magnet loses any of its inherent power; nothing, therefore, appears to be communicated; the whole result is entirely a species of molecular excitation, or a calling into sensible activity certain forces already existing in the magnetic substance, and which, under ordinary circumstances, remain in a quiescent or neutral state. No means yet devised have ever insulated these forces in such way as to enable us to obtain one of them only, independently of the other. We cannot, for example, produce a magnetic bar having a single pole; for although we touch one extremity of the bar only with one pole of the loadstone, still two poles will appear in the bar, although the one induced by the presence of the other may not be so forcible.

Methods of communicating magnetism to steel bars.—The first means of imparting magnetism to steel was, as we have already described, by contact with the armed loadstone or other magnet. A more efficacious method, however, of magnetizing small needles or bars by simple contact, consists in placing the bar or needle between the opposite poles of powerful magnets, as, for example, in the magnetic field S N, Fig. 2681, immediately between the poles S N.

We are indebted to Dr. Gowan Knight, F.R.S., a London physician, for the first important step in the communication of magnetism to bars of steel. His method, as given in the Philosophical Transactions for the years 1746 and 1747, vol xliv., is as follows: two powerful magnetic bars M M′, Fig. 2685, are placed in the same straight line, with their opposite poles N S very near each other; the needle or bar *n s* to be magnetized is laid flat on the surface of the bars, immediately over the opening N S, between them. If the bar *n s* be a magnetic needle, having a cap for suspension, then the cap is allowed to rest between the bars: if the surface be unimpeded by this, the bars M M′ may be brought very near each other. Things being thus disposed, the bars M M′ are gradually withdrawn in opposite directions, and immediately under the bar *s n*; the result of which operation is, on the principles already explained, that each half of the bar *s n* being acted on by opposite polarities, the two magnetic forces resident in it become separated; the pole N of the bar M attracts all the south polarity and repels the north, whilst the pole S of the bar M′ attracts all the north polarity and repels the south: hence a final and permanent magnetic state is imparted to the bar *s n*, the position of the poles *s n* being the reverse of the poles N S of the bars.

2685.

2686.



Small needles will become magnetized to saturation by one operation of this kind performed on each of its surfaces; for larger bars, two or three, or more, repetitions are desirable. This method is very effectual, especially for single bars, and there is not, perhaps, any better for certain purposes, even at the present day.

After this method of Dr. Knight's had become known and practised, M. Du Hamel, member of the Royal Academy of Sciences at Paris, was led, about the year 1749, to a further and still more extensive application of it. Two bars N S and T P, Fig. 2686, required to be magnetized, are laid on a table parallel to each other, and their intended opposite poles united by pieces of soft iron N T, S P, so as to form a closed rectangular parallelogram, as seen in the figure. The opposite poles *n s* of two powerful magnets A B, either simple or compound, are then applied to the centre C of one of the bars N S, and drawn away from each other in opposite directions C N, C S, being held all the while at an inclination of about 40°: this operation is repeated several times; the magnets A B are now either reversed, or their relative positions changed, by turning them round; they are then applied in a similar way to the other bar P T, so as to bring the poles *s n* opposite to their former position: the same operation is now repeated on the bar T P, and this process is to be further repeated on each surface of the bars T P, N S. M. Du Hamel's method is effective and expeditious; the elementary forces resident in the bars being by the joint operation of the magnets easily separated, whilst the union of the opposite poles N T and S P by soft iron, further tends to increase the effect, by holding together, as it were, the two separated magnetic elements, and thus allowing the exciting magnets A B to operate with more considerable effect.

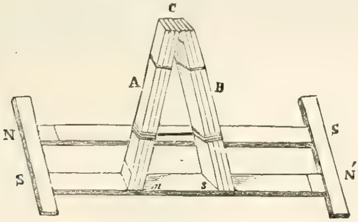
Bars of the horse-shoe form may be rendered magnetic in a similar way, by uniting their near extremities or intended poles with soft iron, and then drawing the magnets away from each other, commencing at the centre of the curve, and terminating at each extremity.

A high magnetic development may be obtained in a series of straight bars, without the aid of powerful magnets, by a successive touching in combination one with the other. We are indebted to Mr. Canton for this process, which is as follows:

Having a set of 12 bars, however slightly magnetic, two of the series S′ N′, N S, Fig. 2687, are laid

with reverse poles parallel to each other, and the rectangle closed by pieces of soft iron S N′, N S′, about one-half the length of the bars, and of the same breadth, as in the method of Du Hamel; the remaining 10 bars are separated into two combined systems A B, of 5 bars each, placed on one of the bars N′ S′, with their remote and opposite poles C in contact, and their lower poles *n s* somewhat open. This arrangement being made, the bars S′ N′ and N S are rubbed with these systems in the way already described, and being thus strengthened by the united powers of all the rest, are now removed,

2687.



and placed at the back of the others, as at A B, whilst the two interior bars of each system C *s*, C *n*, are withdrawn, and subjected to the same operation as the preceding; in this way we continue to strengthen each pair of bars by the acquired power of those last touched, until the whole become magnetized to saturation. This process is very useful when powerful magnets are not at hand; for however weak may be the magnetic state of the bars, even although two of them only be slightly magnetic, we may from these render the whole series very powerful.

The combined systems A B may be temporarily bound together by a little common tape, and a small block of wood placed between them, so as to support the whole in position during the process of magnetizing.

Besides these direct methods, we have other processes for obtaining a magnetic development in steel and iron, of much practical importance. Marcel, so long since as the year 1722, observed that a bar of iron acquired a temporary magnetic state by position alone; and he succeeded in imparting magnetism to a piece of hard steel placed on an anvil, merely by rubbing it with the lower end of a bar of iron about 33 inches long, set upright upon the steel. The temporary magnetic state thus induced by position in the iron bar is such, that the lower extremity, in these latitudes, becomes a south pole, and the upper extremity a north pole; and the forces are much increased by placing the bar in the direction of the inclined needle: in southern latitudes the reverse of this occurs—the lower extremity is then a north pole, and the upper end a south pole. Mr. Canton, by an ingenious manipulation of this kind, succeeded in communicating a weak degree of magnetism to steel by means of a common poker and a pair of tongs, and from this magnetized his series of bars to saturation by the process we have described: the bar to be rendered weakly magnetic was attached to the upper end of the poker by means of thread, and the whole placed in the direction of the dipping needle; whilst in this position the bar was repeatedly touched with the closed extremities of the tongs, carried from one end of the bar to the other, from below upward, the marked end of the bar being below.

Another method of developing magnetism in steel bars, without the aid of common magnets, consists in subjecting the bar to sharp concussion. This principle was well known to Gilbert so long since as the year 1570, who, in his celebrated work "De Magnete," represents a blacksmith hammering a steel bar in the position of the inclined needle. Smiths' tools, such as drills, broaches, &c., which have undergone pressure and motion, are generally magnetic. When a steel punch is driven hard into iron, the punch is not unfrequently rendered magnetic by a single blow.

In the Philosophical Transactions for 1738 we find an account, by Desaguliers, of iron bars rendered magnetic by striking them sharply against the ground whilst in a vertical position, or otherwise striking them with a hammer when placed in a horizontal position at right angles to the magnetic meridian. Such bars attract and repulse the poles of the needle. According to Du Faye, whose experiments are quoted, it is no consequence how the bar is struck: all that is required is to impart to the bar a vibratory state whilst in a vertical position.

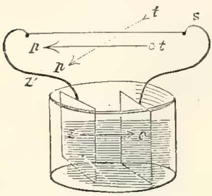
Availing himself of these facts, Scoresby, after a further and critical examination of the subject, succeeded in obtaining magnetic bars of extraordinary power by percussion. In the course of these inquiries, a considerable advantage was found to arise by striking the bar whilst resting in a vertical position upon a rod of iron. A cylindrical bar of soft steel, 6½ inches long, and ¼ of an inch diameter, resting on stone, and struck with a hammer weighing 12 ounces, could only be made to lift about 6½ grains; whereas when resting on a bar of iron, and struck in a similar way, it lifted 88 grains. Scoresby, in developing magnetism in this way by percussion, first struck a large iron bar in a vertical position, and then laid it on the ground with its acquired south pole towards the north; he then proceeded to strike sharply with a hammer a soft steel bar, 30 inches long and an inch square, resting vertically on the south pole of the iron bar. A second similar bar was treated in the same way; then, placing one of these steel bars vertically, he proceeded to strike upon them, as supports, a series of flat bars of soft steel, 8 inches long, and ½ an inch broad, and in a few minutes they had acquired a considerable lifting power. The series of bars being now touched one with the other, after the manner of Canton became very soon magnetized to saturation; each pair readily lifted 8 ounces.

Dr. Scoresby observes that large iron and steel bars are not absolutely requisite to the success of this process, common pokers answering the purpose very well.

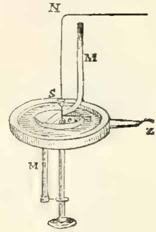
The next series of phenomena claiming attention, arise out of a property peculiar to natural and artificial magnets, by which they tend, when freely suspended, to arrange themselves in a certain relative position to a wire carrying a current of Voltaic electricity. These phenomena have been hence termed *electro-magnetic*, and although of sufficient moment and extent to come under a separate and peculiar branch of physical science, yet so far demand a brief notice here, as constituting a very important property of the natural and artificial magnet.

With a view to a clear conception of these reciprocal magnetic and Voltaic actions, it is requisite to understand that two plates of zinc and copper, z c, Fig. 2688, placed near each other in a vessel of di-

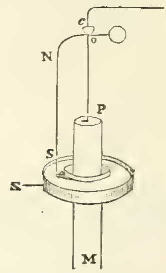
2688.



2689.



2690.



lute acid, and connected by a metallic circuit c' S N z', turned or directed in any manner, give rise, during the solution of the zinc in the acid, to a peculiar electro-chemical action, by which a current of electricity is supposed to flow from the zinc plate z in the direction of the small arrow, through the acid upon the copper plate c, and from thence through the metallic circuit c c' S N z' z back again upon the zinc plate z. A combination of this kind has been termed a Voltaic circle, and the metallic circuit c' S N z' the uniting wire.

This understood, let S N be a perfectly straight portion of this circuit, which, as a standard of reference as to position, we will suppose to be in the direction of the magnetic meridian. Let p t be a magnetic needle, suspended below and parallel to N S; then, directly we complete the communications N z' z—S c' c with the zinc and copper plates z c, the needle p t varies from the meridian, and tends to place itself across the wire N S, and in such way that whichever pole of the needle is next the copper plate c, that pole moves to the right hand, or towards the east. If, therefore, the current flow over the needle from c to z, through the wire S N, from south to north, and the observer be looking over the wire in the same direction, then the south pole t, next the copper plate c, turns to his right hand, or to the east, and the north pole p to his left hand, or west. If we suppose the position of the plates c and z to be changed, and the direction of the current reversed, by connecting the extremity N with c, and the extremity S with z, so as to cause the current to flow from north to south, then these deflections are also reversed. The south pole t now goes to the left hand, and the north pole p to the right hand—that is to say, the north pole p being now next the copper plate, goes to the right hand.

Place the needle above, and parallel to the wire S N, then the reverse of all the former deflections will be obtained; whichever pole of the needle is now next the copper plate, that pole moves to the left hand, or west When the current, therefore, flows from south to north, the south pole t, which before went to the right hand, or east, now goes to the left hand, or west, whilst the north pole turns to the right hand; if we reverse the current, and cause it to flow from north to south, as in the last experiment, then these deflections are again reversed; the north pole of the needle, being now next the copper plate of the battery, goes to the left hand.

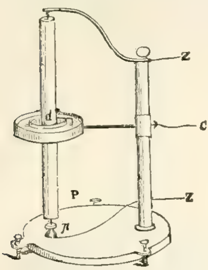
If the needle be immediately in the plane of the uniting wire, on either side of it, no motion is obtained in that plane; but if it be suspended in a vertical plane, on a horizontal axis, so as to admit of a deflection of inclination, then it tends to place itself across the wire as before. If the needle be on the east side of the uniting wire, that is, on the right hand, taking the current and direction as at first, then the south pole, next the copper side of the battery, dips below the horizontal plane, and the north pole, next the zinc plate, rises. If the current be reversed, the deflections are also reversed. If the needle be placed on the left hand, or west side of the uniting wire, then the south pole, next the copper plate, rises, and the opposite north pole dips. By reversing the direction of the current, these deflections are again reversed.

It is apparent, from the successive directions of the bar as it becomes placed above, at the sides, or below the wire S N, that the force affecting the magnet is a force transverse to the pole of the bar, by which, if the bar had complete freedom of motion in every direction, the poles would actually turn round the wire, but in different directions; and, conversely, supposing the bar fixed, and the wire S N carrying the current free to move, then those parts of the wire parallel to the magnet would rotate about the magnetic poles in opposite directions, in a similar way. If both are supposed free to move in any direction, then the wire and magnet would turn round each other, and such is really found to happen, giving rise to a very important series of electro-magnetic actions.

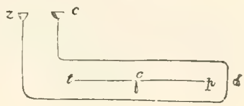
Let a magnetic bar M M′, Fig. 2689, be bent so as to produce a short oblique portion at the middle of the bar, with two vertical arms M M′; poise it on a fine central point *c*, and let a wire N S be placed near and parallel to one of the arms M. Then, supposing a descending current to flow from the copper plate *c*, Fig. 2688, through the wire in the direction N S, upon the zinc plate Z, the magnet M revolves about the wire N S, upon the central point *c*; and if the north pole of the bar be uppermost, the motion will be direct, or from the left hand to the right.

Conversely, if the magnet M be fixed as in Fig. 2690, and the wire N S be movable on a fine centre *o*, then, on transmitting the current as before, through the wire N S, it immediately revolves about the pole P of the magnet, with a direct screw motion, supposing the current to descend the wire, and the pole P to be a north pole. To enable these motions to go on without disturbing the progress of the current and the connections with the Voltaic plates, the movable parts dip into small cups and cisterns containing mercury, and with which the plates of the Voltaic circle, Fig. 2688, communicate, as indicated in the figures.

2691.



2692.



The tangential or transverse force, by which a magnetic pole is caused to revolve about a wire transmitting a current of Voltaic electricity, is equally apparent when the magnetic bar itself becomes the conjunctive wire of the battery; so that an electrical current flowing over or through a magnetic bar from one of its poles to the equator, or from the equator to either of the poles, causes such a bar to revolve upon its axis, the requisite mechanical arrangements for motion being complete.

Let a magnetic bar, S P, Fig. 2691, be mounted vertically between two delicate centres; the bar may be about 18 inches in length, 1 inch wide, and ¼ of an inch thick. Let an electrical current be caused to flow from either of the poles P S to the equator *d*, or from *d* to either of the poles P; the bar will immediately revolve upon its axis P S, the direction of the motion being such, that supposing the bar to rest upon its north pole P, the centre *d* being in communication with the copper plate of the battery C, and either or both of the poles P S in communication with the zinc plate Z, electrical currents will flow from the equator *d* to the poles, and the bar will revolve from left to right, as in the motion of the hands of a watch, or a common right-handed screw. By reversing the communication with the Voltaic plates, that is, placing the poles P S in connection with the copper plate, and the centre *d* with the zinc plate, the electrical current will flow from the poles to the equator *d*. In this case, the direction of the motion will be the reverse of the former; it will be from right to left, or backward, as it were.

If the position of the magnet be changed, that is, if we place it to rest with its south pole below, then, the communication with the Voltaic circle remaining as in the first instance, we also reverse the motion. If now the communications be changed, as in the last instance, we again reverse the motion, and obtain, as at first, a motion from left to right.

To facilitate the passing of the electrical current over the magnet, the bar is supported between fine centres P S by a light vertical column fixed on a firm base; a small ring or cistern of mercury *d*, also supported from the vertical column, surrounds the equator of the bar; the bar turns within this, and it is connected with the mercury in turning by a small bent wire dipping into the cistern; the lower centre P turns upon an agate contained in a small cup at P, connected with the point Z′; this cup contains a small globule of mercury, to keep up the metallic connection with the magnet; there is a similar globule in a small cavity at the upper end of the bar for the centre S; this upper centre is supported by a wire extending from the head of the pillar Z Z′. It is here evident, that in connecting the points C Z or C Z′ with the plates of the Voltaic circle, an electrical current will flow between these points through C *d* S Z, or C *d p* Z′, the direction depending on the respective connections with the zinc or copper plate of the circle.

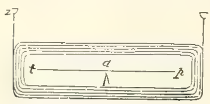
A recollection of the relative direction of the motions we have been describing will be facilitated by keeping in mind the following simple formula: a descending current moves a north pole to the right hand, or will give rise to a direct screw-motion; from this simple fact all other relative motions are easily determined.

The reciprocal action of a magnetic needle and uniting wire, together with the series of deflections in given directions, have led to the invention of a very important magnetical instrument, termed the Electro-magnetic Multiplier, or *Galvanometer*, by which extremely small magnetic and electro-magnetic forces may be detected and measured.

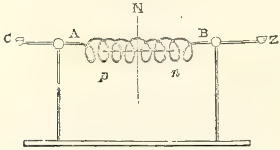
It will be apparent, as already observed, that a current flowing both above and below a needle, in

opposite directions, deflects the needle in the same direction; hence it follows that if a magnetic needle *p t*, Fig. 2692, be suspended on a delicate centre *c*, within the bite of a returning wire *z d c*, and the extremities *z c* of the wire connected with the zinc and copper plates of the Voltaic circle by means of two little cups containing mercury, then a current will flow longitudinally round the needle, both above and below it, and in opposite directions, that is to say, in the direction *c d* above the needle, and in the direction *d z* under it; the effect of this will be to deflect the needle with twice the power by which it would be deflected with a single current only, as in Fig. 2688.

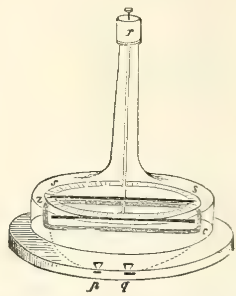
If we imagine the wire *z d c* to be several times turned longitudinally about the needle, as in Fig. 2693, then the effect would be still further increased; it would, in fact, become multiplied in proportion to the number of turns of the wire, which would represent so many additional currents. It is only requisite to cover the wire with silk thread, or some other imperfect or non-conducting matter, so as to avoid metallic communication between the coils, and oblige the current to traverse the whole length of the wire. This is the principle upon which the electro-magnetic multiplier rests, and the delicacy of the effect is such that the needle will become deflected by the immersion of two pieces of zinc and platinum wire less than $\frac{1}{8}$th of an inch long, and $\frac{1}{50}$th of an inch in diameter, in water slightly acidulated. Fig. 2694 represents this instrument under one of its most perfect and delicate forms. Two



2695.



2694.



magnetic needles, with their poles reversed to each other, are fixed on a central rigid axis, so as to neutralize the directive power of the needles, merely allowing a sufficient force to bring the whole into the meridian. This system is suspended by two parallel threads of unspun silk *r n*, one of the needles being within a rectangular coil of wire *z d c*, and the other needle immediately without it, and over the upper part of the coil. The wire *z c* is covered with silk thread, so that the coils may not have metallic communication, and the extremities *p q* are brought out near each other, and terminate in small cups *p q*, containing a little mercury, for the better convenience of communicating a current to the coil from any given source. The coils are separated a little near the centre, to allow the axis of the astatic system of the two needles to pass through them.

The slightest current transmitted through the coil from *p* to *q*, or *q* to *p*, causes the needles to deviate from their constant position. Both the needles, as is evident, will be impelled in the same direction; the lower needle being in the position just described, Figs. 2692 and 2693, whilst the upper needle, its poles being reversed, is impelled in the same direction by the upper side of the coil.

The threads of the double or bifilar suspension *r n*, in tending to cross each other as the needles turn, give rise to a reactive force, which may be set against the deflective force employed to measure it: for this purpose a graduated circle *s s* is fixed under or round the upper needle, so that the angle of deflection may be accurately estimated. If the earth's directive force be completely neutralized by the reversed positions of the needles, then this would be the only force opposed to the deflective force; i not, then it becomes mixed with the little directive power left in the system, but which is generally so small as not to be of much moment.

The instrument is set upon a convenient stand, and may be inclosed within a glass shade, the bifilar suspension being sustained within a tube of glass.

Steel magnetized by the electrical current.—One of the many important results of these discoveries is the means of imparting a high degree of magnetism to iron and steel, and to so great an extent as to give a soft iron rod a lifting power of more than a ton.

We have seen that the electrical and magnetic forces are so related that the one is exerted at right angles to the other. We derive from this elementary principle a means of disturbing the latent magnetic forces resident in magnetic substances, by which these forces become separated, and the body rendered magnetic, precisely in the same way as effected by the contact of an ordinary magnet.

Let a long piece of copper wire be wound round a piece of glass tube of about $\frac{1}{2}$ an inch or less in diameter, and from 6 to 10 inches in length, so as to produce a helix or spiral, A B, Fig. 2695, and mount this spiral between two vertical supports, as represented in the figure. Place a perfectly neutral piece of hard steel wire *p n*, of about $\frac{1}{10}$th of an inch in diameter, or a large sewing needle within the helix, and connect the extremities A B with the zinc and copper plates of the Voltaic circle, the steel *p n* will become immediately magnetic; in fact, each turn of the spiral causes electrical currents to flow in reverse directions above and below the steel. If the coils of the spiral be numerous and close, they may

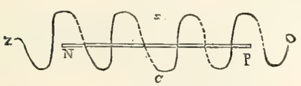
be regarded as parallel circles standing at right angles to the direction of the inclosed wire, and with which the axis of the helix may be made to coincide. The effect of a helix of this kind on a fine magnetic needle placed within it is so powerful, that with a strong Voltaic current the needle is frequently caught up and retained on the axis of the spiral, as if liberated from the trammels of gravity.

The kind of polarity given to steel or iron thus circumstanced will depend on the direction of the current with reference to the axis of the helix, and this again will depend on the connections with the plates of the Voltaic circle and the direction in which the helix is turned. Now, the spiral may evidently be turned either direct, like the threads of a common cork-screw, forming what is termed a right-handed helix, or they may be turned in the reverse direction, in which case we have a left-handed helix.

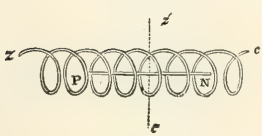
If we suppose the helix to be a reverse or left-handed helix, as in Fig. 2696, the current flowing from *c* to *z*, round a small cylindrical steel needle or wire P N, and the coils standing in the direction of the magnetic meridian *c′ z′*, so that the current may flow under the wire in the direction *c′ z′*, from south to north, as indicated by the dotted lines, and over the needle in direction *z′ c′*, from north to south, as indicated by the full lines, then the positive pole P will be determined to the right hand, and the extremity P, of the wire next the copper plate *c*, will be a north pole: by similar reasons the opposite extremity N will be a south pole, and next the zinc plate of the battery.

If we take a direct or right-handed helix and an inclosed wire P N, as in Fig. 2697, and transmit the current as before from *c* to *z*, then the reverse of all this occurs; the currents flow *under* the wire from north to south in direction *z′ c′*, and over the wire from south to north in direction *c′ z′*. Under these conditions the positive pole P is determined to the left hand, so that the extremity P of the steel cylinder P N next the zinc plate becomes a north pole, and, by similar reasoning, the opposite extremity next the copper plate *c*, a south pole. Supposing the current to be reversed and to pass through a direct helix from left to right, the copper plate of the battery being to the left hand, and which is the ordinary form of the experiment, the north pole will be always determined next the zinc plate, that is, to the right hand.

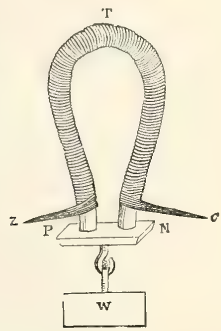
2696.



2697



2698.



It will be useful to the student to remember as a general fact, that supposing, Fig. 2695, the observer to be facing the north, N, and the helix A B placed transversely before him so that its axis may lie east and west, then if the current be *descending* the coils of the spiral directly before him, the north pole is determined to the right hand, and the south pole to the left. Reciprocally, if the current be *ascending* the coils of the spiral directly before him, then the south pole is determined to his right hand, and the north pole to the left. Hence, with a direct helix, the north pole will be always found next the zinc plate, and with a left helix next the copper plate.

The magnetic power developed in soft iron closely surrounded by heliacal coils transmitting electrical currents all in the same direction is so great, that a curved iron rod, during the action of the battery, may be caused to sustain an enormous weight. The usual form of the experiment is as follows:

A cylindrical bolt of soft iron P T N, Fig. 2698, about an inch or more in diameter, and from 30 to 40 inches long, is bent into the horse-shoe form, as indicated in the figure. It is then surrounded by several long coils of copper wire *z* T *c*, covered with silk or other insulating thread, so as to interrupt all metallic communication or coil with the other; one set of coils is superposed on another, and all the ends of the wires P N on each side united into common terminations *z c*, to be connected with the battery.

If, when the currents are passing through the coils, we apply a soft iron keeper P N, and cross the projecting poles, it will be held fast with an enormous force, so that several hundred weight, W, may be suspended without breaking the contact. An electro-magnet of this kind may become so powerful as to support upwards of 2 tons.

Instruments for indicating the presence and determining the polarity of magnetic forces, and measuring their quantitative power under various conditions.—Instruments for indicating the mere presence of magnetic force, and determining its peculiar polarity, may be termed, as before observed, magnetoscopes; those for its quantitative measurement, under various conditions, may be considered as magnetometers.

Magnetoscopes generally consist of light bars or needles, either suspended by a delicate flexible thread, or attached to an agate or metallic cap, and set on a fine central point. Of these two forms of suspension, the filar suspension is the most sensitive. The Rev. A. Bennet, F. R. S., employed filaments of a spider's web, which proved so extremely delicate, that two small pieces of straw, placed at right angles to each other, in the form of the letter T inverted, would, when thus suspended under a closed receiver, turn towards a person coming within 3 feet of the glass, and would move so decidedly towards wires merely heated by the hand, as much to resemble magnetic attraction. A fine and weakly magnetic steel wire, suspended from a spider's thread of 3 inches in length, would admit of being twisted round 18,000 times, and yet continue to point accurately in the meridian—so little was the thread sensible of torsion.*

Magnetometers.—The quantitative measurement of magnetic forces may be either direct applications of equivalent weight, or any species of equivalent reactive power, as in the reactive force of torsion; or may consist of indirect determinations of force, through the medium of certain relative effects, as in the amount of deviation of a suspended magnetic needle from its line of direction by the influence of a magnet placed at a given distance from the needle.

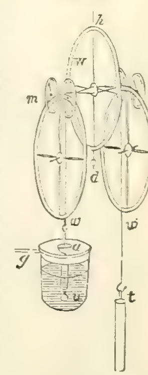
Scale-beam magnetometer.—The common scale-beam has been occasionally applied to the measurement of magnetic forces. A small cylinder of iron or a magnet is to be suspended from one arm of the beam, and counterpoised by weights in a scale-pan suspended on the opposite arm. The beam being sustained on any convenient support in the usual way, a second magnet or iron is placed on the table, immediately under this, and the attractive force at any given measured distance is estimated by additional weights placed in the scale-pan.

Much care is requisite in effecting this experiment. The beam should not be allowed any very considerable play, but be limited in its motions by two vertical forked stops, one under each arm. If the beam, with a given added weight in the scale-pan, be overset by the attractive force, and rest on the stop, we may either increase the distance of the attracting bodies, or increase the weight, so as just to catch the instant of the balance of the force. Or, supposing a given added weight in the scale-pan, we may continue to approximate a magnet towards the suspended iron or other magnet over a divided scale of distance, and catch the point at which the beam turns.

The bent lever, or any self-adjusting balance, may be also employed in a similar way to the measurement of magnetic force.

The hydrostatic magnetometer.—This instrument, shown in its general form in Fig. 2700, and partially explained in the following figures, is of such convenient and universal application to the measurement and exhibition of elementary magnetic phenomena and forces, that a particular description of it appears essential.

2699.



A light grooved wheel, W, Fig. 2699, about two inches in diameter, being accurately poised on a firm axis, *m n*, is mounted on the smooth circumferences of two similar wheels, *m w*, *n w'*. The extremities of the axis *m n* are turned down to fine long pivots, and whilst resting on the friction-wheels *m w*, *n w'*, pass out at *m n* between other small check-wheels, two at each extremity of the axis, so that the wheel W cannot fall to either side: great freedom of motion is thus obtained. These friction and check wheels are set on points or pivots in light frames of brass, and the whole is supported on short pillars screwed to a horizontal plate or stage, as shown at A B, Fig. 2700. The stage is sustained on a vertical column, A E, fixed to an elliptical base of mahogany, E, supported on three levelling screws.

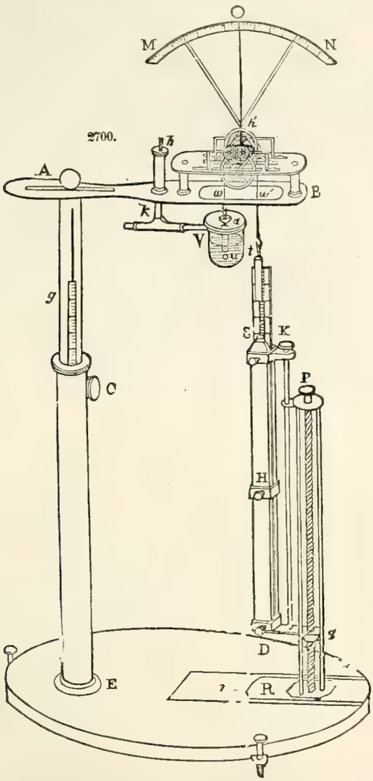
There is a short pin *h*, Fig. 2699, fixed in the circumference of the wheel W, to receive an index of light reed, cut to a point, and movable over a graduated arc M N, placed behind the wheel, as represented in Fig. 2700: the weight of this index is balanced by a small globular mass *d*, movable on a screw in the opposite point of the circumference; so that the wheel alone with the index would rest in any position, or nearly so. The arc M N is a quadrant divided into 180 parts: 90 in the direction I M, and 90 in the direction I N, the centre 0 being marked zero. Two fine holes are drilled through the wheel, one on each side of the point *h*, for receiving and securing two silk lines, *w w'*: these lines pass over the circumference on opposite arms of the wheel, and terminate in small hooks, *t* and *w*. A cylinder of soft iron *t*, or a small magnet, rather less than 2 inches in length and ¼th of an inch in diameter, is suspended by a silk loop from one of these lines, *w'*, and a cylindrical counterpoise of wood, *a u*, weighted at *u*, and partly immersed in water, is hung in like manner from the other line, *w*. The weights, and altitude of the water, and of the vessel *q* containing it, are so adjusted, that when the whole system is in equilibrio, the index *b o* is at zero of the arc M N. With a view to a perfect adjustment of the index, the water-vessel *q* is supported in a ring of brass at the extremity of a rod *q*, movable in a tube *k*, Fig. 2700: this tube is attached to a sliding piece *b h*, acted on by a milled head at *h* and a screw within the cylinder, which is fixed to the stage A B, so that the water-vessel may be easily raised or depressed by a small quantity, and thus the index be regulated to zero of the arc with the greatest precision; for it is evident, by the construction of the instrument, that the position of the index will depend on the greater or less immersion of the cylindrical counterpoise *a u*, the weight of which being once adjusted to a given line of immersion, and a given position of the wheel W and index O, any elevation or depression of the water-vessel *q* must necessarily move the wheel. The counterpoise *a u* is about 1½ inch in length and full ·3 of an inch in diameter: a small ball of lead is attached to its lowest part, in order to give it a sufficient immersion, and at the

* Phil. Trans. for 1792, p. 86.

same time balance the iron cylinder t when the float is about half immersed in the water. With a view to a final regulation of the weight, a small hemispherical cup a is fixed on the head of the counterpoise for the reception of any further small weights required. This counterpoise is accurately turned out of fine-grained mahogany, and is freed from grease or varnish of any kind, so as to admit of its becoming easily wetted in the water.

The column A E supporting the stage A B consists of two tubes of brass, one, G, movable within the other, E C, so that by a rack on the sliding-tube G, and a pinion on the fixed tube at C, the whole of the parts just described may be raised or lowered through given distances, as shown by a divided scale G, adjustable to any point by means of a slide and groove in the movable tube G. The brass tubes composing the column are each about a foot in length and an inch in diameter.

2700.



It will be immediately perceived, from the general construction of this instrument, that if any force cause the cylinder t to descend, then the index $h\,o$ will move forward in the direction O N, until such a portion of the counterpoise $a\,u$ rises out of the water as is sufficient to furnish, in the fluid it ceases to displace, an equal and contrary force. In like manner, if any force cause the cylinder t to ascend, then we have the reverse of this—the counterpoise obtains an equivalent increased emersion, and the index moves in the opposite direction, O M. Thus if we place a weight of 1 grain, for example, on the iron cylinder t, the index will indicate, in the direction O N, a given number of degrees equal to a force of 1 grain. If we double this weight, we obtain a force of 2 grains, and so on. The converse of this arises on placing the weights in the cup of the counterpoise $a\,u$. We may thus reduce the indications to a known standard of weight. It is further evident, that, whether we operate on the system by gravity or by the attractive or repulsive force of a magnet, the indications of force are equally true.

If the instrument be well constructed, and the counterpoise freely wetted in the water, the march of the index in either of the directions O N or O M will correspond to the added weights. Thus, if 1 grain

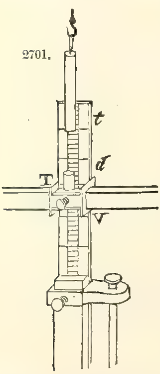
gives 3 degrees, 2 grains will give 6 degrees, and so on. And thus we obtain a continual and known measure of the force we seek to examine, within a given range of degrees of the arc, which will be more or less extensive according to the dimensions of the cylindrical counterpoise, the intensity of the force, and the rate of its increase. When we require to examine very powerful forces, or forces operating on the suspended iron t at small distances, it is requisite to increase the size of the counterpoise float, the indications of which we may always find the value of in grains, as before.

Previously to suspending the cylindrical counterpoise $a\,u$, the iron cylinder t should be placed in equilibrio on the wheel W, with an equal and opposite weight, as previously determined by an accurate scale-beam, in order to observe if, when loaded with the whole, the wheel W and index are indifferent as to position on any part of the arc, or nearly so. The instrument will be sufficiently delicate, if, when loaded in this way with 350 grains, it is set in motion by something more than ½ a grain added to either side.

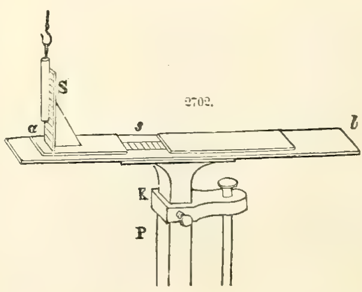
In order to retain the wheel W, Figs. 2699 and 2700, in its position at the time of removing either of the suspended bodies, a small brass prong is inserted at h into the arms of the circular segment M N, so as to inclose the pin h carrying the index: the wheel is thus prevented from falling to either side.

The forces requiring to be measured are brought to operate on the suspended cylinder t through the medium of induction on soft iron, or by a magnetic bar placed immediately under it, either vertically or horizontally. In the vertical arrangement, shown in Fig. 2700, the magnet or iron is fixed against a graduated scale S, by which the distance between the attracting surfaces or bodies is estimated. This scale, together with the magnet H, is secured by light bands s, of brass, united by a rod D K. The lower band and rod D are both fixed to a stage D, movable between guide-pieces, and acted on through a nut at q by a vertical screw P q, about 6 inches in length and ⅜ths of an inch in diameter; so that the whole may be raised or depressed, and hence the suspended cylinder and magnet placed at any required distance apart. The regulation of this important element in the operation of magnetic forces is hence provided for in two ways, viz., by the rack at G and the milled head at P, either of which may be employed, as found most convenient. The scale S is of boxwood, 1 foot in length, ⅝ths of an inch wide, and ⅛th of an inch thick: it is divided into inches, subdivided into tenths and twentieths of an inch. About 6 inches of the upper part is divided in this way, viz., 3 inches on each side of a central division which is marked zero; the rest of the piece extends to the stage D. The magnetic bar H is tied to the scale by compressing screws and simple brass bands, either fixed, as at D and K, or movable, as at H. This adjusting apparatus is secured to a stout brass plate R, fitted by a dovetail into a sliding piece v, forming part of the mahogany stand E, so that it may be removed at pleasure. The brass bands and frames at D H K are sufficiently capacious to inclose two bars together if required, the superabundant space being filled when only one magnet is employed, either by a bar of wood or small wedge pieces in the brass frame.

2701.



2702.



When we require to examine the forces in different points of a moderate-sized magnetic bar, the bar is laid in a small frame piece T V, Fig. 2701, temporarily fixed by a compressing screw to the divided scale S, in the way already described, the force on the suspended cylinder t being caused to operate through a small cylinder of soft iron d, accurately fitted to the surface of the bar; and thus, by sliding the bar along in the holding-frame, we may get, approximatively, by induction on the iron d, the force of any point in the bar.

When the bar is of considerable magnitude and weight, or we require to examine inductive forces, the magnets may be placed on a narrow table, $a\,b$, Fig. 2702, supported on a central square pillar P, fitted to the frame-pieces, K P, of the adjusting apparatus already described, so that the whole may be raised or depressed through any given distance. In this case the divided scale S, which measures the distance a between the attracting or repelling surfaces, is a detached piece fixed against one of the perpendicular sides of a right-angled triangle, so as to be anywhere placed upright on the bar: the

table $a\ b$ also has a divided scale s, movable in a wide groove through its centre, by which any distance s between magnetic masses may be also shown. When the bars are very ponderous, two supports are required, one at each end of the table $a\ b$.

Inductive forces are examined vertically by fixing the masses by compressing bands against the scale S, Fig. 2702, and of which we may have, if requisite, two or three in succession.

These arrangements put us in a position to note readily and simultaneously all relative distances and forces under a great variety of magnetic and apparently complicated conditions.

We have been somewhat prolix in our description of this instrument, but not unnecessarily so. There is scarcely any elementary experiment in magnetism which it does not completely and satisfactorily illustrate, besides furnishing quantitative measures of great importance to the mathematical inquirer into the laws and operations of magnetic force. See ELECTRO-METALLURGY.

MAHOGANY. The beautiful reddish-brown colored wood, of which household furniture is now chiefly made. It is a native of the warmest parts of America and the West Indies. It thrives in most soils in the tropical climates, but varies in texture and grain according to the nature of the soil. On rocks it is of a smaller size, but very hard and weighty, of a close grain, and beautifully shaded; while the produce of the low and richer lands is observed to be more light and porous, of a paler color, and open grain; and that of mixed soils to hold a medium between both. The tree grows very tall and straight, and is usually four feet in diameter. On account of the difficulty of transporting the mahogany timber from the forests, when the tree is of great thickness they cut it into short logs, otherwise the great weight and bulk would be unmanageable with the restricted means available on the spot; and with the view of equalizing the burden or draft of the cattle, (oxen,) the logs are long in proportion to their diminished thickness. The largest log ever cut in Honduras was of the following dimensions: length 17 feet, breadth 57 inches, depth 64 inches; measuring 5421 feet of plank, of one inch in thickness, and weighing upwards of 15 tons.

MANOMETER. An instrument for measuring the rarefaction and condensation of elastic fluids, but especially that of the atmosphere. It differs from the barometer, which shows only the weight of the superincumbent column of air; whereas the manometer shows the density, which depends on the combined effect of weight and the action of heat. It is sometimes called manoscope. Among the various contrivances of this kind may be mentioned that of the Hon. Robert Boyle, which he calls a statical barometer, which consists of a bubble of thin glass, about the size of an orange, which, being counterpoised in an accurate pair of scales, rises and sinks with the alterations of the atmosphere. This instrument, however, does not show the cause of the difference of density in the atmosphere, whether it be from a change of its own weight, or its temperature, or both. The manometer constructed by Mr. Ramsden, and used by Capt. Phipps in his voyage to the North Pole, was composed of a tube of small bore, with a ball at the end; the barometer being 2·97, a small quantity of quicksilver was put into the tube, to take off the communication between the external air and that confined in the ball, and the part of the tube below this quicksilver. A scale is placed on the side of the tube, which marks the degrees of dilatation arising from the increase of heat in this state of the weight of the air, and has the same graduation as that of Fahrenheit's thermometer, the point of freezing being marked 32°. In this state, therefore, it will show the degrees of heat in the same manner as a thermometer. But if the air becomes lighter, the bubble inclosed in the ball being less compressed, will dilate itself, and take up a space as much larger as the compressing force is less; therefore the changes arising from the increase of heat will be proportionably larger, and the instrument will show the differences in the density of the air, arising from the changes in its weight and heat. Mr. Ramsden found that a heat equal to that of boiling water increased the magnitude of the air from what it was at the freezing point by $\frac{414}{1000}$ of the whole. Hence it follows, that the ball and part of the tube below the beginning of the scale, is of a magnitude equal to almost 414 degrees of the scale. If the height of both the manometer and thermometer be given, the height of the barometer may be determined also.

When used for measuring pressure above that of the atmosphere, the instrument (as usually constructed) is in all respects the same, except that the tube is not filled with mercury, but inverted, while full of atmospheric air, into a reservoir of mercury, and the scale is differently marked. When the pressure on the surface of the mercury in the reservoir is that of the atmosphere, the mercury will rise in the tube nearly to the level of that surface, (but slightly lower, owing to the resistance of the air in the glass tube.) As soon, however, as the pressure communicated exceeds that of the atmosphere, the mercury will be forced up into the tube, and the inclosed air condensed, until its elastic resistance is just equal to the pressure. The height of the mercurial column will of course vary with any variation of pressure, and thereby indicate the degree of pressure at every moment by means of the scale, which is divided, according to Mariotte's law, into atmospheres, pounds, or the like.

The high degree of pressure to which the last-described form of manometer may be subjected without error from friction or loss of mercury, the permanent elasticity, and the every-where existing and exactly defined qualities of the material of resistance, (atmospheric air, or other fluids of the same nature,) its comparatively small dimensions and convenient form, make it a very desirable instrument for measuring the pressure of steam. As usually constructed, however, it has defects, which have prevented its general use as a steam-gage. Among these defects were the coating and consequent opacity of the glass tube, by the deposition of an oxide of mercury when acted on by the inclosed atmospheric air; the expansion and partial loss of air from within the tube whenever any partial vacuum was produced in the boiler, and so allowing the mercury to rise higher in the tube with the same pressure; its oscillation, especially when there is a varying pressure, as in engines working expansively; the almost constant tendency of the condensed steam to insinuate itself between the mercury and the glass, and to find its way into the tube above the mercury; and the great inequality in the divisions of the scale, arising from the peculiarities of the law that governs the volume of aeriform fluids under pressure.

The improvements by which these defects have been remedied, at the same time rendering it more

serviceable for determining pressures less than that of the atmosphere, have recently been made the subject of a patent to Mr. Paul Stillman, of New York.

Fig. 2703 is the usual form of the patent manometer for showing a pressure up to eight atmospheres Fig. 2704 represents the form of one for showing a pressure up to twenty atmospheres.

Fig. 2705 is the form used for showing less than one atmosphere. The arrangement of the glass tube is quite similar in all the forms usually given to the instrument.

Fig. 2706 is a longitudinal section through the centre of the glass tube, in which A is the tube; B is an iron piece in which the tube is firmly secured by means of the stuffing-box G. It is screwed at one end to receive the brass case C, and in the middle to confine it in the reservoir of mercury into which the lower end of the tube is to be immersed. D D are scales divided into atmospheres, pounds, or inches of pressure, as desired. E E are blocks to secure the scales in their proper places. F is a gland which protects the lower end of the tube, and compresses the packing in the stuffing-box G. H is a cap or plug loosely screwed into the gland to facilitate the operation of charging the tube, and also, by admitting the mercury into the tube only through the interstices of the screw, prevent its oscillation, and at the same time allow the orifice to be made the full size of the tube whenever it may be necessary to clean the tube.

In Fig. 2703 the reservoir for mercury is a deep cell, with an iron tube communicating from the

2706.

2704.

2703.

2705

cock at the bottom to the middle of the chamber above the surface of the mercury. In Fig. 2704 it is divided, the glass tube being inserted into a cell of greater depth, while the reservoir of mercury is in the bulb, to which a sufficient elevation is given to compress the gas within the tube to two or three times the density of the atmosphere, according to the density of the steam of which it is to serve as the gage. In this, as in the other form, an iron tube communicates the pressure from the cock below to the surface of the mercury in the bulb above. The subdivisions of the scale are by this means much more uniform and distinct than when used at atmospheric pressure only.

In all cases, the mercury should be seen above the junction of the tube with the tube-holder, so as to indicate the initial pressure, or 0. In Fig. 2703 it is brought up by partially exhausting the tube at the time it is erected. In Fig. 2704 it is forced up by the superincumbent weight of the mercury in the bulb. The oxidation of the mercury within the tube is prevented in the latter form of the instrument by charging the tube with nitrogen or hydrogen gas; but in the former, on account of the difficulty of preventing the admixture of atmospheric air, while exhausting a portion of the contents of the tube, for the purpose above referred to, atmospheric air only is used, and a drop or two of naphtha or other fluid answering the end, is introduced within the tube, on the surface of the mercury, to prevent the oxidation.

When designed to show a pressure less than atmospheric, but not less than that shown by two inches of mercury, the tube is to be perfectly filled with mercury, and inverted in the reservoir, and the pressure will be determined by the number of inches sustained above the level of the mercury in the reservoir below; but if it is to be used for a pressure less than the weight of two inches of mercury—that being the distance from the lowest visible part of the glass tube to the surface of the mercury in the reservoir—it will be necessary to use the bulb shown in Fig. 2704, but with such an elevation only as

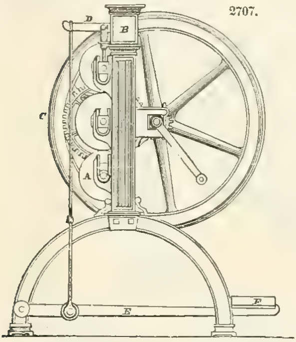
will bring the surface of the mercury in it to a height equal to the lowest visible part of the glass tube; or it may be done equally well by using the form shown in Fig. 2704, if a scale is properly made for the purpose, and the bulb elevated so as to compress the air so high in the tube as to allow the mercury to have sufficient fall without going out of sight, when the pressure of the atmosphere is removed from the surface of the mercury in the bulb above.

It will be seen that either of these arrangements would resist the tendency of such partial vacuum as is generally formed in steam-boilers, when they are allowed to cool down, from disturbing the quantity of air within the tube of the manometer.

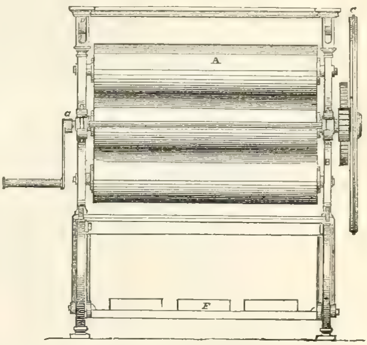
If the initial quantity of air or gas in the tube be deranged by a change of temperature, or by any other cause, it becomes necessary to know the extent of the variation occasioned thereby. To ascertain this, (if inexpedient to correct it at once,) a simple arrangement is adopted, viz., 1st, to remove the pressure by closing the stop-cock and opening the small waste-cock between it and the reservoir—this will allow the mercury to fall to a place in which it will be at equilibrium with the atmosphere; 2d, to note the point to which it descends. The variation from the original place of 0 will be, in addition to the pounds shown on the scale-plate, such part of the whole as the variation from 0 bears to the whole length of the tube above 0. To determine this proportion, a series of decimals is placed on the scale at fixed distances, and the one of these nearest to where the base of the column of air within the tube rests, is to be used as a multiplier, by which the pressure of steam indicated on the scale is to be multiplied. Their product, less the pounds of variation shown on the scale, will be the true pressure. Thus, for example, if the mercury in the tube falls until the base of the column of air rests at the decimal ·96, which would be near to the place due to 1 pound pressure, and if, on opening the communication to the boiler again, it should rise to 130 pounds, this apparent pressure of 130 pounds is to be multiplied by ·96, and deduct from their product the 1 pound, thus giving as the true pressure 123·8 pounds, showing a variation of 6·2 pounds. See GAGE, INDICATOR.

MANGLE, *house.* Figs. 2707 and 2708 exhibit a house mangle for swathing cloth, the action of which is obvious.

2707.



2708.



MAPLE-WOOD, is found growing in mountain districts, is indigenous to the United States, and valuable for its lightness; and not being subject to warp or split, it will take any color, and a fine polish. When green, it weighs 61 lbs. 9 oz. a cubic foot; and when dry, 51 lbs. 15 oz.

The *bird's-eye maple*, from the beauty of its grain and the shades of its spots, is much employed for veneering; by sawing the timber nearly parallel with the concentric rings, the effect of its marking or pencilling is much improved. In this country wheelwrights employ it, after giving it a seasoning for two or three years; and when constantly under water it will not readily perish.

MARBLE-SAWING AND POLISHING MACHINERY, *worked by steam-power.* Marble has of late years been extensively worked by machinery driven by steam-power; the processes are closely analogous in principle to those pursued by hand, but with various modifications of the apparatus, and it is proposed to explain briefly some of the peculiarities of the machine processes.

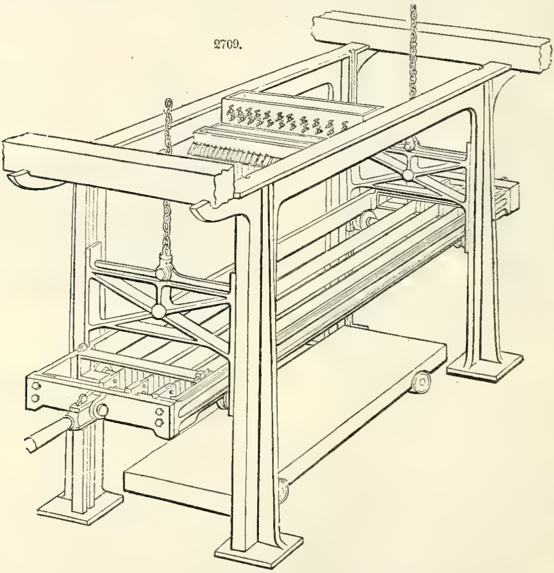
In the simplest application of machinery to sawing marble, as for making one or two cuts in a large block, the construction of the ordinary stone-saw is closely followed, but the frame is made much stronger, of squared timber firmly bolted together, and stayed with chains; to constitute three sides of a rectangular frame, the place of the pole and tightening chain of the saw is occupied by two fixed beams, and the saw is held and stretched by means of two clamps with screws passing through the ends of the frame, and tightened by nuts on the outside. The saw-frame works between vertical guide-posts to keep it upright, and it is reciprocated horizontally by a connecting-rod fixed to a crank driven by the engine. The connecting-rod is attached to the frame by a loop, which can be placed at various heights, so as always to keep the stroke of the connecting-rod nearly horizontal, notwithstanding the gradual descent of the saw in the cut.

These saw-frames are sometimes made as large as 16 feet long and 10 feet high, for cutting huge blocks of marble; and to prevent the great weight of these frames from pressing on the cut, they are suspended at each end by chains or slings which vibrate with the saw, and are connected with a counterpoise weight, that is adjusted to allow of the necessary pressure for the cutting, which is effected

with sand and water supplied in the same manner as for the stone-saw used by hand, but the introduction of the guide principle renders the chasing of the stone for the entry of the saw unnecessary. In some cases smaller saws of similar construction are used for cutting thick slabs into narrow slips, and sometimes several cuts are made at once by an equal number of saw-blades, arranged in a rectangular frame that is suspended horizontally by vibrating slings, and works between vertical guide-posts.

In the horizontal sawing machine for marble patented by Mr. James Tulloch, in 1824, the entire arrangements are combined in a very effective manner, for cutting a block of marble into a number of parallel slabs, of any thickness, at the one operation. The iron frame-work of the machine, shown in Fig. 2709, consists of four vertical posts strongly connected together at the top and bottom, to form a stationary frame from 10 to 14 feet long, 4 to 5 feet wide, and 8 to 12 feet high, within which the block of marble to be sawn is placed. The two upright posts at each end of the stationary frame have, on their insides opposite to each other, perpendicular grooves, within each pair of which slides up and down a square vertical frame; to the lower end of each of these slides is affixed a spindle carrying two guide-pulleys, or riggers, upon which the horizontal saw-frame rests, and is reciprocated backwards and forwards. The saw-frame is thus traversed within the fixed framing, and supported upon the four guide-pulleys of the vertical slides, which latter are themselves suspended by chains coiled upon two small drums placed overhead. On the same spindle with the drums is a large wheel, to which a counterpoise weight is suspended by a chain. The weight of the counterpoise is so adjusted as to allow the saw-frame to descend when left to itself, and which thus supplies the necessary pressure for causing the penetration of the saws.

2709.



The saw-frame is made rectangular, and from two to three feet longer than the distance between the vertical slides, in order to permit of the horizontal traverse of the saws, which is from 18 to 20 inches. To allow of the blades being fixed in the frame with the power of separate adjustment, every blade is secured by rivets in a clamp or buckle at each end. The one extremity of the buckle embraces the saw, the other is made as a hook; the buckle at one end of the saw is hooked upon a horizontal bar fixed across the end of the saw-frame, and the opposite end of the frame has a groove extending its entire width, through which a separate hook, provided with a vertical tightening wedge, is inserted for every saw, which thus admits of being replaced without deranging the position of the neighboring blades.

The distances between the saws, and their parallelism with the sides of the frame, are adjusted by means of iron blocks made of the exact thickness required in the slabs of marble; the blocks and blades are placed alternately, and every blade is separately strained by its tightening wedge until it is sufficiently tense; the blocks are sustained between two transverse bars, called *gage-bars*, and are allowed to remain between the blades to give them additional firmness.

The traverse of the saw-frame is given by a jointed connecting-rod, attached by an adjustable loop to a long vibrating pendulum, that is put in motion by a pair of connecting-rods, placed one over the other, and leading from two cranks driven by the engine. All three connecting-rods admit of vertical adjust-

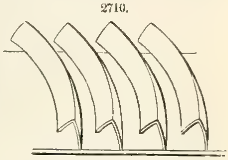
ment on the pendulum. The connecting-rod of the saw-frame is placed intermediately between the other two, but its exact position is regulated by the height at which the saws are working, as it is suspended by a chain and counterpoise weight, which allow it to descend gradually downwards on the pendulum with the progress of the cut, so as always to keep the connecting-rod nearly horizontal.

In the London Marble Works four of these sawing-machines of different sizes are grouped together, with the driving-shaft and pendulums in the middle, and so arranged that each pair of saw-frames reciprocate in opposite directions at the same time, in order to balance the weight, and reduce the vibration.

Another mode of traversing the saw-frame sometimes adopted, is by means of a vertical frame that is reciprocated horizontally on slides, and the connecting-rod, instead of being jointed, is fixed rigidly to the saw-frame, and slides upon a vertical rod. Various other unimportant modifications in the construction of the machines are also adopted.

One of the most difficult points in the application of these machines, was found to be the supplying of the sand and water mechanically to the whole of the cuts at the same time. This is now successfully effected by the following arrangement. Above the block of marble to be sawn is fixed a water cistern, or trough, extending across the whole width of the frame, and measuring about 1 foot wide, and 1 foot deep; about 20 small cocks are arranged along each side of the cistern, and a small but constant stream from each of the cocks is received beneath in a little box; a sloping channel leads from every box across the bottom of a trough filled with sand, which mingles with the water, and flows out in separate streams, that are conducted to each of the saw-cuts. In the first construction of this apparatus for the feed, the sloping channels were led straight across the bottom of the sand-trough, but it was then found that the water excavated little tunnels in the sand, through which it flowed without carrying the sand down. This difficulty was overcome by leading the channels across the bottom of the trough in a curved line, when viewed in plan. The form of the channels is shown in Fig. 2710, which represents four channels cut across the middle of their length, to show their section, from which it will be seen that the channels are made as a series of Gothic shaped tunnels, supported only on one side, and open on the other for the admission of the sand; the water flows through these tunnels, and continually washing against the convex side of the channel, undermines the sand, which falls into the water and is carried down: to assist this action the attendant occasionally stirs up the sand to loosen it. There is a sand-trough and set of channels on each side of the water cistern, so that every saw-cut receives two streams of sand and water in the course of its length.

2710.



The saws having been adjusted to the proper distances for the required slabs, the saw-frame is raised by means of a windlass and the suspended chains attached to the vertical frames, and the block of marble to be sawn is mounted upon a low carriage, and drawn into its position beneath the saws, and adjusted by wedges. The saws are then lowered until they rest upon the block, the counterpoise weights are adjusted, and the mixed sand and water allowed to run upon the saw-blades, which are put in motion by attaching the connecting-rod to the pendulum. The sawing then proceeds mechanically until the block is divided into slabs, the weight of the saw-frame and connecting-rod causing them gradually to descend with the progress of the cutting.

To allow the sand and water to flow readily beneath the edges of the saw-blades, it is desirable that the horizontal frame should be slightly lifted at the end of each stroke. This is effected by making the lower edges of the frame, which bear upon the guide-pulleys, straight for nearly the full length of the stroke, but with a short portion at each end made as an inclined plane, which on passing over the guide-pulleys lifts the frame just sufficiently to allow the feed to flow beneath the saws.

For cutting slabs of marble into narrow pieces, such as shelves, and which is effected by hand with grub-saws, a machine called a *ripping bed* is employed, in which as many cuts as may be required in the one slab are effected simultaneously, by an equal number of circular saws with smooth edges, revolving vertically, and fed, as usual, with sand and water. This machine consists of a bench about 12 or 14 feet long, 6 or 7 wide, and about 2 feet 6 inches high; upon the top of the bench is fixed two rails, upon which a platform, mounted on pulleys, is drawn slowly forward by a weight. The horizontal axis carrying the saws revolves about 9 inches above the platform, and to insure the rotation of the saws, the axis is provided with a projecting rib or feather extending its whole length. The saws are made as circular plates, about 17 inches diameter when new. The saws, or cutters, are clamped between two collars about 6 inches diameter, fitted so as to slide upon the spindle, and be retained at any part of its length by side screws.

The saws having been adjusted to the required distances for the widths of the slips to be cut, and fixed by the side screws, the slab of marble is imbedded in sand upon the platform, and the edge of every saw is surrounded on one side with a small heap of moist sand. The saws are then set in motion, so as to cut upwards, and the platform is slowly traversed under the saws by the weight, which keeps the slab of marble constantly pressing against the edges of the revolving saws, until the slab is entirely divided into slips.

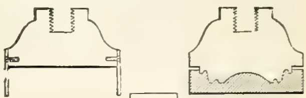
When the saws are new, they nearly reach the upper surface of the platform, and a moderate thickness of sand, just sufficient to form a bed for the slab of marble, raises it high enough to allow the saws to pass entirely through the thickness of the slab; but as the saws are reduced in diameter by wear, it becomes necessary to employ a thicker layer of sand, or to use a supplementary platform to raise the slab to the proper height. To avoid this inconvenience, an improvement has been recently introduced by mounting the axis of the saws in a vertical slide, which is adjusted by a rack and pinion, so as to allow the edges of the saw to penetrate exactly to the required depth.

Circular pieces of marble, such as the tops of round tables, and other objects, from about 6 feet diameter to the small circular dots sometimes used in tesselated pavements, are sawn to the circular form

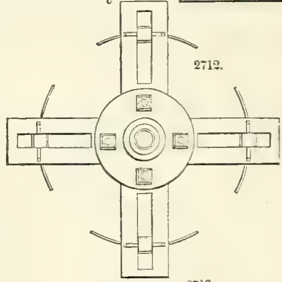
by means of revolving cylindrical cutters, constructed on much the same principle as the crown saws for wood. The slab to be sawn is placed horizontally on a bench, and the axis of the machine works vertically above it in cylindrical bearings, which allow the spindle to slide through them, so as to be elevated or depressed according to circumstances. The spindle is suspended at the upper end by a swing-collar attached to a connecting-rod, that is jointed to the middle of a horizontal lever. The weight of the vertical rod and cutter supplies the pressure for the cutting, and the whole is raised for the admission of the work by a rope attached to the end of the lever, and passed over a pulley.

For circles of small diameter, the cutters are made as hollow cylinders of sheet-iron, of various diameters, and each attached by screws to a circular disk of cast-iron, as shown in section in Fig. 2711. The cutter is screwed on the lower end of the spindle, just the same as a chuck on a lathe mandrel, except that the spindle is placed vertical instead of horizontal. To insure free access for the sand and water beneath the cutter, one or two notches, about three-quarters of an inch wide, are generally made in the lower edge.

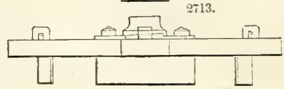
2711.



2712.



2713.



For large circles, the apparatus is made strong, and the vertical spindle is fitted at its lower extremity with a circular plate, to which is bolted a wooden cross, shown in plan in Fig. 2711, and in elevation in Fig. 2713; the cross has radial grooves about 18 inches long, near the outer extremities of the four arms. The cutters consist of detached plates of iron, from 6 to 18 inches long, of various widths, according to the thickness of the work. The cutters are curved as segments of a cylinder, of the particular diameter they are required to cut, and are each riveted to a clamp that passes through the radial groove, and is retained by a wedge. The number and length of the cutters is solely a matter of convenience, as a single cutter, when put in rotation, would make a circular groove, and several cutters are only employed in order to expedite the process. But every different diameter requires a different curve in the cutters, and which must all be placed at exactly the proper distance from the centre of rotation.

The horizontal bench upon which the marble is laid, is generally a temporary structure, adjusted to suit the thickness of the object to be sawn. Works of large diameter are seldom more than one or two inches thick, but those of small diameter are frequently much thicker, and sometimes three or four thin pieces are cemented upon each other, and cut at one operation. Short pillars are sometimes sawn out of an irregular block in a similar manner, instead of being chipped and turned. And it has been proposed that long cylinders, and tubes of stone, should be cut with cylinders of sheet-iron of corresponding length, put in rotation, and supplied with sand and water.

Marble works of small and medium size, are ground flat upon horizontal revolving laps, after the same general method as that pursued by the lapidary, but with a proportionate increase of size in the lap, which is supplied as usual with sand and water. The laps for marble works are made as circular plates of cast-iron, from 6 to 14 feet diameter, and about 3 inches thick when new; they are mounted in various ways upon vertical spindles, so that their upper sides or faces may be about 2 feet 6 inches above the ground. Across the face of the lap, or, as it is called, the *sanding plate*, one or two strong square bars of wood, faced with iron, are fixed so that their lower sides may just avoid touching the face of the lap, and their edges present perpendicular faces, from 5 to 6 inches high, at right angles to the face of the lap. The wooden bars serve as stops to prevent the work from being carried round by the lap, and also as guides to insure the work being ground square.

The piece of marble is laid flat upon the lap, with the face to be ground downwards, and the side of the work in contact with the guide-bar. Water is allowed to drip upon the plate from a cistern fixed above, and small quantities of sand are thrown on as required. During the progress of the work the workman leans upon the marble, the position of which is shifted occasionally to expose both the work and the lap to an equal amount of wear, and prevent the formation of ridges, but which is less likely to occur with iron laps used for grinding large surfaces of marble, than when small objects are applied upon lead laps, as by the lapidary and mechanician.

The one side of the marble having been reduced to a flat surface, the work is turned over to grind the adjoining face, and the first face is held in contact with the perpendicular side of the guide-bar, in order to present the second face of the work to the lap exactly at right angles to the first. When two pieces of similar size are to be ground each on the one face and two edges, as for the upright sides of a chimney-piece, the two pieces of marble are cemented together back to back with plaster of Paris, (a process that is called *lining*,) and the pair are ground as one piece on all four faces; in this case the flat sides are first ground parallel to each other, or of equal thickness on the two edges, and the latter are then ground square by placing the sides in contact with the guide-bar.

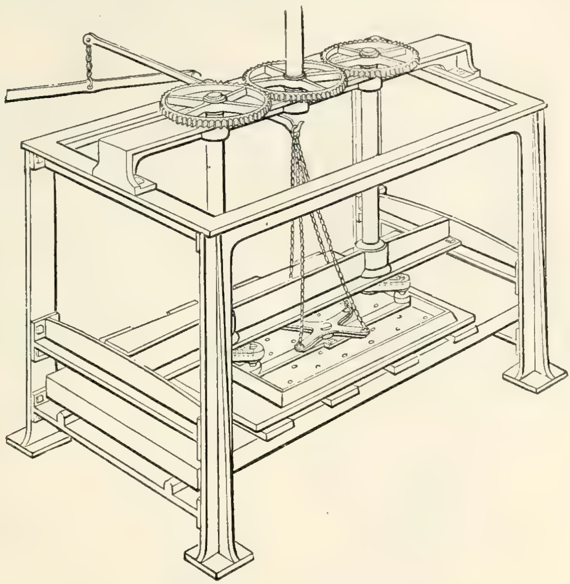
When the lap is of moderate size, one guide-bar only is employed, and it is fixed across the diameter of the plate, which then allows of two workmen being employed on the opposite sides; but large grinding plates sometimes have two or three bars placed at equal distances across the face, and four or six workmen may then be employed at the same time upon separate pieces of marble.

The sand and water are continually thrown from the lap by the centrifugal force, and the large size of the works sometimes applied prevents the use of a rim standing up above the level of the lap to catch the wet, as used by lapidaries. Every workman, therefore, stands within a kind of trough like a box, about three feet high, without a top or back; the troughs serve as a protection to the workmen, who would otherwise be exposed to a continued shower of sand and water.

The surfaces of large slabs are in some cases ground upon revolving plates; in this case the axis is placed entirely beneath the surface of the plate, somewhat as in Fig. 2714, and the slab is traversed by two men over the face of the plate to grind it equally, but the machine next described is better adapted for large slabs of marble requiring tolerable accuracy.

Large slabs of marble and stone are ground very accurately in a machine patented by Mr. Tulloch and called a grinding bed. In this machine, represented in Fig. 2714, the slab to be ground is placed

2714.



horizontally upon a moving bed, and the grinding is effected by sand and water, by means of a large flat plate of iron resting upon the surface of the slab. The two surfaces are traversed over each other with a compound motion, partly eccentric and partly rectilinear, so as continually to change their relative positions. The machine consists of a frame about 9 feet long, 6 feet wide, and 8 feet high; about 2 feet from the ground is mounted a platform, that is very slowly reciprocated horizontally for a distance of from 1 to 2 feet, according to the size of the slab, by means of a rack and pinion placed beneath, and worked alternately in both directions.

Above the platform are fixed vertically two revolving shafts, having at their upper extremities horizontal toothed wheels of equal diameter, which are driven by means of a central toothed wheel keyed on the driving-shaft. The two vertical shafts are thus made to revolve at equal velocity, or turn for turn, and to their lower ends are attached two equal cranks, placed parallel to each other; the extremities of which, therefore, describe equal circles in the same direction. To these cranks the iron grinding plate or runner is connected by pivots fitting two sockets placed upon the central line of the plate. The cranks are made with radial grooves, so that the pivots can be fixed by wedges at any distance from the centre of the cranks. When the machine is put in motion, the grinding plate is thus swung round bodily in a horizontal circle of the same diameter as the throw of the cranks, which is usually about 12 inches, and consequently every portion of the surface of the grinding plate would describe a circle upon the surface of the slab being ground, if the latter were stationary. But by the slow rectilinear movement of the platform, the slab is continually shifted beneath the plate, so as to place the circles, or rather the cycloids, in a different position; and it is only after many revolutions of the cranks that the same points of the surfaces of the grinding plate and slab are a second time brought in contact.

The grinding plate is raised for the admission of the slab by means of four chains suspended from a

double lever, and attached to the arms of a cross secured to the centre of the upper surface of the plate, which is thus lifted almost like a scale pan. For slabs that are much thicker or thinner than usual, the principal adjustment is obtained by the removal or addition of separate beds, or loose boards, laid upon the platform to support the slab at the proper height. Slabs that are too large to be ground over the whole surface at the one operation, are shifted once or twice during the grinding, to expose the surface equally to the action of the grinding plate.

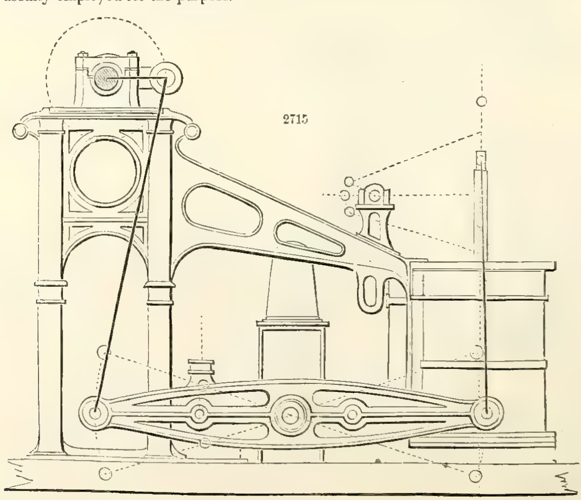
The necessary pressure for grinding, is given by the weight of the horizontal plate, which is supported almost entirely by the work, as the pivots of the cranks merely enter the sockets, and allow the plate to descend when left to itself. For delicate works a counterpoise weight is attached to the double lever so as to regulate the pressure on the work.

The sand and water are applied to the grinding surfaces in much the same manner as in the iron runners used by hand, previously described. The grinding plate is made on the upper side with a raised rim like a tray, and the bottom of the tray is perforated with numerous holes about 1½ inch diameter arranged at equal distances apart. The sand and water are thrown into the tray at intervals in small quantities, and run through the holes and between the surfaces of the slab and grinding plate, which are thus uniformly supplied with the feed that ultimately makes its escape around the edges of the grinding plate.

Various qualities of sand may be employed according to the perfection of surface required, and very flat surfaces are produced by this machine. The *grounding* or smoothing of the best works is effected with a succession of fine emeries, with which the surfaces may be made very smooth, and almost polished; but from motives of economy, the grounding of ordinary works is more frequently completed by hand, with grit-stone and snake-stone, before the work is finally polished on another machine.

Rectilinear mouldings in marble are wrought by machinery in a manner altogether different from the hand process of working mouldings, in which, as previously described, nearly the whole of the material is removed with chipping chisels, and the surfaces of the mouldings are only smoothed by abrasion. In the machine process, on the contrary, the whole of the material is removed with revolving grinders, by which the work is reduced to the required form, and left smooth at the one operation.

The machine for working rectilinear moulding, or as it is called *the moulding bed*, closely resembles in its construction the ripping bed described previously, except that the frame carrying the revolving grinders is provided with the power of vertical adjustment by a screw placed beneath, in order to raise the grinder to the proper height to suit the thickness of the marble, and that instead of the grinders being thin circular sheets of iron, they consist of solid cylinders of cast-iron turned to the counterpart forms of the required mouldings. Indeed the ordinary ripping bed is occasionally used for working mouldings on large works, and when it is provided with the vertical adjustment for elevating or depressing the axis to any required position, the ripping bed is equally suitable for working mouldings but as the latter are in general only required on slips of marble only a few inches wide, a narrow machine is usually employed for the purpose.



MARINE ENGINES, *Steam.* Marine engines may be divided into two broad classes, viz: beam or lever engines, and direct acting engines. These may be either condensing or non-condensing engines, the former, however, are the most extensively used. With the exception of small screw-propellers and tow-boats, and steamers on the western waters, the condensing or low-pressure engines are almost

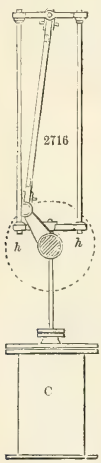
wholly used in this country. The terms high and low pressure are in general used to designate respectively the non-condensing and condensing engine, although the terms are not in truth sufficiently distinctive, as the condensing engine may be, and in connection with the expansion principle, frequently is, used with what may be called high steam. What would be considered in this country a low pressure steam, say 40 lbs. to the inch, would be considered in England as high-pressure.

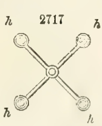
These two classes admit of subdivision into many varieties, but may, for all practical purposes, be confined to the following system of arrangement:

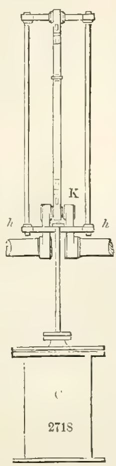
Beam-engine..Side-lever.

Direct-acting engine... {
- Vertical.. { Square engine. / Steeple engine. / Trunk engine. / Gorgon. / Fairbairn. / Double-cylinder engine.
- Oscillating,
- Rotatory.

The Direct-Acting Engines differ from the beam-engine simply in the method of taking the power from the piston-rod. In the one the head of the piston-rod is connected either directly with the crank, or by means of a connecting-rod or rods; in the other, the working-beam or great lever, vibrating on its centre, receives at one end the power from the piston-rod through the modifying action of "parallel motion" rods, or plain slides, and communicates it to the crank-shaft by a connecting rod attached to its other extremity.







The Side-Lever Engine is a modification of the beam-engine. In our river and coast boats the walking-beam or lever is above the engine, and single; but in the sea-going steamers two of these beams are used instead of one, and instead of being above the engine they are brought down to the bottom, one on each side, and being connected by a cross-tail, they act as a single beam or lever. Hence is derived the name from this disposition of the working-beam, the "side-lever engine."

The Beam-Engine, illustrated in fig. 1511, is the engine of the "Osceola," running on the North River, and may be taken as the type of a large class of engines in use on our coast and rivers. The boats worked by these engines are frequently on an immense scale, with engines of the most perfect construction, and are managed with great skill, very frequently attaining a speed of over 20 miles an hour. They have been employed successfully for sea-going steamers, as in the North Star and Vanderbilt, and come properly under the head of marine engines.

Fig. 2715 will give an idea of the general appearance of the *side-lever engine*, in outline. Of this character are the engines of the Collins line of steamers, as also the Cunard, the Havre, Charleston, New Orleans, and Chagres steamers, and in fact a very large majority of all sea-going steamers are of this description of engine. So universal indeed is its use, that when we speak of the marine engine, this form of engine is ordinarily understood, unless otherwise specified. For although other forms of engines may become of as much importance to steam navigation, certain it is that at this day no engine has been found to equal it in point of general efficiency. The description of engine called *oscillating* is, however, coming into favor, from other considerations to be noticed subsequently.

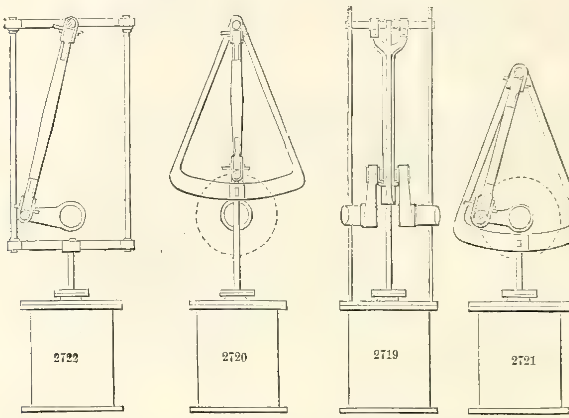
Passing to the varieties of the direct-acting engine, already defined, we find that the attempt to produce engines more compact and of less weight and bulk, has extended the examples of this class of engines into an almost endless variety of modifications. Scarcely any two are alike; and in our classification above, we have retained only those whose features are sufficiently distinctive to admit of generalization. Some engineers regard those engines only as direct-acting, where the piston itself seizes the crank, without the intervention of any connecting-rods. Such are the trunk and oscillating engines; but the classification we have used is simple, and sufficiently minute for all purposes.

In the first species of the direct-acting engine, namely, the vertical, the paddle-shaft is directly over the axis of the cylinder; but the method has the disadvantage of admitting only a short stroke and a short connecting-rod, and requires that the height of the axis above the bottom of the cylinder should be at least three times the length of the stroke. Thus one of the extremes, too short a connecting-rod, too short a stroke, or a paddle-axis too high above the floor of the vessel is incurred.

In this country the square engine, the first variety of the vertical engine, has its cylinder immedi-

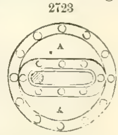
ately over the axis and cranks, to which motion is communicated from the cross-head of the piston by means of side-rods, the air-pump being worked by a separate beam connected with the cross-head by proper links; but this is equally unsuited to sea-going steamers on account of the height of the cylinder above the paddle-shaft.

To obtain the object sought without incurring these evils, many descriptions of engine have been contrived; among others the steeple engine, so called, where the piston-rod is made forked, so as, passing round the shaft, to rise above it to a considerable height, from which again descends the connecting-rod to the crank. Figs. 2716 to 2721 illustrate the principle. The top of the piston-rod carries a four-armed cross-head *h h*, on each end of which stands a pillar *h h;* these four pillars again unite in another quadruple cross-head, sustained upright by a vertical guide; and it is from this summit that a connecting-rod descends to the crank K.

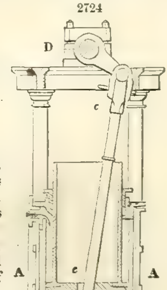


After passing through a great variety of phases the steeple engine appears to have settled down into the two following shapes. In figs 2720 and 2721 the piston-rod is seen united to a triangular frame, from the apex of which the connecting-rod descends to the crank. In fig. 2722 this frame is shown to be square, and fig. 2719 is the side view of both varieties.

2723



2724



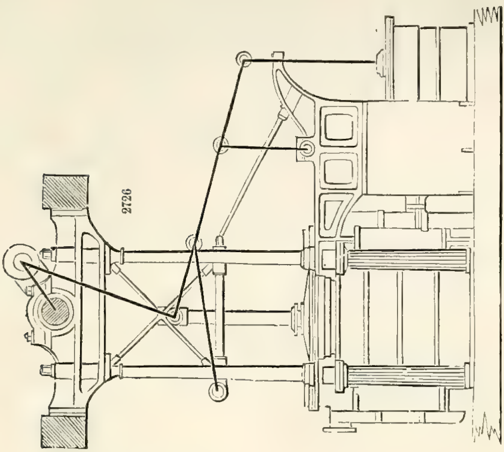
Another method of accomplishing the direct connection without encumbering the deck is called the *trunk engine.* The axis is placed at the height of half the stroke, or more, above the cylinder, and a connecting-rod unites immediately the crank-pin with the centre of the piston. In this way the connecting-rod, passing through the top of the cylinder, would allow the steam to escape but for a large trunk or casing with which it is surrounded, and which, passing through a chasm of large area conceived to be steam-tight, rises and falls with the piston to which it is attached. In fig. 2724, A A is the cylinder; to its piston is attached a trunk B, which works through a stuffing box in the cylinder cover; to the piston the connecting-rod *c c* is attached. Fig. 2723 represents the top of the cylinder A A, with its stuffing-box and the trunk.

These engines were first used for marine purposes with vertical cylinders, and were again introduced into use by Penn, of Greenwich, with horizontal cylinders. The first application of it was to H. M. S. Encounter, a vessel of 360 horse-power. The cylinders are horizontal, and connected at once to the screw-shaft. These engines make between 78 and 80 revolutions per minute, which was sufficient to propel the ship about eleven knots. They were fitted with locomotive slides, and worked with two eccentrics. The air-pumps, like the cylinders, were horizontal; and indeed all the parts of the engines were as low as they possibly could be, for the purpose of bringing the machinery below the water line.

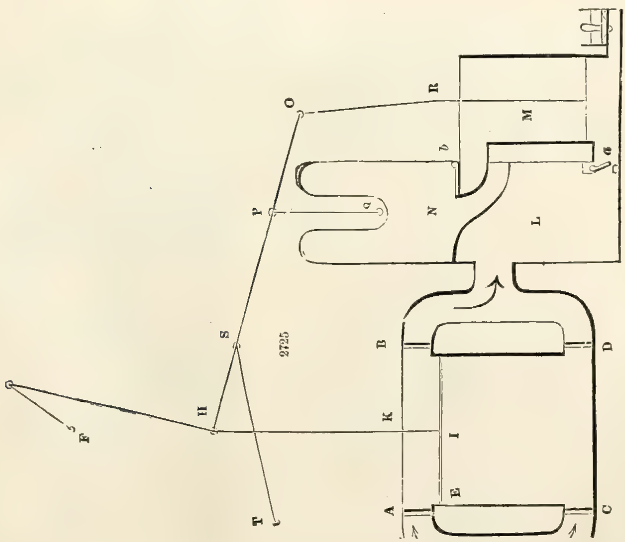
This form of engine was used by the Messrs. Kemble, for the steamers "Pioneer" and "City of Pittsburg." In these the cylinders are again brought back to the original vertical position, and form, notwithstanding, a most compact form of engine.

The Gordon, Fairbairn, and the double-cylinder engines are English varieties of direct-acting engines extensively used abroad, but little used in this country; they deserve a passing notice, as illustrative of the efforts made to reduce the dimensions of marine engines within the least possible limit.

The principle of construction of the *Gorgon engines* will be clearly seen by reference to fig. 2725, which represents a section of one of such engines; and the several parts, for simplicity sake, are represented



2726

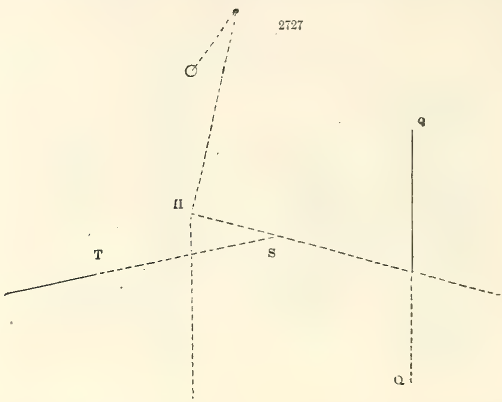


2725

only by lines. Here A B C D represent the cylinder, F is the centre of the shaft, directly over the middle of the cylinder; I E is a section of the piston; I H the piston-rod, working steam-tight in a stuffing-box at K; H G is the connecting-rod, and G F the crank It is easily seen that as the piston is

forced up and down by the steam, the crank will be made to revolve, and consequently cause the paddle-wheel to rotate. The remaining parts of the engine will be readily understood: L is the condenser, M the air-pump, N the hot well, *a* and *b* are the foot-valve and delivery-valves respectively. There are two particulars deserving special notice in this engine, viz.: the slides for admitting the steam and allowing it to escape, and the parallel motion, or the means of keeping the piston-rod in its vertical line. It is observable that there are four slides, viz.: A, B, C, and D, two of which, A and C, are for allowing the ingress of steam, and the other two, B and D, for allowing it to escape to the condenser L. The following is an outline of the parallel motion: H O is a beam called the "rocking-beam," one end of which

2727



fitted to the upper extremity H, of the piston-rod. P Q is a vertical frame, called the 'rocking-standard;" the lower end of this is connected with some convenient point Q, about which it can move, and the upper end P will therefore describe a small circular arc about Q; but this arc will be so small that it may be practically looked upon as a straight line. T S is a bridle-rod, secured at one end T to the framework of the engine, and at the other to the rocking-beam. If, now, these rods have the proper proportions, the motion of H will be vertical. The rocking-beam is continued along to O, and the air-pump rod is fitted to it by means of the intermediate rod R O. The air-pump rod is kept in a vertical line by means of guides.

2728

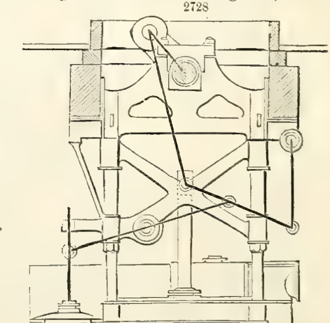


Fig. 2726 represents an outline of the Gorgon engine.

The chief peculiarity of Fairbairn's direct-acting engines is in the parallel motion, which is somewhat similar to that of the Gorgon engines.

The dotted lines, fig. 2727, represent the Gorgon engines. H P O is the rocking-beam; H the point to which the piston-rod and connecting-rod are attached; P the point of attachment of the rocking-standard; then, to construct Fairbairn's parallel motion, let the rocking-standard P Q be inverted, as in the figure, so as to hang down from a point Q′ in the entablature of the engine. In the Gorgon engines, H P is prolonged to O, as before described, and the air-pump is worked from this extremity; but in Fairbairn's engines the radius-gear S T will be produced to some point O′, and O′ T serves as the beam for working the air-pump. The steam is admitted and allowed to escape by means of a slide-valve, worked by an eccentric.

The four main parts of each engine, viz.: the cylinder, slide-valves, condenser, and air-pump, form a square, and thus occupy little space.

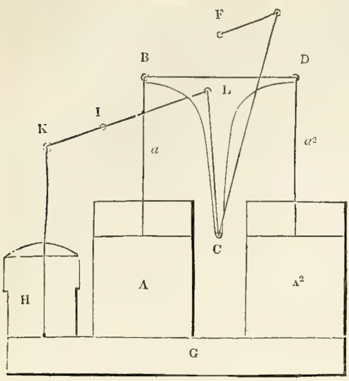
Fig. 2728 represents in outline one of the Fairbairn engines.

Maudslay's Double-Cylinder Engines. In the foregoing direct engines the connecting-rod is necessarily shorter than it would have been if side-levers had been used; and consequently the force exerted on the

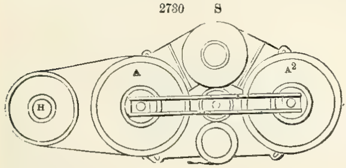
crank alters more suddenly as the motion is alternated from the up to the down stroke, and *vice versa*, than would have been the case had the connecting-rod been longer.

Now, in most direct engines a long connecting rod is an impossibility; for the distance from the shaft to the bottom of the vessel being limited, the depth of the cylinder, the radius of the crank, and the length of the connecting-rod, must all be accommodated to it. Messrs. Maudslay and Field proposed to remedy it by adapting two cylinders to each engine, instead of one; the cylinders having one connecting-rod between them. In figs. 2729 and 2730 A and A^2 are the two cylinders of one of the engines; a a^2 the piston-rods; these rods are connected together at their upper extremities by the cross-piece

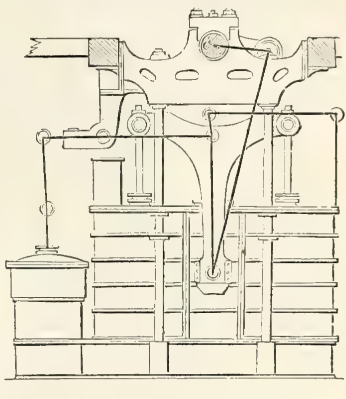
2729



2730 S



2731



B C D, called (from its form) the T-plate; the lower end C of the T-plate is attached to the connecting-rod C E, which again being connected with the crank E F communicates with the paddle-shaft F. The condenser G is underneath the cylinders. It is clear that if steam be admitted below both pistons at the same time, the pistons, in rising, will force up the T-plate, and with it the connecting-rod, &c.; and conversely these will again descend as the piston is forced down. Hence the working part of the engine can be comprehended. It remains to be shown how the steam is admitted to both cylinders simultaneously. Looking at the plan of the figure, the circle S represents a slide-valve, different in form from the common slide-valve, inasmuch as it is circular instead of being semicircular; it has one upper and lower face in contact with the ports of the cylinder A, and one of each in contact with the cylinder A^2, so that as the valve is raised or depressed, the steam is admitted above or below both pistons at the same instant of time. H is the air-pump, the bucket of which is worked by the beam K L moving round the centre I.

2732

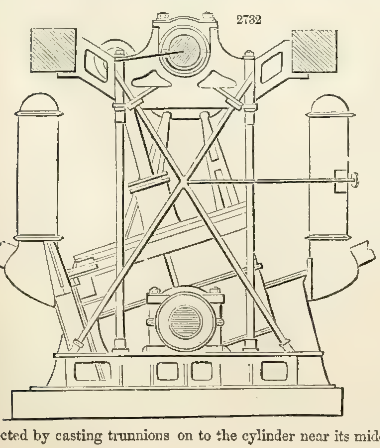


Fig. 2731 is an outline elevation of the double-cylinder engine.

In the *oscillating engines* the connecting-rod is altogether dispensed with, the piston-rod being attached directly to the crank; and because the piston-rod from this mode of attachment, must either be bent when motion ensues, or the top of the cylinder must move laterally, this is provided for by allowing the cylinder itself to vibrate in a small arc, effected by casting trunnions on to the cylinder near its middle, as an axis upon which it oscillates.

Fig. 2732 will give an idea of the appearance of the oscillating engine.

Many nautical men, and some engineers, have objected to oscillating engines on account of the movement of the cylinder, which, they imagined, would become a formidable evil in the case of a vessel rolling heavily at sea. These objectors do not seem to have remarked that the rolling of the cylinder is neither dependent upon, nor proportionate to, the rolling of the ship, but is regulated exclusively by the movement of the piston; and it is difficult to see why a mass of matter, in the form of a cylinder, should be more formidable or intractable in its movements than a similar quantity of matter in the form of a side-lever, or in any other shape whatever. It has also been objected against the oscillating engine, that the eduction passages are more tortuous than in common engines, so that the steam gets out of the cylinder less freely. We do not believe such to be the fact, if the comparison be made with the common run of marine engine; and in practice, no diminution of efficacy from this cause is appreciable. All the objections that have been raised to the oscillating engine are hypothetical; they are anticipations of defects *to be* found out in large engines on the oscillating plan, and would probably be plausible enough to carry some weight, were it not the fact that they have been completely controverted by experience. The remark, indeed, is heard sometimes even yet, that the oscillating method may do very well for small engines, but is of doubtful efficacy for large ones. But the definition of large engines has been continually changed, to escape the contradiction experience afforded, and that size is, in every case, decided to be large, which just exceeds the size of the oscillating engine last constructed. The grounds of this skepticism, however, are now being fast contracted; and, indeed, experience has now demolished every objection that theory had raised. Some persons have apprehended that it would be difficult in large oscillating engines to obtain sufficient surface of trunnion to prevent the trunnions from heating; yet we have never been able to learn that any heating of those bearings has been found to occur in practice, and it appears probable that any such disposition would be resisted by the cooling effect of the steam passing through them, which, though hot, is of greatly inferior temperature to that of a hot bearing. It does not appear to us, however, that the trunnions may not be made with any amount of surface that is thought desirable, but we believe the proportion adopted by Messrs. Penn have been found adequate, and are generally adopted in this country.

Rotatory Engines are engines for obtaining a motion round an axis by the direct action of the steam, without involving the necessity of reciprocation. Some of them operate on the principle of reaction of which the engines of Avery and others may be taken as specimens; others operate on the principle of impulse; a third kind trusts to the intervention of some liquid to produce the desired effect, as in the mercury engine of Watt and the wheel of Amonton; while in the fourth class the piston moves in a circle round the axis. It is impossible to give any enumeration even of the numberless schemes for rotatory engines that have at various times been projected; but none of them have been applied with any prospect of success to the purposes of navigation, and in their present state, need scarcely be ranked as marine engines.

MARINE STEAM-ENGINE, *of one hundred and forty-five horse-power.* By Caird & Co., Greenock. The following figures illustrate very fully the form and construction of marine engines made by Messrs. Caird & Co. of Greenock, for the steam-packets Actæon and Achilles, and also for the royal mail-packet Urgent, still plying betwixt Liverpool and Dublin. The drawings were made from the engines of the Actæon, since lost on the West-India station; but in order to render them more complete, and therefore more acceptable to the engineer, the expansion-geer subsequently applied to the engines of the Achilles has been embodied. It may also be remarked, that by proportionally reducing the scale of the drawings, they will be found to agree in every respect, beyond a few very slight modifications of a technical kind, with the larger class of engines, since constructed by the same spirited firm for the West-India mail-packets Clyde, Tay, Tweed, and Teviot, of 225 horse-power each engine. The figures may thu be regarded as giving a general representation of the form of marine engines built by a firm to whose engineering skill the profession is indebted for a design of engine equally remarkable for elegance of appearance and compactness of arrangement. In lightness of material it is no doubt surpassed by the recent introduction of malleable-iron framing, and direct-action; but in the class to which it belongs, known as *side-lever engines*, it exhibits a massiveness of appearance and an economy of weight which, in combination with equal strength, has not hitherto been surpassed.

Enumeration of the figures.—Fig. 2714½ exhibits a complete side elevation of the engine, showing the general design and arrangement of the framings, and the relative positions and connections of the working parts; the valve, expansion, and starting geer, parallel motions, and situation of the pumps. In this view the side of the vessel is supposed to be removed and the engine seen *in situ.*

Fig. 2715 is a plan of the sole-plate of the engine with all the parts removed, but showing the position and provision for fixing the steam-cylinder bottom and valve casing, the hot-well, placed on the top of the condenser, the air-pump, and the soles of the main framing.

Fig. 2716 is a general plan of the engine, exhibiting very fully the starting and eccentric geer, the mode of working the pumps, the direction and position of the steam-pipe, and mode of connecting the diagonal framing; also the horizontal relation of the valve and expansion geer.

General description.—Sole-plate and condenser.—The sole-plate, marked A A, with the condenser U, consists of a single casting, double-ribbed on the under side, to give it additional strength and rigidity. For facility of fitting it is provided with fitting-strips on its upper surface; these are faced true to receive the soles of the main frame and cylinder bottom, which are fitted upon it metal to metal, and consequently are likewise provided with corresponding fitting-strips, faced in the same manner. The sole-plate is firmly secured to the keelsons of the vessel by sixteen strong malleable-iron bolts marked *a* in the elevation, and the recesses for which are similarly designated in the plan of the sole-plate The middle of the plate, falling between the two keelsons, is depressed to allow the condenser and its appendages to stand lower in the vessel than they otherwise would, as shown in the general section.

Framing.—The main framing of the engine consists of four strong fluted columns, cast pair and pair

with their soles and entablatures. The soles, as above observed, are fitted upon the sole-plate metal to metal, and are secured to it by bolts and keys, for which snugs are cast on the sole-plate. The entablature is completed by two cross-beams corresponding in form with the sides, into which they are fitted and secured by bolts. The form of their cross-section is shown in the general section of the engine.

The upper or crank framing consists likewise of four columns cast pair and pair with their soles and entablatures; but in this case there are no cross pieces, the two sides being simply braced together by two strong malleable-iron stays marked *c*. One of these passes between two strong lugs cast on the back columns near the top, and the other between the cheeks of the *diagonal framing* marked C. The crank-framing rests on the entablature of the main frame to which it is fitted, and secured by bolts and by two centre keys in each sole, driven on the right and left of a dovetail snug cast on the entablature of the lower frame, and which enters a similarly formed but larger recess in the sole of the upper frame —an arrangement which is clearly shown both in the general elevation and section. This framing is further secured between the ship's beams by the strong stays *b b* cast upon the entablatures. These stays usually abut against cast-iron face-plates, bolted upon the paddle-beams at the points of contact, but they are neither bolted nor otherwise fixed to the facings, but are left free to slide vertically upon them in obedience to any spring which the vessel may have when under way, and which is often considerable, especially in a rough sea. The crank-framing is also braced to the steam-cylinder by the diagonal framing C C, consisting of two strong parallel struts cast upon the inner columns of the crank-framing, from which they spring. These struts terminate in rectangular flanges, answering to similarly formed projections cast on the cylinder on opposite sides of the valve-casing at top; and to these they are carefully fitted metal to metal, and secured by bolts, as partially shown at *d* in the elevation and plan.

The principal use of the crank-framing, and that from which it takes its name, is to support the crank-shaft. This is accomplished in each of the engines by two plummer-blocks, one on each side of the crank, secured by bolts and keys on the entablatures of the frames. The soles of the plummer-blocks are in this, as in all highly finished engines of the same class, likewise faced and fitted metal to metal.

Steam-cylinder.—The steam-cylinder E is cast open, and with broad and strong flanges at both ends. It is placed upon a separate bottom piece, flanged like the cylinder, to allow of their being bolted together. This bottom piece being truly faced, above and below, is secured to the sole-plate of the engine by strong bolts, and rusted. The lower end of the cylinder being truly faced is similarly fitted upon and secured to the upper flange of this bottom piece, so that the whole may be perfectly steam-tight.

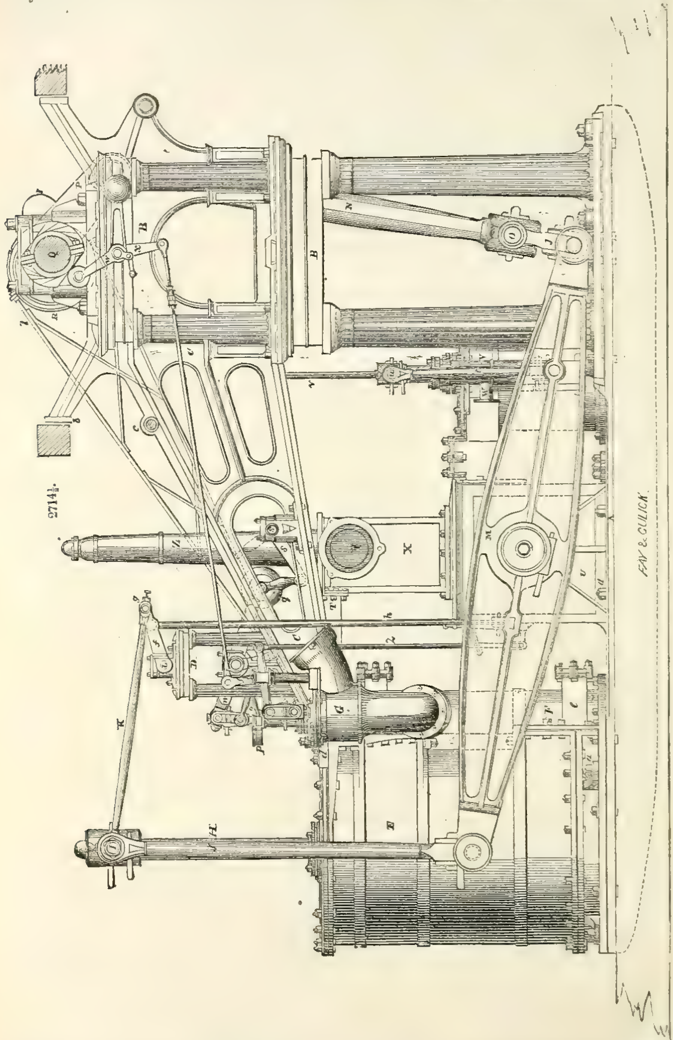
The interior of the cylinder is bored as truly as possible of a uniform inside diameter of sixty-two inches. The cover *d'* which, as will be observed from the section, is cast hollow, is fitted by turning and grinding, into the upper end to nearly the depth of the steam-port. On the inside is a circular recess to receive the heads of the bolts of the junk-ring of the piston; and the exterior plate is expanded by a strong flange to the same diameter as the flange of the cylinder, to which it is secured by bolts. In the centre is formed the stuffing-box through which the piston-rod ascends.

The projecting corner pieces marked *d* are those to which the diagonal framing is attached; they are faced both on their horizontal and vertical surfaces, so that the corresponding flanges, in which the struts of the framing terminate, may be fitted truly upon them. The projecting valve facings are cast of a piece with the cylinder. These are carefully dressed and the whole surface of both exactly reduced to the same plane; and to complete them, a carefully finished facing of brass, but of less breadth, (two inches,) is applied steam-tight round each of the ports, and projects on each side, by runners of a length corresponding to the length of the ledgings of the valves. The outlines of these facings are indicated in the view above referred to, and the transverse form in the general section of the engine.

The piston.—The body of the piston consists of a single hollow casting, strengthened by radiating feathers, with a strong eye in the centre to receive the piston-rod. The under side is a portion of a sphere answering to the curvature of the bottom of the cylinder. The upper side in like manner is convex to its junction with the ring, which is horizontal, and corresponds to a horizontal part round the inside of the cover, within which the cover is a segment of a hollow sphere of the same radius as the top of the piston. By making these parts of a curvilinear section, they are better secured from rupture by changes of temperature; and the piston being symmetrical in its outlines with the cover and bottom, the loss of steam due to the *clearance* is reduced to a minimum.

The under side of the piston only is cast of a diameter equal to that of the cylinder, the deficiency on the upper side being made up by the *junk-ring.* This ring is fitted steam-tight, first by turning and subsequently by grinding. Packing-rings, consisting of two thicknesses, made up of overlapping segments, are likewise fitted into their place between the junk-ring and the flange corresponding on the under side of the piston, and are rendered steam-tight by the same means. The whole of these thicknesses, composing the edge of the piston, are simultaneously turned of a uniform diameter, precisely equal to the internal diameter of the cylinder, in which they are intended to work steam-tight; but as this condition would endure only for a short period, however carefully and exactly the fitting might be effected, were no provision made for compensating the wear incident to the continued motion of the piston, and especially under variations of temperature, as in starting, the packing-rings are rendered capable of adjusting their diameter to that of the cylinder, by springs placed behind them. The springs employed in this piston are of a U-form, placed vertically, the strong side bearing upon the piston, and the elastic side against the adjacent ends of two of the segments. The number of springs and segments is thus necessarily equal, and so arranged that every segment is supported at each end by a spring. By this means the piston is made to work in the cylinder steam-tight, and to accommodate itself to any slight variations due to the contraction and expansion of the materials; and likewise to compensate for wear of its own circumference and that of the cylinder.

The junk-ring is secured in its place by bolts and nuts; the nuts are placed in recesses provided for them in the metal of the piston, and the bolts are screwed into them from the outside. The heads thus project on the surface of the ring, and would come into contact, at the end of the up-stroke, with the cylinder cover, but for a circular recess formed in it for their reception, as before noticed.

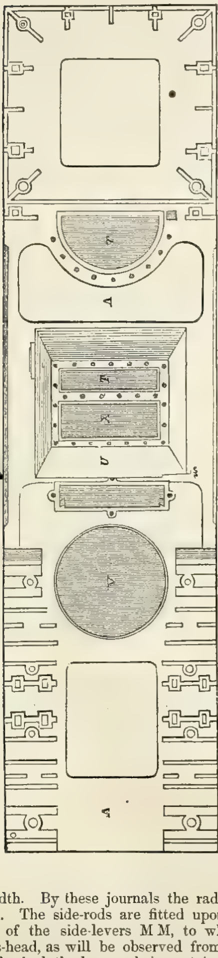


The piston-rod H is inserted into the piston through the eye in the centre, which is bored and tapered from the under side. The rod is of malleable iron, and turned, the body of it truly cylindrical, so that it may work freely in the stuffing-box through which it ascends, and the lower end with the same taper as the eye into which it is fitted, and in which it is secured by a cotter-key traversing the metal of the

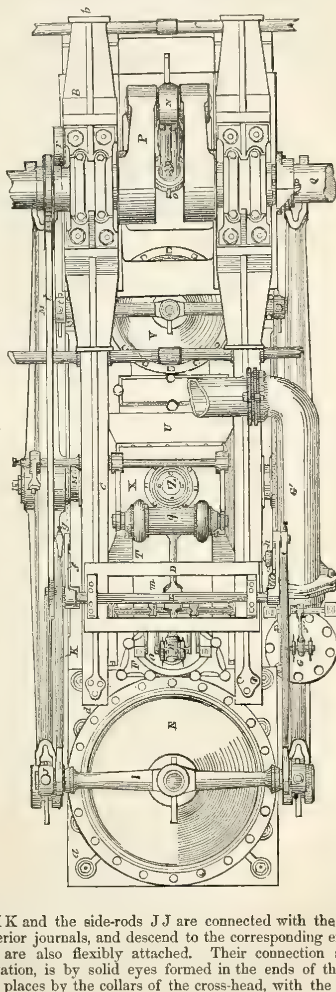
eye and the thickness of the rod thereby effectually binding the latter to the piston. For convenience of inserting the key a recess is left in the upper plate of the piston, which is afterwards filled, to prevent the steam gaining admission to the hollow interior of the piston.

Piston cross-head and connections.—The piston-rod, ascending through a packed stuffing-box, is inserted into an eye, bored a little smaller than its own diameter in the cross-head I, equidistant from the two extremities; and is then fixed by two gibs and cotter in the usual manner. The cross head has two journals turned on each of its ends, separated from each other by ruffs of an inch

2715.



2716.



breadth. By these journals the radius-bars K K and the side-rods J J are connected with the cross-head. The side-rods are fitted upon the exterior journals, and descend to the corresponding extremities of the side-levers M M, to which they are also flexibly attached. Their connection at the cross-head, as will be observed from the elevation, is by solid eyes formed in the ends of the rods and bushed, the brasses being retained in their places by the collars of the cross-head, with the assistance of a key bearing against the back of the lower brass; but the connection with the side-levers is effected differently. Here the brasses are placed within strong malleable-iron straps, bent at the mid

dle of their length till their projecting ends fit closely upon the rectangular ends of the side-rods, to which they are secured by a gib and cotter. This species of connection, technically known as the *butt-end and strap*, and universally adopted in like circumstances, provides for any slight wear of the brasses for should these become too large, they can be brought closer together by driving the cotter more tightly, the holes through which the gib and cotter pass being so disposed in the strap and butt that the gib shall only be in contact with the ears of the strap and the cotter with the butt on its under edge. The holes in both strap and butt being thus of greater breadth than the gib and cotter together, the connection admits of adjustment to the extent of the difference, and no further, for then the edges of the holes being in the same plane, the relative positions of the strap and butt will not be altered by any subsequent action upon the cotter.

The side-levers are divided at their extremities at the point of connection with the side-rods J J and the links *j j*, which connect them with the cross-tail. The joints are completed by strong malleable-iron pins which pass through the jaws of the levers, and the bushes of the straps which are placed between them. These centre pins are turned with a little taper on the parts which pass through the levers, and the holes made for their reception are accurately bored to the same diameter and ground. The studs are driven in tightly from the outside, and secured in their places by riveting at the opposite extremity.

Both levers are suspended upon the same axis called the *main centre*, M′, which passes through and is fixed in the sides of the condenser. It will be observed that the eye of the lever is fitted with brasses which can be tightened as they wear by a pair of cotter-keys, passing through the boss and bearing against the back of the under brass. Inside, and bearing against the shoulder of the boss, is a ring of malleable iron, of sufficient breadth to cover the margin of the eye to fully an inch beyond the circumference of the brasses, thereby preventing the lever from deviating inwards: and to prevent it from shifting its position outwardly, a plate of the same external diameter is applied by a strong bolt screwed into the end of the main centre.

The side-levers are connected with the connecting-rod N by means of the cross-tail O and links *j j*. The connecting-rod passes through an eye at the middle of its length, and is fixed by two gibs and a cotter, in the same way as the piston-rod is attached to the cross-head, while the links are connected in the same manner as the side-rods, except that the upper ends do not admit of adjustment, being simply riveted in the eyes. The attachment of the connecting-rod with the crank is likewise by a butt-end and strap, the cotter of which is tightened and maintained in its place by a screw and nuts. The crank-shaft Q rests, as before observed, on pedestals fixed upon the entablature of the crank-framing, and is prevented from moving on end by ruffs on the outsides of the pillows, and by the shoulders of the crank-brasses inside.

It may be noticed that the piston-rod, side-rods, cross-head, main centre-shaft, cross-tail and links, connecting-rod, and crank-shaft are all formed of the best malleable iron, and turned and pared to the requisite forms and dimensions.

The parallelism of the piston-rod is maintained when the piston is in motion, by the two radius bars K K, by the radius levers *f f*, fast upon the ends of the shaft L, called the *parallel-motion shaft*, and by the parallel bar *h*. The ends of the radius bars K K, on the cross-head are formed with solid eyes, fitted with brasses, the inner of which are tightened by keys, in the same manner as those of the side-rods which are attached at the same points. The eyes at the opposite ends, which work upon studs in the radius levers *f f*, are formed in the same way, but are smaller, and have the outer brasses adjustable by screwed-pins *g g*. The length of the bar thus admits of slight adjustment between its centres, to compensate for errors of workmanship and wear of the bushes. The parallel bar *h* is also attached by a solid eye and stud to the lever *f*, and admits of still more extensive adjustment at its lower end. This bar, it will be observed, is formed in two pieces, with the contiguous ends screwed right and left, and embraced by a long nut similarly screwed. By turning this nut to the right or left it is obvious that the upper and lower ends will be made to approach or recede, and the distance between the centres be thereby diminished or increased. The upper end of the rod is formed with a solid eye bushed, and the lower with a butt-end and strap in the usual way; it is attached to the exterior side-lever by a malleable-iron stud inserted into a rectangular eye formed in the latter.

The disposition of the flexible points of these connections being such, that in every position of the piston the angles of the parallelogram formed by the part of the side-lever comprehended between the stud of the rod *h* and the junction of the side-rod, opposed to the radius bar K, and by the parallel bar *h* and the side-rod J, shall change proportionally, always preserving the same constant ratio, it follows that the piston-rod cross-head will move constantly in the same place and the parallelism of the piston be thereby maintained.

The parallel-motion shaft L is supported by two plummer-blocks, resting on the entablatures of the small pillar-framing D. This framing, called the *parallel-motion framing*, consists of four columns, cast, like the larger framings, pair and pair, with their soles and entablatures, and with provision on the latter for bolting and keying the pedestals. The soles rest upon oblique flanges cast on the diagonal framing C C, to which they are secured by bolts and keys.

The valves and valve-geer.—The valve casing F is cast of a semi-cylindrical form, corresponding to the form of the valves, which are of that kind designated, in accordance with their outline, short D-slides.

The casing is fitted steam-tight and bolted to the side of the cylinder by projecting flanges cast on both for that purpose; and also to the sole-plate over the recess T′, shown in the general elevation The flat side, as will be observed from the general section, occupies only about a third of the whole length equidistant from both ends, and is cast with projecting flanges, which are carefully fitted steam-tight between the ends of the projecting faces of the cylinder. These faces thus project inside, but are concealed by the circular part of the casing, in which, it will be observed, when the cover is applied, there is no communication with the external atmosphere; through the passages T it communicates

with the condenser U, and through the steam-ports with the cylinder. The steam-pipe G likewise opens into it, and a communication is thereby effected with the boilers.

The valves, as already noticed, are of the kind known as short D-slides. There are two of these, one to each port of the cylinder. The backs are turned truly circular, and the faces are planed and ground to the brass facings of the ports, so that they may slide upon them steam-tight, and with as little friction as possible. They are kept tight against the faces, and also rendered steam-tight in the casing by hemp packings, introduced through the *packing-ports* cast in the casing. These packings are covered by the packing-rings which are pressed against them by set pins acting in nuts between the packing-rings and the port-covers, as fully shown in the general section. These set pins can be tightened at pleasure by a box key, inserted through holes formed in the covers, and filled with hollow plugs, which can be withdrawn when necessary.

The planes forming the faces of the valves are slightly less than double the breadth of the port, but the circular parts are necessarily much larger. The faces and backs are connected by strong diaphragms, through which pass the ends of the rods which couple the two valves together. These rods are turned to an exact length between the ruffs, against which the contiguous sides of the diaphragms bear, and are kept fast in their places by nuts upon their protruding ends. They are stiffened at the middle of their length by a cross-stay. A strong stud is inserted downwards in the middle of the diaphragm of the upper slide, and is retained in its place by a nut on the end projecting below. The upper end is formed with strong projecting lugs, between which the enlarged square end of the valve-spindle is received, and retained by a strong square pin which passes through the lugs of the stud and the end of the spindle, thereby forming an inflexible joint at the point of connection.

The valve-spindle passing through a packed stuffing-box in the cover of the valve casing, is attached by means of a small cross-head and side links, to the lever *n*. This lever is fast upon the transverse shaft *m*, which has its bearings immediately under those of the parallel-motion shaft in the framing D. On the opposite end of the lever *n*, is fixed a weight *q*, sufficiently heavy to counterpoise the weight of the valves. This weight is connected with the shaft S, called the *starting-shaft*, by two small levers *s s*. These levers are fast upon the shaft S, but are flexibly connected to the axis of the weight *q*, by two short connecting-rods jointed to each. The shaft S is carried on pedestals fixed upon the cheeks of the diagonal framing C C, and has a short lever crank keyed upon the end projecting to the inside of the engine. A long lever is fitted to this fixed piece by a hollow boss which passes upon the tail, but, being required only occasionally, it is not fixed, that it may be removed when not in use, and for that reason it is not shown in the drawings; but supposing it applied, it is plain that by moving it towards the right and carrying the shaft S with it in the same direction, the balance weight *q* will be elevated and the valves depressed. The reverse action will produce the reverse effect by again lowering the weight and raising the valves. Now, observing in the section that the lower steam-port of the cylinder is open to communication with the condenser, and that the upper port communicates only with the interior of the casing, if the weight *q* be raised until the valves descend through a space equal to the breadth of the faces, it is clear that the conditions will be reversed, and that the upper port will be opened to communication with the condenser, through the passage T, and that the lower passage will be shut, and the lower port will communicate with the interior of the casing.

Upon one end of the traverse-shaft *m*, is a crank-arm, upon the pin of which a gab formed in the end of the compound rod *l l*, called the *eccentric rod*, rests. This rod, which consists of two bars of malleable iron stiffened by diagonal braces, is attached at its base to the two opposite lugs of the eccentric ring R, which works freely upon the eccentric embraced by it, and which revolves with the crank-shaft of the engine; consequently, supposing the crank to revolve, the rod *l l* will at the same time receive an alternating rectilineal motion, which being transferred to the crank-lever of the traverse-shaft *m*, will cause the ends of the lever *n* alternately to ascend and descend. But the valve-spindles being attached to this lever, its motion will be transferred to the valves, which will thus be made alternately to ascend and descend in the same manner as when a lever is applied by manual strength to the shaft S. This is the action necessary to maintain the motion of the engine, as will be explained.

As in the case of the piston-rod, the parallelism of the valve-spindle is maintained by means of the links *o o*, arranged as in the common parallel motion of stationary engines. The radius rods are attached to opposite sides of a small framing consisting of two columns, fixed on the cover of the valve casing, and having their entablature *p* of a semicircular form to allow the cotters of the cross-head links to pass when the engine is in action.

The condenser and its appendages.—The condenser U and the lower exhaust passage T′ T′ are cast of a piece with the sole-plate. Two strong eyes are cast in the sides of the condenser to receive the main centre-shaft M′, which passes completely through it. In the top is an opening for the upper exhaust passage T T, the vertical part of which is cast of a piece with the hot-well X. This also rests upon the condenser, but is separated from the interior by an inflected partition.

The cold water for effecting the condensation of the steam which passes into the condenser by the exhaust ports, when the engine is in action, is admitted by an injection-pipe. This pipe passes through the side of the vessel and communicates with the water without; but in order to regulate the supply a valve is placed in the pipe, close upon the condenser; its position is marked by *v* in the plan of the sole-plate. The face upon which the slide works is formed on the side of the condenser at *v*, over which the casing is fixed. The mode of working the valve is by a small brass spindle which rises through a packed stuffing-box in the cover of the casing; this is attached to a long lever passing to the opposite side of the engine, and which can be more or less depressed at pleasure, to allow of a larger or smaller supply of injection.

The part of the pipe within the condenser, passes completely across, and is perforated with numerous small holes to diffuse the water more completely in the body of the condenser, and thereby render it more effective. To prevent the water from passing into the lower exhaust passage, a shelf is

attached over the opening, which, throwing the water over the edge of the partition into the body of the condenser, prevents it from accumulating in the passage, and at the same time renders the water of more avail than if it had been allowed to strike against the side of the condenser.

The air-pumps and valves.—The condenser communicates at bottom by a valve, called the *foot-valve*, with the air-pump V, the barrel of which is $4\frac{1}{2}$ inches, clear of the sole-plate, thereby leaving space for a body of water to enter it from below. The barrel of the pump is bored and lined with a thin cylinder of brass turned to fit within it. A strong flange is cast round it at 11 inches from its lower end, which is fitted water-tight, and bolted to the margin of a circular opening cast in the upper division of the sole-plate, for the reception of the lower end of the barrel, as shown in the section, and also in the plan of the sole-plate.

The bucket consists of a ring connected to the eye at the centre, into which the rod is fitted by four arms. The under side of the ring has a flange cast upon it of one inch breadth, between which and the projecting ledge of the junk-ring, bolted on the upper side, a packing of hemp is retained. But before applying this packing, both the flange and the junk-ring are turned to work easily in the barrel. The pump-rod is sheathed also with brass, to prevent corrosion by contact with the water. To apply this sheathing, the rod, which consists of malleable iron, is first roughly turned; it is then thoroughly cleaned and taken to the brass foundry, where the covering of brass is cast upon it, of somewhat more than the required thickness. It is again put into the lathe and turned to the requisite diameter. The rod, which thus possesses all the advantages of strength and diminished liability to corrosion, is retained in the tapered eye of the bucket by a cotter, and passes through a packed stuffing-box in the cover of the pump. The bucket-valve is of that kind technically known as the *pot-lid valve*, in contradistinction to the *butter-fly valve*, which consists of two hinged flaps. The pot-lid valve consists of a circular plate, which slides vertically on the pump-rod by means of a bored eye at its centre; the plate is strengthened by ribs radiating from the eye, and terminating in a narrow ring on its circumference, which is faced, and fits water-tight upon the similarly faced edge of a ring projecting round the plane of the bucket.

To understand the action of this valve it is only necessary to conceive the under part of the barrel to be filled with water, and the bucket to be forced to descend in it; it is then obvious that the water passing between the arms will meet the under surface of the valve, and prevent it descending with the bucket; for being inelastic, and also being prevented from returning into the condenser by the foot-valve, it must force a passage at the least resisting point; but the only resistance which the valve offers being its own weight, the water will bear it up and force a passage at its circumference, over the ring of the bucket, and will continue to ascend *relatively* in the barrel so long as the bucket continues to descend; but when the bucket has attained the lowest point of the stroke and begins to return, then the valve, being of greater specific gravity than the water, will shut by its own weight, and will carry whatever water is above it to the height of its own ascent. The water thus carried up is ejected by the valve called the discharge-valve, into the *hot-well* X, so called because the water thus thrown into it by the air-pump, being that employed in condensation, has its temperature proportionally increased.

It may be observed that the bucket and valve are of brass, as are also spindles which form their axes. The box-framings of these valves are formed of cast-iron, faced with brass, and fitted water-tight into their seats, where they are each retained by two long copper keys, one at each side, inserted from above before the covers are put on. The covers are likewise fitted water-tight and bolted down.

The valves are prevented from opening beyond the requisite distance, by projecting bridges situated before them, as shown in the section.

The hot-well.—The hot-well, as already observed, is situated above the condenser. The part marked X, with the vertical part of T, of the upper exhaust passage, is formed of a single casting, fitted water-tight to the top of the condenser. In one side of the well, as shown in the section, is a rectangular recess covered by a door, through which admission can be obtained to the interior; and in the side adjacent to that of the vessel, as shown in the elevation, is a circular opening to which the discharge-pipe Y is bolted. Through this latter the excess of water beyond that required for supplying the boilers, is discharged into the sea. The pipe consists of a single length outside of the condenser, to which it is fitted by an expansion joint, to compensate for the spring of the vessel when at sea; and has also a valve in it capable of opening outwards, but which being shut resists the pressure of the water inwards.

An air-vessel Z is placed over the hot-well and fitted to it air and water tight. The object of this vessel is to create an elastic pressure by means of the air contained within it, to assist in ejecting the water through the discharge-valve should the hot-well from any cause become surcharged. The pressure thus brought into action by continuing to increase with the exigency of the case will, under all ordinary circumstances, prevent accumulation of water in the well to any detrimental extent.

Feed and bilge pumps.—The same cross-head *u* by which the air-pump is worked, serves also to work two other pumps of smaller dimensions. These are the feed-pump, by which water is supplied from the hot-well to the boilers, and the bilge-pump, by which leakage water is withdrawn from the hold of the vessel. These are very nearly identical in construction with the bilge-pump. The barrel is formed of cast-iron, but the plunger, which is made hollow for the sake of lightness, is formed of brass. It is connected to the cross-head by a cotter, a portion of the end being made solid for that purpose.

This pump communicates with the hot-well by a pipe projecting from the side of the barrel, a portion of which is shown in the general elevation, where it is marked W. The feed-box is bolted upon the side of the part of the hot-well formed in the condenser, at the position marked *w'* in the plan of the sole-plate, by square flanges upon the face. In the side of the hot-well are two square holes corresponding to the two openings in the feed-box, and these being made to coincide, the pipe from the feed-pump is attached to the lower of the two circular openings in front of the box corresponding to the lower of the square openings, and the upper communicates by a copper pipe with the boilers. This

connection being effected, and a clack-valve, opening towards the pump, being placed in the lower division of the box, and a similar valve, opening reversely, being placed in the upper division; if the plunger be made to ascend in the barrel of the pump, leaving a corresponding space unoccupied, the water will flow from the hot-well, by its own gravity, into the pump; but on the plunger beginning to descend the valve in that division of the feed-box will be closed by the pressure of the water tending to return to the hot-well, and consequently will be forced through the upper valve, and along the feed-pipe, to the boilers. But if more water be drawn by the pump than is required for the boilers, it is simply ejected through the valve in the upper division of the box, and thus returned to the well. The pressure of water in the box is maintained by a loaded conical valve placed on the top: this can be adjusted at pleasure to suit the pressure of steam in the boilers.

Instead of being guided by parallel-motion bars, the pump cross-head is restricted in its vertical path by two guide-rods *v v* attached to the flanges of the feed and bilge pumps at their lower ends, and to the diagonal framing above; these pass through bushed eyes in the cross-head which is thus confined at the same time that it slides freely upon the rods in its alternating ascent and descent.

The cross-head is connected to the side-levers by the rods *t t*, which are formed with solid bushed eyes at their upper ends, and with butts and straps at their lower extremities.

Snifting-valve.—The bottom of the air-pump well communicates by a pipe with a small conical valve, which is technically called the *snifting-valve.* This valve is kept shut by a screwed pin passing through a malleable iron bridge made fast upon the mouth of the pipe. To the side of this pipe, above the valve, is cast a small return branch, by which the water passing through the valve is carried off.

The use of this valve is to admit of the escape of the air within the condenser, air-pump, and steam-passages, on starting the engine, and before these have been filled with steam. When about to start, the pin is simply unscrewed by hand, to permit the valve to rise and allow the air and water to escape, and give place to the steam, which now flows onwards from the valve-casing, occupying all the passages and condenser, and finally begins to issue by the valve itself.

Blow-through valve.—This valve is situated at the position marked *u'* in the plan of the sole-plate. It is placed in a chest fixed upon the steam-valve casing at the lower end, and has two openings, one above and the other below the packing port. The valve itself is placed between these two apertures.

This valve is used simultaneously with the snifting-valve, to allow the steam to fill the passages and condenser, when preparing to start the engine, and thereby to displace the air and water which may be lodged in them, through the snifting-valve.

Priming-valves.—These are two small valves, situated in the steam-ports of the cylinder, and are called *priming-valves* from their being intended to discharge any water carried over into the cylinder with the steam, and which is technically termed priming. These valves are kept shut by springs acting against them externally, and of such strength as to resist the ordinary pressure of the steam; but should water lodge in the passages, owing to its non-elastic properties, it will be ejected through the valves by the action of the piston tending to compress it.

Expansion geer.—The expansion geer consists of an apparatus by which the amount of steam admitted during a stroke of the piston can be diminished at pleasure, when it is not required to work the engines to full power. The first part of the apparatus consists of a cam with five faces fixed on the crank-shaft, as shown in the elevation and plan of the engine. These faces are of different lengths, giving five different degrees of expansive action. They are so formed that the friction roller on the end of the lever *w*, and bearing against any one of them, is thrown forward through the same space; but the time of action varying as the length of the face, the effect will depend upon the particular face in contact with the roller; and this, according to its distance from the frame, may be made to bear against either one or other of the faces. The position of the roller, and consequently of the lever to which it is attached, is regulated by a screw and nut; the last is formed in the back lever *x*, which is forged of a piece with the weighted lever, and has a long hollow boss working on a stud fixed in the framing. The screw has a handle upon the projecting end, which being turned causes the lever *w* to advance or recede upon the boss of the double lever on which it slides by a sunk key. The roller is kept against the face of the cam by the action of the weighted lever; the weight tending to descend and carry the lever with it, causes the opposite lever to press upwards against the face of the cam.

The lever *x* is connected by a joint with an adjustable rod, carried forward to the lever *y*, which is fast upon a cross-shaft supported by two small columns on the flange of the expansion chest, marked G in the elevation. On the same shaft is keyed the double-ended lever *y'*, one end of which is connected, by flexible links, with the spindle of the expansion-valve, which is of the kind known by the name of *equilibrium* valves. The opposite end of the lever *y'* communicates by a rod *z* with an arrangement of levers attached to the side of the condenser, by which the apparatus can be thrown into geer and disengaged at pleasure. Thus the end of the crank lever *z'* being moved to the right, the rod *z* will be drawn down, and with it the end of the horizontal lever *y'* to which it is attached; but the lever *y'* being fast upon the same axis as the vertical lever *y*, this lever will be thrown back, and at the same time the lever *x*, with which it communicates; and again the lever *x* being fast upon the same axis as the lever *w*, this last will be projected forward, and the roller thrown out of contact with the cam, and the engine will receive the full supply of steam.

Action of the engine.—To bring the engine into action, the steam is allowed free admission into the valve-casing by the steam-pipe G G, leading from the steam-chest over the boilers. To prevent the pipe being injured by expansion, arising from the variations of temperature to which it is liable, it is provided with expansion-joints which allow the ends to slide upon each other, and thereby maintain the same aggregate length between the two extremities. It has also a valve, called the throttle-valve, placed in it to regulate the supply of steam, and to cut off the communication between the boilers and the casing when necessary. The valve is placed close to the junction of the pipe with the casing; it is

simply a disk of the same diameter as the inside of the pipe, with a rectangular eye cast in it to receive the spindle upon which it works.

The steam-ports of the cylinder being both shut by the valves, and the blow-through and snifting-valves open, the steam is allowed to pass into the valve-casing by opening the throttle-valve, partially at first, which fills the steam-passages and condenser, driving the air and water before it. When this has been accomplished, and steam alone issues by the snifting-valve, the blow-through valve is closed, and the injection-valve is opened; the cold water now rushing into the condenser effects the condensation of the steam with which it was filled, and creates the desired vacuum. The eccentric-rod *l* being out of geer with the crank upon the traverse-shaft *m*, and a long lever, as before described, being applied to the starting-shaft S, the steam-valves are raised until the under port communicates by the passage with the condenser, and the upper port with the interior of the valve-casing, now full of steam, which, in consequence of this disposition, will flow into the cylinder above the piston and force it to descend. The next operation is to reverse the pressure upon the starting-lever and thereby to reverse the position of the valves, shutting off the communication of the upper port with the casing, and opening it to the condenser, at the same time that the communication of the lower port is cut off from the condenser and opened to the interior of the casing. This being done the steam will flow from the cylinder into the condenser, and encountering there a shower of cold water from the injection-pipe, will be condensed, and a vacuum thereby formed in the cylinder above the piston. By that means the pressure over the piston is removed, and the steam flowing into the cylinder beneath it, forces it to ascend to the top of the cylinder.

But the piston being connected by the cross-head and side-rods, with the side-levers, carries these with it in its ascent and descent, through an arc, whose chord is equal to the length of the stroke of the piston; and the side-levers being connected at their opposite ends by means of the cross-tail and connecting-rod, with the crank, the motion of the piston is thus transferred to the crank-shaft, and through it to the paddles, which are fast upon its extremities.

After two or three strokes of the piston the moving parts will have acquired a certain degree of momentum, and this is taken advantage of to render the engine self-acting. The crank-shaft being in motion, if the eccentric-rod *l* be thrown into geer with the traverse-shaft, exactly the same effect will be produced upon the valves as by the lever applied to the starting-shaft S; for by the alternating thrust and pull of the rod, communicated to it by the eccentric R, the crank of the traverse-shaft will be made to describe a certain portion of a revolution, proportional to the eccentricity of the eccentric, and the valve lever *n* being fast upon that shaft, the valves must consequently ascend and descend regularly with the revolutions of the crank-shaft; and these revolutions are performed uniformly with the alternating ascent and descent of the piston.

The water is drawn out of the condenser by means of the air-pump with the same regularity; for the air-pump cross-head being worked by the side-levers, it will move simultaneously with them; the feed-pump being also attached to the same cross-head, the boilers will be furnished with water in proportion to the speed of the engine, and consequently in proportion to the quantity of steam used.

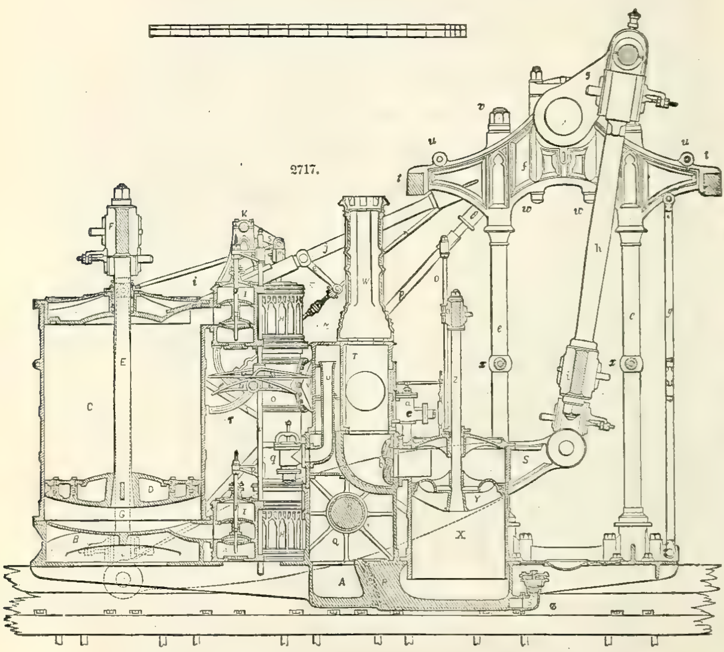
Literal References to Fig. 2717.

A, the bed-plate, upon which the engine stands.
B, the cylinder bottom, cast upon the bed-plate, in which is the lower steam opening.
C, cylinder.
D, steam piston.
E, piston-rod.
F, cylinder cross-head, attached to the piston-rod, and also to the side levers, by two side-rods.
G, cylinder side-rods.
H H, upper and lower steam-chests, in which are fitted valves for the induction and eduction of steam to and from the cylinder.

I I, steam-valves.
J J, valve-stems, on which are keyed the steam-valves.
K, parallel-motion shaft and standard.
L, lifting-rods, for lifting steam and exhaust valves, worked from an eccentric on the water-wheel shaft.
M M, steam-toes, keyed to the lifting-rod.
N N, feet for lifting-rod, attached to the rock-shaft.
O, steam and exhaust side-pipes.
P, foot-valves and seats.
Q, condenser, cast upon bed-plate.
R, side-lever shaft, passing through and firmly keyed to condenser.
e e, pillow-block columns, keyed into sockets cast upon the bed-plate.
f, pillow-blocks for water-wheel shafts.
g, cranks.
h, main connecting-rod, connecting cross-tail and crank-pin.
i, cross-tail, attached to the side-levers by two short links, also the main connecting-rod.
j, main-braces from pillow-blocks to cylinder.
k, steam-valve lifters, keyed to the lifting-rods.
l, parallel bar for parallel motion.
m, parallel motion connecting-rod
n, eccentric-rod.
o, guide-rod for air-pump cross-head.
p, brace from pillow blocks to bed-plate.



2717.

S, side-levers.
T, hot-well.
U, injection-pipe.
V, connection, from exhaust-pipe to condenser.
W, air-column, to receive the air arising from the waste water, thereby facilitating its discharge.
X, air-pump.
Y, air-pump piston.
Z, air-pump rod.
a, air-pump cross-head.
b, delivery valves and seats.
d, force-pump chest.
q, injection-valve.
r, centre-bearing for rock-shaft.
s, brace from cylinder to bed-plate.
t t, cross-beams for pillow-blocks.
u u, studs and transverse braces.
v, nuts for securing pillow-blocks to columns.
w, bolts for holding down pillow-block caps.
x x, studs between columns and bolts, running transversely through each set.
y, braces from pillow-blocks to bed-plates, in the centre of each and between engines.
z, snifting-valve.

Engines of the Golden Gate. Plate II. is the front elevation, and Plate III. the side elevation and section through air pumps. *a* main shaft, *b* crank-pin, *c c c c* cylinder; *d* trunnions on which the cylinder oscillates to accommodate itself to the motion of the crank; *e* stuffing box on the cylinder-head. This is made as long as practicable, to give as much bearing as possible for oscillating the cylinder. *f f* belt-passage connecting the trunnion with *g g* side-pipe. *h h* valve-stems, connecting with the balance puppet-valves in *i i i* valve-chests. The lower valve on the right or steam side is concealed by *j j j j*, air-pump; the air-pump bucket is provided with India-rubber valves, and is worked by *k*, crank on the intermediate shaft. *l l l l*, condenser: there are two condensers and two air-pumps; they are located between the cylinders and inclined towards each other, one only being represented.

The passage *f f*, together with the side-pipes, valve-chests, and appurtenances, are fixed to the cylinder, and oscillate with it, the steam being received through one trunnion and allowed to escape to the condenser through the opposite one. *m* is an injection-cock admitting the water upon a scattering plate in the condenser. These are the first oscillating engines to which balance puppet-valves have ever been applied; and the constructors, Messrs. Stillman & Allen, deserve great credit for successfully carrying out so decided an improvement.

The valves are worked by the toes *o o* in the usual manner. The rock-shafts *p p* receive motion partly from the movement of the cylinder, and partly from the eccentric. Levers are permanently attached to the trip-shafts *q q*, the ends of which work in a slotted piece curved to the centre of the trunnion. This piece is guided, as represented in the engraving, by vertical rods sliding in bushes attached to the fixed framing, and is connected by a rod to the starting lever *r*, all the levers for working by hand being so balanced, that the engineer with one hand can work the engine up to the usual speed. The cut-off valve is placed outside the trunnion, and is a balance puppet-valve, worked by the ordinary cam motion, and so arranged as to act either as cut-off or throttle, or both, the levers being placed within reach of the engineer when working the engine.

The Golden Gate has four return tubular boilers—two forward and two aft of the engines. They are placed at the sides of the ship, leaving room for the fire-room in the centre. The furnaces are consequently athwart-ships instead of ranging fore and aft as usual.

The Illinois, plying between this city and Chagres, the John L. Stevens, the Augusta, plying between this city and Savannah, the Republic, the Agnes, a vessel constructed for the Spanish government in 1850, the Arago of the Havre line, the Adriatic of the Collins line, are among the American examples of paddle-wheel steamers fitted with oscillating engines.

The Golden Gate is of the following principal dimensions: Length on deck, 265 feet; beam, 40 feet; depth of hold, 22 feet; tonnage, 2030 tons; diameter of cylinders, 85 inches; stroke, 9 feet; average revolutions, 18¼; average pressure in boilers above atmosphere, 12 lbs.; cut-off from commencement, 3 feet; amount of fire surface, 12,052 square feet; tube surface, 8396; grate surface, 367; calorimeter of tubes, 61¾ feet; paddle-wheels, diameter 31 feet; length of paddle, 12 feet; depth, 24 inches; number of paddles in each wheel, 30.

Barrows' Double Acting Reversible Rotary Steam Engine.—Arranged for working steam expansively.

Plate IV. is a perspective view of two cylinders or engines fixed on one shaft for the expansive working of the steam. The cylinders are of equal diameter but of unequal length. The steam is first admitted to the smaller: after doing its work in which, the greater part is admitted at a lower pressure to the larger cylinder. In this respect, working the steam through two engines, it somewhat resembles the well-known Woolf engine, but with this difference, that the steam is taken from the first engine at such a point that it exerts no back pressure. This will be understood by examining Plate V., which represents a vertical and horizontal section of the smaller engine only. The larger engine resembles this, except in having but four instead of eight pistons, or leaves, and in having no outlets for the steam at the top and bottom, as in the smaller.

c is a pedestal of cast iron on which the cylinder rests, forming the whole of the frame of the engine; *a* is the cylinder, whose inner periphery is turned perfectly true, and whose ends are closed by heads *d d*, in each of which heads is a groove *h h*, the form of which is best shown in fig. 5 by dotted lines, being that of a circle with segments cut off on opposite sides, leaving only two-fourths of its circumference. On opposite sides of the cylinder are abutments *n n*, cast upon the steam-heads *m m*; on either side of which abutments are quadrangular openings *t t'*, *u u'*, connecting with the double three-way cocks *q q'*. To the inside of the cylinder is fitted the steam-wheel *ee ee e'e'*. The ends of the steam-wheel are formed of two plates *ee*, *ee*, of a diameter equal to the interior of the cylinder, and secured by bolts *ii*, to a ring *e'e'* of less diameter, which forms the bottom of the channel *f*, in which the steam acts. Its axle *j* passes through boxes in the cylinder ends, packed with metallic packing, and lined with anti-friction rollers. The rollers may, no doubt, be omitted in practice, as a refinement of little use, if not positively productive of derangement. The peripheries of the two plates *ee*, *ee*, forming the ends of the steam-wheel, are made to fit steam-tight to the interior of the cylinder, by means of metallic packing-rings let into the interior of their flanges as represented. The abutments *n n* are packed with metallic packing *o* to the bottom, and *p* to the sides of the channel *f*; the packing-pieces *o* and *p* being dove-tailed together, so that *p* will slide with *o*, but at the same time slide outwards, independently of it as they wear. The steam acts in the passage *f* upon 8 slides or leaves *g g*, which we will term pistons, which revolve with the steam-wheel, but are capable of sliding to or from the centre through slots in the ring *e'e'*. It will be seen that the sides of the channel *f* are formed by the plates *ee*, before described, so that the channel is, in fact, wholly sunk in the rim of the steam-wheel. The pistons are made a little wider than the channel, and partially supported by shallow radial grooves on the inside of the plates *ee*. The pistons are packed on their edges both to the inner periphery of the cylinder and to the grooves in the sides of the channel *f*. This packing is shown on the right hand of fig. 2, Plate V., in section, the section being taken through the centre of the piston, and exhibiting the end and side packing dovetailed

loosely together in the same manner as already described in the packing of the abutments. The slots through which the piston slides are also packed, as represented in fig. 1. All the packing pieces are kept to their work by small helical springs at their backs. From the inner edge of each piston at each side, a square stud b' projects through a radial slot f', in the plates ee, and at the end of each stud is a pivot g', carrying a friction-roller. These friction-rollers travel in the grooves $h\,h$, inside the fixed cylinder head, and during the revolution of the wheel cause the pistons to alternately project and withdraw into the wheel. By the form of the groove, it will be seen that each piston will project across the channel f during two-fourths of the revolution, while during the remaining two-fourths, it will be wholly or in part withdrawn into the interior of the wheel. At the moment of passing either abutment $n\,n$, the outer edge of the piston will coincide with the outer surface of the ring $e'e'$, so that the packing pieces oo of the abutments have presented to them by the revolution of the steam-wheel simply a continuous cylindrical surface.

The steam-heads or cocks $m\,m$, through which the steam is admitted to the cylinder, and which supply the place of valves, valve-gear, and reversing-gear in ordinary engines, are of peculiar construction, having six ways or passages in each. There are conical seats in each to receive the plugs $q\,q'$, in which are passages to correspond with the ways in the steam-heads. The steam-pipe s has two branches leading to the two steam-heads. Of the six ways or passages in each steam-head, two $t\,t'$ are steam-passages leading from the cock-seats into the channel f, the former above and the latter below the abutment, (see the right-hand side of fig. 1, Plate V.); $n\,n'$ are exhaust passages leading from the cylinder to the cock-seats, the former from above and the latter from below the abutments (see left-hand side of fig. 1, Plate V.). In addition to the four already described, one r leads from the steam-pipe to the cock-seat, and the remaining one v, fig. 2, Plate V. is a continuation of the cock-seat, provided with a flange at its extremity for connecting to the exhaust-pipe. The vertical section, fig. 1, is taken through the steam-passages on the right side, but through the exhaust-passages on the left. The plugs $q\,q'$ have each two passages, the first k, fig. 2, being for the purpose of communication between the steam-pipe and either of the passages $t\,t'$, and admitting steam on either the upper or lower side of its corresponding abutment, the other l, in a hollow part of the plug, being for forming a communication between the exhaust-passage v, and the opposite side of the abutment to that which is in communication with the steam-pipe. The two plugs $q\,q'$ are furnished with levers (see Plate IV.), by which they are turned to admit the steam on either side of the abutment, and allow the escape of the exhaust from the opposite side, and the levers are connected, so that both are reversed at the same instant. Whatever relation, therefore, exists between the several passages in one steam-head and cock, the opposite relation must exist between the passages in the other. In fig. 1, Plate V., the cock on the right-hand side of the figure is in such position, that steam is admitted through the passage t above the abutment, the passage t' being effectually closed, while in the same cock the exhaust passage u', imperfectly represented by dotted lines as being more distant from the eye, is open, and admits the exhaust steam to escape from the lower side of the abutment into the hollow portion of the plug at its further end. In the other steam-head, the lower steam and the upper exhaust are supposed to be open, the dotted steam-passages $t\,t'$ being on this side nearer the eye than the exhaust passages $n\,n'$, through which this section is taken.

It will be recollected that there is no movement of these cocks, except in reversing, all the passages being full open, and the steam exerting its full force in every possible position of the wheel. The arrows indicate the movements of the steam, and also the direction in which the wheel revolves, every particle of steam expended being effective in driving the wheel, without loss by filling any cavities uselessly, as in the valve passages and clearance of every variety of reciprocating engine.

It now remains to describe the provision for rendering available some portion of the expansive power of the steam. The spaces in the channel f between each piston appear as if filled with steam of full pressure, which is carried along by the revolution of the wheel, and discharged into the exhaust passage of the opposite steam-head. This would be the case but for the passages $w\,w'$, midway between the steam-heads, through which a large portion of the steam thus confined expands itself into the second or mate engine, which is of similar construction, but containing only four instead of eight pistons. The channel in which the steam works in the second engine may also be deeper, and any desired ratio may subsist between the capacities of the two engines. Suppose the boiler pressure to be 60 lbs. per square inch, and the capacity of the second engine be twice that of the first, steam from the boiler at 60 lbs. above the atmosphere, or 75 lbs. total pressure, is expanded in passing the passage w into three times its original space, two volumes going over into the second engine, while one volume remains in the first. The pressure will thus be reduced, according to the law of Boyle and Marriotte, to about $\frac{75}{3} = 25$ lbs. total, or 10 lbs. above the atmosphere. The additional force, therefore, due to the existence of the second engine will be that of 10 lbs. per inch upon a double area, or one-third that of the first engine $[10 \times 2 = 60 \times \frac{1}{3}]$. If the engines are condensing, and exhaust into a perfect vacuum, the power of the second engine will be two-thirds that of the first $[25 \times 2 = 75 \times \frac{2}{3}]$. If the second engine be only equal in capacity to the first, the pressure on its pistons will be half the boiler pressure, or 37·5 lbs.; and the effect of the second will be one-half the first, when both exhaust into a vacuum, or a little more than one-third when exhausting into the atmosphere $[37{\cdot}5 - 15 = 22{\cdot}5$ lbs. $22{\cdot}5 > 60 \times \frac{1}{3}]$. Any one may readily calculate the effect of any other ratio between the cylinders, or of any other initial pressure than 60 lbs. The inventor prefers a second cylinder of about twice the capacity of the first.

A considerable advantage to be derived under some circumstances from the existence of two engines, is the possibility of using both for a few minutes on any extraordinary occasion, under full pressure, by connecting each directly with the boiler. In Plate IV., a represents the first and b the second engine. Under ordinary circumstances, the stop-valves c and d being open, the steam from the boiler would be admitted through e into a alone, after working through which, a portion would pass over through the stop-valve d into the cylinder b. Should occasion require an extraordinary effort, the valve d may be closed and e opened, thus shutting the communication between the engines, and opening each to the full

pressure of steam from the boiler. Both might be thus worked so long as the boiler could generate a sufficient supply of steam.

Compound Engines of the Steamship Thorwaldsen (Plate VI.), constructed by Messrs. Oswald & Co., of Sunderland, Eng. The engines are of the overhead cylinder type with an intermediate receiver, the cylinders—not steam jacketed—51″ and 86″ in diam., with a stroke of 3 ft. 6″. The intermediate receiver surrounds the high-pressure cylinder, and is of the same capacity. The valve-chest of the high-pressure cylinder is situated at the forward end of the engines, that for the low-pressure cylinder between the cylinders. The valves of both cylinders are double-ported, that for the high-pressure cylinder being equilibrated by a ring at the back.

High-pressure cylinder.	Feet.	Inches.	*Low-pressure cylinder.*	Feet.	Inches.
Length of ports,..................	2	6	Length of ports,..................	5	0
Width of steam ports, ...	0	$3\frac{1}{4}$	Width of steam ports,.............	0	$3\frac{3}{4}$
" exhaust ports,...........	0	9	" exhaust ports, ...	0	$9\frac{3}{4}$

The maximum travel of the valves is in each case 8″, and each of the valves has its weight counterbalanced by the pressure of the steam acting on an 8-inch piston working in a balance cylinder.

Besides the stroke of main valves being adjustable by means of the link motion, the high-pressure cylinder is fitted with a separate expansion-slide which works on a face at the side of the main valve chest, and which has an adjustable travel. For starting the engines, or moving them by hand, small supplementary slide-valves are provided, at the front of the cylinders, moved by hand-levers. By means of one of these slides steam can be admitted direct to the low-pressure cylinder.

Between the exhaust-pipe and the low-pressure cylinder a chamber is interposed, fitted with an injection-pipe, to form a feed-heater by which the temperature of the feed is raised to about 160°.

The circulating pump is driven by a prolongation upward of the air-pump rod, both pumps being actuated by back levers connected to the crosshead of the low-pressure cylinder. To the air-pump crosshead are also connected the feed and bilge pumps, these pumps having $6\frac{1}{2}$-inch plungers, and stroke 1 ft. 9″. The air-pump is single-acting, and has a diameter of 36″.

The piston-rods are each 8″ diam. below the piston, and they are continued upward, working through stuffing-boxes in the top cylinder-covers. The crosshead gudgeons are $10\frac{1}{2}$″ in diameter by 11″ long, and the guide-blocks are 15″ wide by 2 ft. 5″ long. The connecting-rods are 7 ft. 9″ long, and the crank-pins have bearings $13\frac{1}{2}$″ long by $13\frac{1}{2}$″ diam. The diameter of the crank-shaft is $13\frac{1}{2}$″ throughout, with 4 bearings, and each 18 inches long.

The thrust bearing has 9 collars placed $1\frac{1}{2}$″ apart, these collars being each $1\frac{1}{4}$″ thick and 15″ diam. outside. The diameter between the collars is 12″. The intermediate shafting is 12″ in diam., with bearings of the same diameter, and 12″ long, while the propeller shaft is $12\frac{3}{4}$″ diam., and the lignum-vitæ bearings are $14\frac{1}{2}$″ diam., and 2 ft. 7″ and 3 ft. 10″ long respectively.

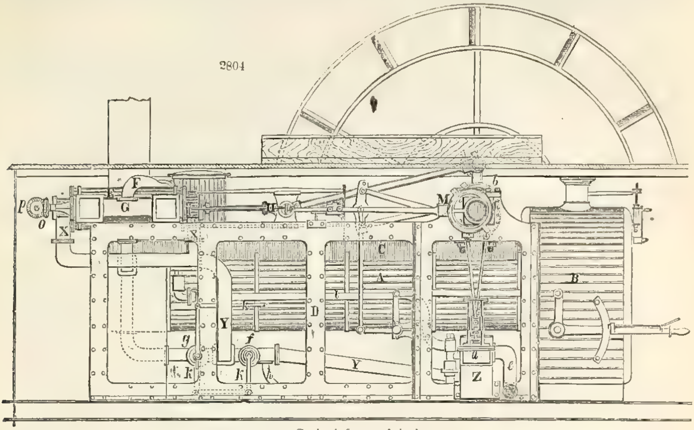
The propeller is 16 ft. 6″ in diameter, and from 18 feet to 22 feet pitch. The boss is 4 feet in diameter, and it has four arms, each with an area of 14 square feet.

The engines are supplied with steam by four boilers, each 12 ft. 3″ diam. by 10 ft. 6″ long. Each boiler contains three furnaces, each 3 feet in diameter. The grates are 6 ft. 6″ long. The boiler-tubes are of brass and are $3\frac{3}{4}$″ diam. by 7 ft. long. The chimney is 8 ft. in diameter, and the safety-valves, which are eight in number, have each a diameter of $4\frac{1}{4}$″. The main steam-pipe is 13″, the waste steam-pipe $11\frac{1}{2}$″. The main feed and bilge pipes are $4\frac{1}{2}$ inches in diameter.

Marine Engines, by Mr. J. Hall, Munich, for the Upper Danube. Fig. 2804 is a side elevation of one of the engines, with boiler and paddle-wheel, as fitted in the vessel. Fig. 2805 is a corresponding transverse section through the vessel, showing both engines, with various parts in section. The view on the right of the centre line represents sections through the paddle-box, air-pump, feed-pump, crank shaft journals, condenser passage, and the barrel of the boiler—the cylinders not being shown. On the left, the air-pump and paddle-wheel are in elevation, the cylinder being in section through its exhaust passage, as in connection with the blast-pipe. Figure 2806 is a plan of the combined engines, one being in horizontal section. The boiler and the fire-box A B, are constructed just as in a locomotive. At C C are two parallel frames of double boiler plate, filled in with timber, running along the boiler, and riveted fast to it. D D are two similar frames, standing up from the bottom of the boat; and these four lines of framing carry, at one end, the four inner journals of the paddle-shaft, and at the other the pair of steam cylinders E E. The steam is admitted in the usual way by a regulator in the dome, through the pipe F, to the steam-chest G. The expansion-vale spindle H, has a right and left-hand screw at I I, each screw having a plain cut-off slide, commanding the steam ports J, leading into the second steam-chest K, and fitted with piston-valves worked by the spindle L. The cut-off spindle H, is worked by the outside eccentric M, the rod of which is linked to it direct. The variation in the expansion is effected by the light shaft N, passing alongside the engines to the engineer's hand, and having a bevel pinion O, gearing with a similar pinion P, on the transverse shaft Q, passing across between both engines. In this way the shaft N, commands the valves of both engines through the two pairs of bevel pinions R R—the result of turning the shaft N to the right or left being to expand or approximate the two cut-off slides by the right and left screws, and thus increase or diminish the degree of expansion without affecting the lead. The cylindrical, or piston-valve chest, has three valves S T and U, on the same rod V; and, as represented in the horizontal section, the engine is upon its bottom centre, and steam is entering between the valves U and T; the valve U being on the point of opening to admit steam to the cylinder—the waste steam of the previous stroke having escaped by the opening cast in the middle of the cylinder, and through similar recesses formed in the valve T, into the blast-pipe W. Now it is to be remembered that the valve U must travel downwards until its port leading into the cyl-

inder is full open; and, as the whole three valves are on one rod, as U is opening to admit steam to the cylinder, T is closing the communication between the cylinder and the blast-pipe. So soon as the ports

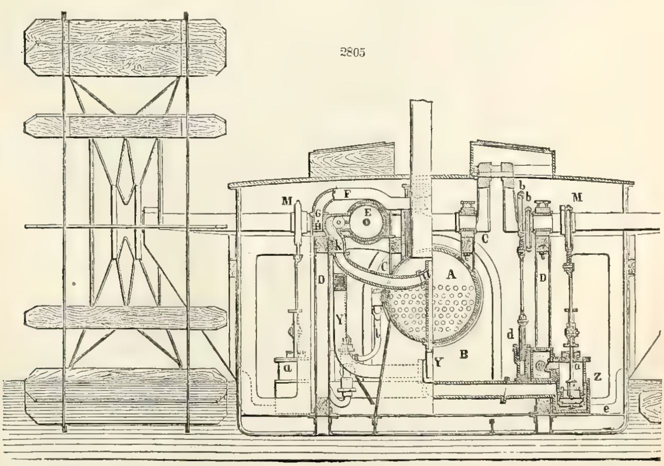
2804



Scale 4 feet to 1 inch.

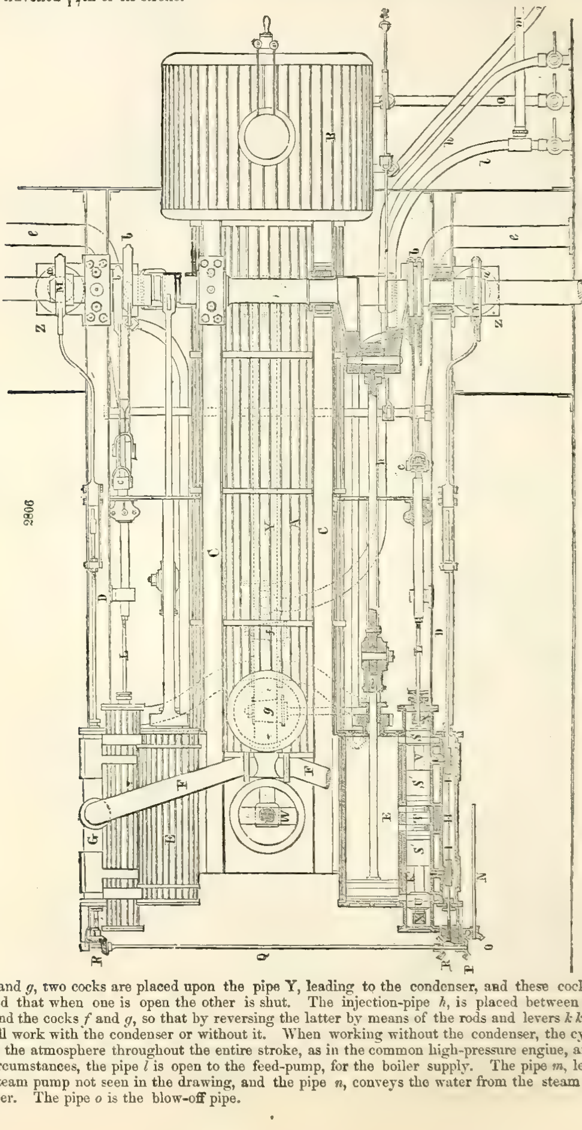
to the blast-pipe—which are only half the width of the valve—are closed, the other valve S opens, and the remaining vapor escapes through the pipes X, cast on the steam-chest, to the pipe Y, leading to the condenser Z. As the expansion at each stroke commences at the face of the cut-off slides, whatever amount of steam may be in the piston-valve chest at the time is also expanded; therefore, to diminish this amount as much as possible, two additional pistons S′ S′, are fitted upon the valve-rod, for the purpose of displacing the steam which would otherwise collect at each stroke in the valve-chest. The air-pump *a*, is of the ordinary construction: it is bolted on to the condenser, and is worked by the same eccentric which works the expansion valves. The piston steam-slides, S T and U, are worked by the back and forward eccentrics *b b*, through the reversing link *c*. The backward eccentric also works the feed-pump *d*—the feed being taken from the hot well, whilst the remainder runs to waste by the pipe *e*.

2805



The steam is admitted to the cylinder when the piston is on the centre, and is allowed to escape to

the eduction-port or blast-pipe when the piston is $1\frac{3}{4}$ths inch from the end of its stroke. The valve S opens to the condenser when the piston has travelled $1\frac{3}{4}$ths inch from the commencement of its stroke—the full length of stroke being 30 inches—so that the cylinder is open to the condenser when the piston has travelled $\frac{1}{17}$th of its stroke.



2806

At *f* and *g*, two cocks are placed upon the pipe Y, leading to the condenser, and these cocks are so arranged that when one is open the other is shut. The injection-pipe *h*, is placed between the air-pump and the cocks *f* and *g*, so that by reversing the latter by means of the rods and levers *k k*, the engine will work with the condenser or without it. When working without the condenser, the cylinder is open to the atmosphere throughout the entire stroke, as in the common high-pressure engine, and under such circumstances, the pipe *l* is open to the feed-pump, for the boiler supply. The pipe *m*, leads to a small steam pump not seen in the drawing, and the pipe *n*, conveys the water from the steam pump to the boiler. The pipe *o* is the blow-off pipe.

MATCHES. The contrivances in which sulphur matches were inflamed by immersion in phosphorus (*phosphorous matches*) were first superseded by the so-called *chemical matches*, which consisted of sulphur matches, with a coating of chlorate of potash. This salt, when brought into contact with concentrated sulphuric acid in the cold, is decomposed with explosion and the production of fire, into bisulphate of potash, perchlorate of potash, and chlorous acid, and by the two latter (one of which is resolved into chlorine and oxygen, and the other into chloride of potassium and oxygen) inflammable matters of all kinds, as sulphur, metallic sulphurets, resin, gum, &c., are inflamed, when within the immediate reach of its action. The sulphur ends of the matches are covered with a composition of chlorate of potash, flowers of sulphur, colophony, gum, and cinnabar, (as a coloring matter:) on dipping this into a bottle containing asbestus, previously moistened with sulphuric acid, it quickly becomes inflamed. These matches are now superseded by the more simple lucifer matches, which inflame without the aid of acid, or any thing of the kind, by mere friction; an invention, the history of which, notwithstanding its novelty, is already lost, partly on account of its simplicity, and from the rapid introduction of similar processes.

Lucifer matches.—These, like the last, are sulphur matches, to which a separate inflammable compound has been added. The primary coating of sulphur cannot be dispensed with, because the inflammable composition burns much too rapidly to set fire to the wood. The flame produced by the combustible mixture is, therefore, first communicated to the sulphur, and from it to the wood. The mixture at first contained chlorate of potash as an essential ingredient, and the production of fire depended upon the power of this substance of inflaming the sulphur, phosphorus, &c., with explosion, the effect being produced even by shaking or friction. Thus phosphorus was mixed with mucilage, at a temperature of 104° F., so as to form an emulsion, to which the chlorate of potash was then added. The phosphorus was sometimes replaced by sulphuret of antimony. The operation of mixing the ingredients in the dry state is at all times dangerous. The unpleasant noise which occurred whenever a match was inflamed, and a certain amount of danger from fire, rendered it desirable to replace the detonating action of the mixture by a slow combustion, and this has been accomplished in the *noiseless lucifer matches.* None of those compositions which inflame *without* explosion contain chlorate of potash, but nitre and phosphorus instead; the latter of which burns at the expense of the oxygen of the former. The general principle concerned in the action of these matches is, that substances (as phosphorus) having a great affinity for oxygen, are mixed with a large amount of it, condensed into a small space, (in the nitre,) so that the slightest cause is sufficient to effect their combination. The peroxides of lead and manganese, which abound in oxygen, are often mixed with the nitre; they act in the same way when they have once attained a red heat.

As the thickness of the match, and the quantity of the composition upon it, must always bear a certain proportion, both because the latter is expensive, and burns with a disagreeable odor, the matches require to be cut by machinery, or planes constructed for the purpose; they are thus obtained thin, sufficiently strong, perfectly uniform, and of an elegant appearance. Moist poplar wood is best suited for this purpose. The round or angular matches are dipped in bundles into melted sulphur, and then coated with the inflammable composition: sixteen parts of gum-arabic, 9 parts of phosphorus, 14 parts of nitre, and 16 of finely divided peroxide of manganese, form a good composition, which must be worked up with water to avoid danger. The mixture then forms a thick paste, into which the matches are separately dipped and then dried. Occasionally, smalt and similar matters are added, to produce certain colors, or to increase the effects of friction. After repeated trials, the inflammability of the composition has been gradually diminished to such an extent, that it only inflames when strongly rubbed against rough surfaces, but not readily by pressure or shaking, especially when the matches are preserved in closed boxes; hence they are much less dangerous than might be anticipated. The slow combustion of the sulphur, with the emission of sulphurous acid, forms a great objection to these matches, as this gas is injurious to respiration. Matches have consequently been introduced into commerce which have been first dipped into fused stearine, instead of sulphur; these, however, frequently miss fire.

According to Ure, the following process answers well:

Phosphorus	4 parts.
Nitre	10 "
Fine glue	6 "
Red ochre, or red lead	5 "
Smalt	2 "

Convert the glue, with a little water, by a gentle heat, into a smooth jelly; put it into a slightly warm porcelain mortar to liquify; run the phosphorus down through this gelatine at a temperature of about 140° or 150° F.; add the nitre, then the red powder, and lastly the smalt, till the whole forms a uniform paste. To make writing-paper matches, which burn with a bright flame, and diffuse an agreeable odor, moisten each side of the paper with tincture of benzoin, dry it, cut it into slips, and smear one of their ends with a little of the above paste by means of a hair pencil. On rubbing the said end after it is dry against a rough surface, the paper will take fire without the intervention of sulphur.

To form lucifer wood matches, that act without sulphur, melt in a flat-bottomed tin pan as much white wax as will stand one-tenth of an inch deep; take a bundle of wooden matches free from resin, rub their ends against a red-hot iron plate till the wood be slightly charred; dip them now in the melted wax for a moment, shake them well on taking them out, and finally dip them separately in the above viscid paste. When dry, they will kindle readily by friction.

For the rapid manufacture of the wooden splints for lucifer matches, a patent was granted to Mr. Reuben Partridge, in March, 1842. He employs a perforated metallic plate, having a steel face, strengthened by a bell-metal back. The size of the perforations must depend on that of the desired splints, but they must be as close together as possible, that there may be a very small

blank space between them, otherwise the plate would afford too great resistance to the passage of the wood. By this construction, the whole area of the block of wood may be compressed laterally into the countersunk openings, and forced through the holes, which are slightly countersunk to favor the entrance and separation of the wooden fibres. A convenient size of plate is three inches broad, six inches long, and one thick. The mode of pressing is by fixing the back of the plate against a firm resisting block or bearing, having an aperture equal to the area of the perforations in the plate, and then placing the end of the piece or pieces of wood in the direction of the grain against the face of the plate within the area of the perforated portion. A plunger or lever, or other suitable mechanical agent, being then applied to the back or reverse end of the piece of wood, it may be forced through the perforations in the plate, being first split as it advances by the cutting edges of th holes, and afterwards compressed and driven through the perforations in the plate, coming out on the opposite side or back of the plate in the form of a multitude of distinct splints, agreeably to the shapes and dimensions of the perforations.

MATERIALS, *properties of, used in the mechanic arts.* The following tables show, in a condensed form, the characteristics of materials.

Experiments on the direct Cohesive Powers of various Materials.

Names of Materials.	Cohesive powers reduced to a sq. inch rod.	Experimenters.	Quoted from.

Acacia	0·00152	Weymouth pine	0·00157
Mahogany, Spanish	0·00205	Larch	0·0019

MEAN. A middle state between two extremes; thus we say, arithmetical mean is half the sum of any two quantities: as $\frac{a+b}{2}$ = arithmetical mean between a and b.

Geometrical mean is the square root of the product of any two quantities; that is, $\sqrt{a\,b}$ is the geometrical mean between a and b.

MEASURE. Measure denotes any certain quantity with which other homogeneous quantities are compared.—See WEIGHTS AND MEASURES.

MECHANICAL POWERS. Power is a compound of *weight*, multiplied by its *velocity;* it cannot be increased by mechanical means.

The weight is the resistance to be overcome, the power is the requisite force to overcome that resistance. When they are equal, no motion can take place.

The powers are THREE *in number, viz.,* LEVER, INCLINED PLANE, *and* PULLEY.

Note.—The wheel and axle is a *continual* or *revolving* lever, the wedge is a *double* inclined plane, and the screw is a *revolving* inclined plane.

LEVER.—*When the fulcrum (or support) of the lever is between the weight and the power.*

Rule.—Divide the weight to be raised by the power, and the quotient is the difference of leverage, or the distance from the fulcrum at which the power supports the weight.

Or, multiply the weight by its distance from the fulcrum, and the power by its distance from the same point, and the weight and power will be to each other as their products.

Example.—A weight of 1600 lbs. is to be raised by a force of 80 lbs.; required the length of the longest arm of the lever, the shortest being 1 foot.

$$\frac{1600\times 1}{80}=20 \text{ feet, } Ans.$$

Proof, by second rule.

$$1600\times 1=1600.$$
$$80\times 20=1600.$$

Example.—A weight of 2460 lbs. is to be raised with a lever 7 feet long and 300 lbs.; at what part of the lever must the fulcrum be placed?

$\frac{2460}{300}=8{\cdot}2$; that is, the weight is to the power as 8·2 to 1; therefore the whole length $\frac{7\times 12}{8{\cdot}2+1}=\frac{84}{9{\cdot}2}=$ 9·13 inches, the distance of the fulcrum from the weight.

Example.—A weight of 400 lbs. is placed 15 inches from the fulcrum of a lever; what force will raise it, the length of the other arm being 10 feet?

$$\frac{400\times 15}{120}=50 \text{ lbs., } Ans.$$

Note.—Pressure upon fulcrum equal the sum of weight and power.

When the fulcrum is at one extremity of the lever, and the power, or the weight, at the other.

Rule.—As the distance between the power or *weight* and fulcrum, is to the distance between the weight or *power* and fulcrum, so is the effect to the power, or the *power* to the *effect.*

Example.—What power will raise 1500 lbs., the weight being 5 feet from it, and 2 feet from the fulcrum?

$$5+2=7:2::1500:428{\cdot}5714+ \; Ans.$$

Example.—What is the weight on each support of a beam that is 30 feet long, supported at both ends, and bearing a weight of 6000 lbs. 10 feet from one end?

30 : 20 : : 6000 : 4000 lbs. at the end nearest the weight; and
30 : 10 : : 6000 : 2000 lbs. at the end farthest from the weight.

Note.—Pressure upon fulcrum is the difference of the weight and the power.

The GENERAL RULE, therefore, for ascertaining the relation of POWER to WEIGHT in a lever, whether it be straight or curved, is, the power multiplied by its distance from the fulcrum, is equal to the weight multiplied by its distance from the fulcrum.

Let P be called the power, W the weight, p the distance of P from the fulcrum, and w the distance of W from the fulcrum; then

$$P : W : : w : p, \text{ or } P \times p = W \times w;$$

and

$$\frac{W \times w}{p} = P. \qquad \frac{P \times p}{w} = W.$$

$$\frac{W \times w}{P} = p. \qquad \frac{P \times p}{W} = w.$$

If several weights or powers act upon one or both ends of the lever, the condition of equilibrium is

$$P \times p + P' \times p' + P'' \times p'', \text{ \&c.}, = W \times w + W' \times w', \text{ \&c.}$$

In a system of levers, either of similar, compound, or mixed kinds, the condition is

$$\frac{P \times p \times p' \times p''}{w \times w' \times w''} = W.$$

Let P = 1 lb., p and p' each 10 feet, p'' 1 foot; and if w and w' be each 1 foot, and w'' 1 inch, then $\frac{1 \times 120 \times 120 \times 12}{12 \times 12 \times 1} = \frac{172800}{144} = 1200$; that is, 1 lb. will balance 1200 lbs. with levers of the lengths above given.

Note.—The weights of the levers in the above formulæ are not considered, the centre of gravity being assumed to be over the fulcrums.

If the arms of the lever be equally bent or curved, the distances from the fulcrum must be measured upon perpendiculars, drawn from the lines of direction of the weight and power, to a line running horizontally through the fulcrum; and if unequally curved, measure the distances from the fulcrum upon a line running horizontally through it till it meets perpendiculars falling from the ends of the lever.

Wheel and Axle.—The power multiplied by the radius of the wheel is equal to the weight multiplied by the radius of the axle.

As the radius of the wheel is to the radius of the axle, so is the effect to the power.

When a series of wheels and axles act upon each other, either by belts or teeth, the weight or velocity will be to the power or unity as the product of the radii, or circumferences of the wheels, to the product of the radii, or circumferences of the axles.

Example.—If the radii of a series of wheels are 9, 6, 9, 10, and 12, and their pinions have each a radius of 6 inches, and the weight applied be 10 lbs., what weight will it raise?

$$\frac{10 \times 9 \times 6 \times 9 \times 10 \times 12}{6 \times 6 \times 6 \times 6 \times 6} = 75 \text{ lbs. weight.}$$

Or, if the 1st wheel make 10 revolutions, the last will make 75 in the same time.

To find the power of cranes, &c.

Rule.—Divide the product of the driven teeth by the product of the drivers, and the quotient is the relative velocity, which, multiplied by the length of the winch and the force in lbs. and divided by the radius of the barrel, will give the weight that can be raised.

Example.—A force of 18 lbs. is applied to the winch of a crane, the length being 8 inches; the pinion having 6, the wheel 72 teeth, and the barrel 6 inches diameter.

$$\frac{6}{72} = 12 \times 8 \times 18 = 1728 \div 3 = 576 \text{ lbs. weight.}$$

Let w represent length of winch,
r " radius of barrel,
P " force applied,
v " velocity,
W " weight raised.

$$\frac{v\,w\,P}{r} = W.$$

$$W\,r = v\,w\,P.$$

$$\frac{W\,r}{v\,w} = P.$$

Example.—A weight of 94 tons is to be raised 360 feet in 15 minutes, by a force the velocity of which is 220 feet per minute; what is the power required?

$$\frac{360}{15} = 24 \text{ feet per minute.}$$

$$\frac{24 \times 94}{220} = 10{\cdot}2542 \text{ tons.}$$

In a wheel and axle, where the axle has two diameters, the condition of equilibrium is

$$W : P : : R : \tfrac{1}{2}(r - r');$$

$$\text{or, } P \times R = W \times \tfrac{1}{2}(r - r');$$

that is, the weight is to the power as the lever by which the power works, is to half the difference of the radii of the axle;

R representing radius of wheel,
r " radius of large axle,
r' " radius of less axle.

Inclined Plane.—*Rule.*—As the length of the plane is to its height, so is the weight to the power.

Example.—Required the power necessary to raise 1000 lbs. up an inclined plane 6 feet long and 4 feet high.

As 6 : 4 : : 1000 : 666·66 *Ans.*

Let W represent weight,			$\frac{W \times h}{l} = P.$
h	"	height of plane,	
l	"	length of plane,	$\frac{P \times l}{h} = W.$
P	"	power,	
b	"	base of plane,	$\frac{W \times b}{l} = p'.$
p'	"	pressure on plane.	

To find the length of the base, height, or length of the plane, when any two of them are given.

Rule.—For the length of the base, subtract the square of the height from the square of the length of the plane, and the square root of the remainder will be the length of the base.

For the length of the plane, add the squares of the two other dimensions together, and the square root of their sum will be the length required.

For the height, subtract the square of the base from the square of the length of the plane, and the square root of the remainder is the height required.

Example.—The height of an inclined plane is 20 feet, and its length 100; what is its base, and the pressure of 1000 lbs. upon the plane?

$$\sqrt{20^2 - 100^2} = 9600 = 97·98 \text{ the base.}$$

As 100 : 20 : : 1000 : 200 lbs. necessary power to raise the 1000 lbs., and $\frac{1000 \times 97·98}{100} = 979·8$ the pressure upon the plane.

If two bodies on two inclined planes sustain each other by the aid of a cord over a pulley, their weights are directly as the lengths of the planes.

Example.—If a body of 50 lbs. weight, upon an inclined plane of 10 feet rise in 100, be sustained by another weight on an opposite plane of 10 feet rise to 90 of an inclination, what is the weight of the latter?

As 100 : 90 : : 50 : 45, the answer.

When a body is supported by two planes, and if the weight be represented by the sine of the angle between the two planes. The pressures upon them are reciprocally as the sines of the inclinations of those planes to the horizon, viz.:

The weight,	are as	Sine of the angle between the planes.
The pressure upon one plane,		Sine of the angle of one plane.
The pressure upon the other plane,		Sine of the angle of the other plane.

Thus, if the angle between the planes was 90°, of one plane 60°, and the other 30°—since the natural sines of 90°, 60°, and 30° are 1, ·866, and ·500—if the body weighed 100 lbs., the pressure upon the plane of 30° would be 86·6 lbs., and upon the plane of 60°, 50 lbs., = the centre of gravity being in the centre of the body.

When the power does not act parallel to the plane, draw a line perpendicular to the direction of the power's action from the end of the base line, (at the back of the plane,) and the intersection of this line on the length will determine the length and height of the plane.

Note.—When the line of direction of the power is parallel to the plane, the power is least.

The space which a body describes upon an inclined plane, when descending on the plane by the force of gravity, is to the space it would freely fall in the same time, as the height is to the length of the plane; and the spaces being the same, the times will be inversely in this proportion.

Example.—If a body be placed upon an inclined plane 300 feet long and 25 feet high, what space will it roll down in one second by the force of gravity alone?

As 300 : 25 : : *16·08 : 1·33 feet, *Ans.*

If a body be *projected down an inclined plane* with a given velocity, then the distance which the body will be from the point of projection in a given time will be $t \times v + \frac{h}{l} \times 16·08t^2$; but if the body be *projected upward,* then the distance of the body from the point of projection will be $t \times v - \frac{h}{l} \times 16·08t^2$.

The force which accelerates a body down an inclined plane is that fractional part of the force of gravity which is represented by the height of the plane divided by its length.

Let h represent the height of the plane, l its length, t the time in seconds, s the space which a body will move through in a given time, v the velocity, and i the angle of inclination $\left(\text{sin. } \iota = \frac{h}{t}\right)$.

$$s = \frac{16·08\,h\,t^2}{l}, \text{ or } \frac{t\,v}{2}, \text{ or } \frac{l\,v^2}{64·3\,h}, \text{ or } \frac{v^2}{64·3 \text{ sin. } i}, \text{ or sin. } i \times 16·08\,t^2.$$

$$v = \frac{2\,s}{t}, \text{ or } \frac{32·16\,h\,t}{l}, \text{ or } \sqrt{\frac{64·3\,h\,s}{l}}, \text{ or sin. } i \times 32·16\,t, \text{ or } \sqrt{\text{sin. } i \times 64·3\,s}.$$

* The distance a body will freely fall in one second by the force of gravity.

$$t = \frac{2s}{v}, \text{ or } \frac{lv}{32{\cdot}16\,h}, \text{ or } \sqrt{\frac{ls}{16{\cdot}08\,h}}, \text{ or } \frac{v}{32{\cdot}16 \sin. i}, \text{ or } \sqrt{\frac{s}{16{\cdot}08 \sin. i}}.$$

$$\frac{h}{l}, \text{ or } \sin. i = \frac{v}{32{\cdot}16\,t}, \text{ or } \frac{s}{16{\cdot}08\,t^2}, \text{ or } \frac{v^2}{64{\cdot}3\,s}.$$

The accelerating force on the plane is to the accelerating force of gravity as v^2 is to $64{\cdot}3 \times s$.

If sin. $i = \frac{1}{2}$, it shows that the length of the plane is twice its height, or $\frac{1}{2} = 30°$.

If the proportion which the length of the plane bears to the height be given, substitute these proportions for the length and height in the above rules, and the conclusions will be equally true.

Wedge.—*When two bodies are forced from one another, in a direction parallel to the back of the wedge.*

Rule.—As the length of the wedge is to half its back, so is the resistance to the force.

Example.—The length of the back of a double wedge is 6 inches, and the length of it through the middle 10 inches; what is the power necessary to separate a substance having a resistance of 150 lbs.?

As 10 : 3 : : 150 : 45 lbs., *Ans.*

When only one of the bodies is movable.

Rule.—As the length of the wedge is to its back, so is the resistance to the power.

Example.—What power, applied to the back of a wedge, will raise a weight of 15,000 lbs., the wedge being 6 inches deep, and 100 long on its base?

As 100 : 6 : : 15000 : 900 lbs.,* *Ans.*

Note.—As the power of the wedge in practice depends upon the split or rift in the wood to be cleft, or in the body to be raised, the above rules are only theoretical where a rift exists.

Screw.—As the screw is an inclined plane wound round a cylinder, the length of the plane is found by adding the square of the circumference of the screw to the square of the distance between the threads, and taking the square root of the sum, and the height is the distance between the consecutive threads.

Rule.—As the length of the inclined plane is to the pitch or height of it, so is the weight to the power.

When a wheel or capstan is applied to turn the screw, the length of the lever is the radius of the circle described by the handle of the wheel or capstan bar.

Let P represent power,
R " length of lever,
W " weight,
l " length of the inclined plane,
p " pitch of screw or height of plane,
x " effect of power at circumference of screw,
r " radius of screw.

Then, by the above rules,

As $l : p :: W : P$,	$P : W :: p : l$,
$l : W :: p : P$,	$r : R :: P : x$,
$W : l :: P : p$,	$P : x :: r : R$,
$p : l :: P : W$,	$R : r :: x : P$.

Example.—What is the power requisite to raise a weight of 8000 lbs. by a screw of 12 inches circumference and 1 inch pitch?

$12^2 + 1^2 = 145$, and $\sqrt{145} = 12{\cdot}04159$.

Then, 12·0416 : 1 : : 8000 : 664·36 lbs., *Ans.*

And if a lever of 30 inches length was added to the screw,

$12 \div 3{\cdot}1416 = 3{\cdot}819 \div 2 + 30 = 31{\cdot}9095$, length of lever.

Then, as $31{\cdot}9095 \times 2 \times 3{\cdot}1416 : 12{\cdot}0416 :: 664{\cdot}36 : 39{\cdot}9$ lbs., *Ans.*

Or, let C represent the circumference described by the power, and we have

$P : W :: p : C$,
$C : p :: W : P$,
$P \times C = W \times p$;

When a hollow screw revolves upon one of less diameter and pitch, (or the differential screw,) the effect is the same as that of a single screw, in which the distance between the threads is equal to the difference of the distances between the threads of the two screws.

If one screw has 20 threads in an inch pitch, and the other 21, the power is to the weight as the difference between $\frac{1}{20}$ and $\frac{1}{21}$, or $\frac{1}{420} = 1$ to 420.

In a complex machine, composed of the screw, and wheel, and axle, the relation between the weight and power is thus:

Let x represent the effect of the power on the wheel,
R " the radius of the wheel,
p " the pitch of the screw,
r " the radius of the axle,
C " the circumference described by the power.

* This is exclusive of friction, which in this machine is very great.

Then, by the properties of the screw,

$$P \times C = x \times p;$$

and of the wheel and axle,

$$x \times R = W \times r.$$

Hence we have

$$P \times C \times x \times R = x \times p \times W \times r.$$

Omitting the common multiplier, x,

$$P \times C \times R = W \times p \times r;$$

$$\text{or} \quad P : W :: p \times r : C \times R,$$

$$\text{and } p \times r : C \times R :: P : W.$$

Example.—What weight can be raised with a power of 10 lbs. applied to a crank 32 inches long, turning an endless screw of 3½ inches diameter and one inch pitch, applied to a wheel and axle of 20 and 5 inches in diameter respectively?

Circumference of 64 = 201.

$$1 : 201 :: 10 : 2010.$$

Radii of wheel and axle, 10 and 2·5.

$$2{\cdot}5 : 10 :: 2010 : 8040 \text{ lbs., } Ans.$$

$$\text{or } 2{\cdot}5 \times 1 : 201 \times 10 :: 10 : 8040.$$

And when a series of wheels and axles act upon each other, the weight will be to the power as the continued product of the radii of the wheels to the continued product of the radii of the axles;

$$\text{thus, } W : P :: R^3 : r^3;$$

$$\text{or, } r^3 : R^3 :: P : W,$$

there being three wheels and axles of the same proportion to each other.

Example.—If an endless screw, with a pitch of half an inch, and a handle of 20 inches radius, be turned with a power of 150 lbs., and geered to a toothed wheel, the pinion of which turns another wheel, and the pinion on the second wheel turns a third wheel, to the pinion or barrel of which is hung a weight, it is required to know what weight can be sustained in that position, the diameter of the wheels being 18, and the pinions 2 inches?

$$p \times r^3 : C \times R^3 :: P : W;$$

$$\text{or } {\cdot}5 \times 1^3 : 125{\cdot}6 \times 9^3 :: 150;$$

which, when extended, gives

$${\cdot}5 : 91562{\cdot}4 :: 150 : 27468720 \text{ lbs., } Ans.$$

Note.—The diameter of a screw is not a necessary element in determining the weight it will support when the point at which the power is applied is given.

PULLEY.—*When only one cord or rope is used.*

Rule.—Divide the weight to be raised by the number of parts of the rope engaged in supporting the lower or movable block.

Example.—What power is required to raise 600 lbs., when the lower block contains six sheaves and the end of the rope is fastened to the upper block, and what power when fastened to the lower block?

$$\frac{600}{6 \times 2} = 50 \text{ lbs., 1st } Ans.$$

$$\frac{600}{6 \times 2 + 1} = 46{\cdot}15 \text{ lbs., 2d } Ans.$$

$$\text{or } W = n \times P,$$

n signifying the number of parts of the rope which sustain the lower block.

When more than one rope is used.

In a *Spanish burton*, where there are two ropes, two movable pulleys, and one fixed and one stationary pulley, with the ends of one rope fastened to the support and upper movable pulley, and the ends of the other fastened to the lower block and the power, the weight is to the power as 5 to 1.

And in one where the ends of one rope are fastened to the support and the power, and the ends of the other to the lower and upper blocks, the weight is to the power as 4 to 1.

In a system of pulleys, with any number of ropes, the ends being fastened to the support,

$$W = 2^n \times P,$$

n expressing the number of ropes.

Example.—What weight will a power of 1 lb. sustain in a system of 4 movable pulleys and 4 ropes?

$$1 \times 2 \times 2 \times 2 \times 2 = 16 \text{ lbs., } Ans.$$

When fixed pulleys are used in the place of hooks, to attach the ends of the rope to the support,

$$W = 3^n \times P.$$

Example.—What weight will a power of 5 lbs. sustain with 4 movable and 4 fixed pulleys, and 4 ropes?

$$5 \times 3 \times 3 \times 3 \times 3 = 405 \text{ lbs., } Ans.$$

When the ends of the rope, or the fixed pulleys, are fastened to the weight,

$$W = (2^n - 1) \times P,$$

$$\text{and } W = (3^n - 1) \times P,$$

which would give, in the above examples,

$$1 \times 2 \times 2 \times 2 \times 2 = 16 - 1 = 15 \text{ lbs.,}$$

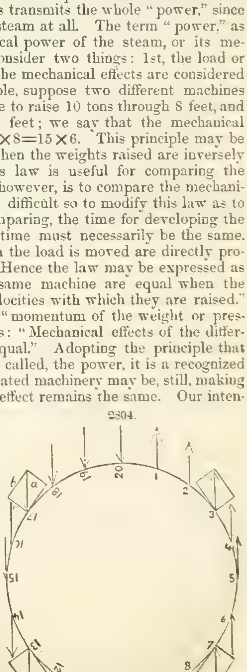
$$5 \times 3 \times 3 \times 3 \times 3 = 405 - 1 = 404 \text{ lbs.}$$

MECHANICAL POWER OF STEAM. Under the head of Crank, in the first volume of this Dictionary, reference is made to this article for an elucidation of the theory of its movement, as also for an explanation of the mechanical laws of steam. These last should be sought under their proper head "Steam," while the theory of the crank will be explained in this place, as reference has been made to it under this head.

If we consider the rotatory engine with revolving piston apart from the practical objections against its application, it is a perfect engine, and is capable of giving out all the effect of the steam. An impression has, however, widely prevailed that this is not the case with the common reciprocating engine with its connecting-rod and crank. Several scientific writers on the steam-engine have pointed out the error of this conviction, so that all the better-informed class of engineers are well aware that the crank, like all other pieces of machinery, fully transmits the power which is communicated to it. There are others, however, who cannot understand this: they cannot set out from the great fundamental principle of virtual velocities, and satisfy themselves with asserting the truth as a simple and inevitable deduction from it. They are continually asking the question, "How is it that, in the common crank, we are able to show that, at two given points in its revolution, the position is such that an infinite power would produce no effect at all; that there are only two positions in which the force and effect are equal; and that, at every other position, the effective pressure given out by the connecting-rod to the crank is less than the original pressure of the steam on the piston—the remainder of the pressure of the steam producing only a useless pressure on the cranks—how then can the crank be conceived to transmit the whole mechanical effect of the steam?" In the present remarks we intend to give an answer to this question. We intend to examine, at considerable length, the action of the crank, and to show that the great fact upon which the whole science of mechanics has rested ever since the time of Galileo, still obtains in all its generality in this particular case. For the purpose of clearly elucidating the subject we intend to consider it at first in a very simple and practical manner, and then to examine it in a more theoretical point of view.

Before proceeding further it is necessary to have a clear conception of the meaning of the term "power." It is obvious that it must be different from the term "force" or "pressure;" for, if its meaning were the same, it would be absurd to say that the crank always transmits the whole "power," since in some positions it does not transmit any of the pressure of the steam at all. The term "power," as generally used by writers on the steam-engine, means the mechanical power of the steam, or its mechanical effect. In estimating the mechanical effect we have to consider two things: 1st, the load or force raised, and 2d, the distance through which it is raised; and the mechanical effects are considered to be equal when the product of these two are equal. For example, suppose two different machines constructed in such a manner that in the one 1 lb. of steam is made to raise 10 tons through 8 feet, and that in the other 1 lb. of steam is made to raise 15 tons through 6 feet; we say that the mechanical effect of the steam is the same in these two machines, because $10 \times 8 = 15 \times 6$. This principle may be expressed in the form of a rule:—"Mechanical effects are equal when the weights raised are inversely proportional to the distances through which they are raised." This law is useful for comparing the mechanical effects of different machines; our purpose, at present, however, is to compare the mechanical effects of different parts of the same machine. It will not be difficult so to modify this law as to suit our purposes. When it is different machines that we are comparing, the time for developing the mechanical effects may be different, but in the same machine the time must necessarily be the same. From this equality of time we infer that the spaces through which the load is moved are directly proportional to the uniform velocity with which they are described. Hence the law may be expressed as follows: "The mechanical effects of the different parts of the same machine are equal when the weights or pressures raised are inversely proportional to the velocities with which they are raised." The product of a weight or pressure into its velocity is called the "momentum of the weight or pressure." After this definition, our rule may be expressed as follows: "Mechanical effects of the different parts of the same machine are equal when the momenta are equal." Adopting the principle that the momentum measures the mechanical effect, or, as it is usually called, the power, it is a recognized principle, proved by all writers on mechanics, that however complicated machinery may be, still, making allowance for the resistances arising from friction, the mechanical effect remains the same. Our intention at present is only to show that it obtains in the particular case of the crank. The crank-pin moves through a greater space than the piston; and when the piston is moving very slowly the crank-pin is moving very quickly, so that the ultimate effect is the same at every moment. By multiplying the pressure into the velocity, it will be found that the same quantity of steam produces the same amount of power at every part of the stroke.

2804.



Suppose the velocity of the piston to be uniform, then the motion of the extremity of the connecting-rod will be uniform also. The extremity of the crank always moves irregularly, but as it moves over a greater space than the extremity of the connecting-rod, its mean velocity must be greater. The proportion is obviously as follows:

Velocity of piston : mean velocity of extremity of crank :: twice the length of stroke : circumference which the extremity of the crank describes.

Let l denote the length of stroke, and π the ratio of the circumference of a circle to its diameter; then we have the proportion, Velocity of piston : mean velocity of extremity of crank :: $2l : \pi l :: 2 : \pi$, and, therefore, mean velocity of extremity of crank $= \pi \times$ velocity of piston $\div 2$. Since the mean velocity of the

crank is greater than that of the piston, then, according to our law, in order to produce the same mechanical effect, the mean effective pressure must be less, and that in the same proportion. We may approximate to the mean effective pressure by calculating it for a great many equidistant positions, and taking the average. Thus let Fig. 2804 represent the circle which the extremity of the crank describes. Divide it into 20 equal parts. Suppose the connecting-rod to remain always in a parallel direction, and the constant pressure in it to be 100. The effective pressure at any point P will be 100 sin. POE. From this we have the following table:

Points in the Figure.		Pressure in the Direction of Revolution.
At 0 and at	20	$100 \times$ sin. $0° =$ 0·00
1	19	$100 \times$ sin. $18° =$ 30·90
2	18	$100 \times$ sin. $36° =$ 58·78
3	17	$100 \times$ sin. $54° =$ 80·90
4	16	$100 \times$ sin. $72° =$ 95·11
5	15	$100 \times$ sin. $90° =$ 100·00
6	14	$100 \times$ sin. $108° =$ 95·11
7	13	$100 \times$ sin. $126° =$ 80·90
8	12	$100 \times$ sin. $144° =$ 58·78
9	11	$100 \times$ sin. $162° =$ 30·90
10	10	$100 \times$ sin. $180° =$ 0·00
		Mean pressure 63·11

From this we learn that the mean effective pressure is to the pressure at piston in the proportion of about 63 to 100. This is very nearly the same proportion as 2 to π; for $110 \div 63 = 1·6$ nearly, and $\pi \div 2 = 1·7$. Hence we have the proportion, pressure at piston : mean effective pressure at extremity of crank :: mean velocity of extremity of crank : velocity of piston. This shows, according to our law, that the mechanical effect of the pressure at the piston is wholly transmitted to the crank.

We have said not only that the mechanical effect is the same ultimately, but that it is the same momentarily; that is to say, that the product of the effective force at any point, and the velocity at that point, is constantly equal to the product of the pressure at the piston, and its velocity at the corresponding position. It is more difficult to illustrate this in the same manner, on account of the difficulty of calculating the relative velocity of the crank and piston. It is very easy to show, however, that at what is called the "position of the centres" no loss of power can really take place. This happens for this very plain reason, that there is no power exerted at that time. It ought to be remembered that at that time the communication which supplies the steam from the boiler is cut off. The steam on one side having done its work, only waits to be released from its chamber, and escapes at the opening of the eduction valve, and at the same instant is in the act of being permitted to enter on the opposite side for reversing the motion. Hence at these points all application of force has ceased, and arrangements are making for reversing the motion; besides which, when the engine is on the centre, the piston has not any motion.

With regard to the remaining points of the circle, at which it is said power is lost, the velocity imparted to the crank is always an exact equivalent for the force which is apparently lost. At present we wish only to illustrate this fact, for its rigid demonstration requires rather abstract considerations. The following table presents the results of the calculations of the power and velocity. The numbers 1, 2, &c., refer to Fig. 2804.

Position of Crank.		Pressure in Direction of Revolution.	Velocity of Crank divided by Velocity of Piston.
At 0 and at	20	0·00	Infinite
1	19	30·90	3·236
2	18	58·78	1·701
3	17	80·90	1·236
4	16	95·11	1·051
5	15	100·00	1·000
6	14	95·11	1·051
7	13	80·90	1·236
8	12	58·78	1·701
9	11	30·90	3·236
10	10	0·00	Infinite

These are obtained on the supposition that the force on the piston and its velocity are constant, and also that the connecting-rod keeps always in a parallel direction. Neither of these suppositions is exactly true in practice. The same law holds, although the pressure on the piston is variable, and also its velocity, and although the connecting-rod takes different inclinations. It will be observed from our table that the smaller the effective pressure in the direction of the revolution, the greater the relative velocity

The rigid demonstration of these facts requires for their proper exhibition the differential calculus which in this work would be out of place.

MEERSCHAUM. This form of silicate of magnesia is employed in manufacturing the celebrated tobacco-pipes known under this name, and its composition is as follows, differing but little from steatite or soapstone; but, unlike the latter, may be artificially produced:

	Levant.	Madrid.	Natolia.
Silica	60·87	53·80	42·00
Magnesia	27·80	23·80	30·50
Lime	27·80	23·80	2·30
Alumina	·009	1·20	2·00
Oxide of iron		1·20	
Water	11·29	20·00	23·00
	100·05	98·80	99·30

It is found in the native state on the shores of the inland seas of Europe. That found in Morocco contains, in addition to the above ingredients, ·52 of potash. It is light and soft, and is employed in the Turkish dominions as fuller's earth. In Germany it is extensively used in the manufacture of tobacco-pipes, which are prepared for sale by being soaked first in tallow, then in wax, and finally by being polished with shave-grass. Imitation meerschaum pipes are sold in large quantities, and the greatest caution is necessary to guard against deception. To the connoisseur, the best criterion is the beautiful brown color which the genuine meerschaum assumes after being smoked some time.

MENSURATION—OF SURFACES. *To find the area of a four-sided figure.*—RULE.—Multiply the length by the breadth or *perpendicular* height; the product will be the area.

To find the area of a triangle.—RULE.—Multiply the length of one of the sides, by a perpendicular falling upon it from the opposite angle; half the product will be the area.

To find the length of one side of a right-angled triangle, when the lengths of the other two sides are given.—RULE 1.—*To find the hypothenuse,* add together the squares of the two legs, and extract the square root of that sum.

RULE 2.—*To find one of the legs,* subtract the square of the leg, of which the length is known, from the square of the hypothenuse, and the square root of the difference will be the answer.

To find the area of a regular polygon.—RULE.—Multiply the length of a perpendicular, drawn from the centre to one of the sides, (or the radius of its inscribed circle,) by the length of one side, and this product again by the number of sides; and half the product will be the area of the polygon.

To find the area of a trapezium.—RULE 1.—Draw a diagonal line to divide the trapezium into two triangles; find the areas of these triangles separately, and add them together.

RULE 2.—Divide the trapezium into two triangles, by a diagonal, and let two perpendiculars fall on the diagonal from the opposite angles; then, the sum of these perpendiculars multiplied by the diagonal, and divided by 2, will be the area of the trapezium.

To find the area of a trapezoid.—RULE 1.—Multiply the sum of the two parallel sides by the perpendicular distance between them, and half the product will be the area.

RULE 2.—Draw a diagonal, to divide the trapezoid into two triangles; find the areas of those triangles separately, and add them together.

To find the area of an irregular polygon.—RULE.—Draw diagonals, to divide the figure into trapeziums and triangles; find the area of each separately, by either of the rules before given for that purpose; and the sum of the whole will be the area of the figure.

To find the area of a long irregular figure.—RULE.—Take the breadths in several places, and at equal distances from each other; add all the breadths together, and divide the sum by this number, for the mean breadth; then multiply the mean breadth by the length of the figure, and the product will be the area.

To find the circumference of a circle when the diameter is given; or the diameter when the circumference is given.—RULE 1.—Multiply the diameter by 3·1416, and the product will be the circumference; or divide the circumference by 3·1416, and the quotient will be the diameter.

RULE 2.—As 7 is to 22, so is the diameter to the circumference;
As 22 is to 7, so is the circumference to the diameter.

RULE 3.—As 113 is to 355, so is the diameter to the circumference;
As 355 is to 113, so is the circumference to the diameter.

To find the area of a circle.—RULE 1.—Multiply the square of the diameter by ·7854; or the square of the circumference by ·07958; the product, in either case, will be the area.

RULE 2.—Multiply the circumference by the diameter, and divide the product by 4.

RULE 3.—As 14 is to 11, so is the square of the diameter to the area;
Or as 88 is to 7, so is the square of the circumference to the area.

To find the length of any arc of a circle.—RULE 1.—From 8 times the chord of half the arc, subtract the chord of the whole arc; one-third of the remainder will be the length of the arc, nearly.

RULE 2.—As 180 is to the number of degrees in the arc;
So is 3·1416 times the radius to its length.
Or, as 3 is to the number of degrees in the arc;
So is ·05236 times the radius to its length.

To find the area of a sector of a circle.—RULE 1.—Multiply the length of the arc by half the length of the radius; the product will be the area.

RULE 2.—As 360 degrees is to the number of degrees in the arc of the sector; so is the area of the circle to the area of the sector.

To find the area of a segment of a circle.—RULE 1.—To the chord of the whole arc, add the chord of half the arc and one-third of it more. Then multiply the sum by the versed sine, or height of the segment, and four-tenths of the product will be the area of the segment.

Rule 2.—Divide the height, or versed sine, by the diameter of the circle, and find the quotient in the column of versed sines, in the table of areas of segments.

Then take out the corresponding area in the next column on the right-hand, and multiply it by the square of the diameter, for the answer.

To find the area of a circular zone.—Rule 1.—*When the zone is less than a semicircle*, to the area of the trapezoid, formed by connecting the extremities of the zone by straight lines, add the area of the circular segments beyond those lines; the sum is the area of the zone.

Rule 2.—*When the zone is greater than a semicircle*, to the area of the parallelogram, formed in like manner as above, add the area of the circular segments, at its extremities; the sum is the area of the zone.

To find the area of a circular ring, or space, included between two concentric circles.—Rule.—Find the areas of the two circles separately; then the difference between them will be the area of the ring.

To find the circumference of an ellipse.—Rule.—Square the two axes, and multiply the square root of half that sum by 3·1416; the product will be the circumference, nearly.

To find the area of an ellipse.—Rule.—Multiply the transverse diameter by the conjugate, and the product by ·7854.

To find the area of an elliptic segment.—Rule.—Divide the height of the segment by the axis of which it is a part, and find, in the table of segments of circles, a circular segment having the same versed sine as this quotient. Then, multiply the segment thus found and the two axes of the ellipse continually together, and the product will give the area required.

When the transverse, the conjugate, and the abscissæ are given, to find the ordinate.—Rule.—Multiply the abscissæ into each other, and extract the square root of the product; this will give the *mean* between them. Then, as the transverse diameter is to the conjugate diameter, so is the *mean* to the ordinate required.

When the transverse, the conjugate, and the ordinate are given, to find the abscissæ.—Rule.—From the square of half the conjugate, take the square of the ordinate, and extract the square root of the remainder.

Then, as the conjugate diameter is to the transverse, so is that square root to half the difference of the two abscissæ.

Add this half difference to half the transverse, for the greater abscissa; and subtract it for the less.

When the transverse, the ordinate, and the two abscissæ are given, to find the conjugate.—Rule.—As the square root of the product of the two abscissæ is to the ordinate, so is the transverse diameter to the conjugate.

Note.—In the same manner the transverse diameter may be found from the conjugate, using the two abscissæ of the conjugate, and their ordinate perpendicular to the conjugate.

When the conjugate, the ordinate, and the abscissæ are given, to find the transverse diameter.—Rule.—From the square of half the conjugate subtract the square of the ordinate, and extract the root of the remainder. Add this root to the half conjugate if the less abscissa be given; but subtract it when the greater abscissa is given.

Then, as the square of the ordinate is to the rectangle of the abscissa and conjugate, so is the reserved sum, or difference, to the transverse diameter.

To find the area of a parabola.—Rule.—Multiply the base by the height, and two-thirds of the product will be the area.

To find the area of a frustum of a parabola.—Rule.—Multiply the difference of the cubes of the two ends of the frustum by twice its altitude, and divide the product by thrice the difference of their squares.

To find the abscissa or ordinate of the parabola.—Rule.—The abscissæ are to each other as the squares of their ordinates; that is, as any abscissa is to the square of its ordinate, so is any other abscissa to the square of its ordinate.

Or, as the square root of any abscissa is to its ordinate, so is the square root of another abscissa to its ordinate.

To find the length of a parabolic curve, cut off by a double ordinate.—Rule.—To the square root of the ordinate, add four-thirds of the square of the abscissa; the square root of that sum, multiplied by 2, will give the length of the curve, nearly.

To find the area of a hyperbola.—Rule.—To five-sevenths of the abscissa, add the transverse diameter; multiply the sum by the abscissa, and extract the square root of the product. Then, multiply the transverse diameter by the abscissa, and extract the square root of that product.

Then, to 21 times the first root add 4 times the second root; multiply the sum by double the product of the conjugate and abscissa, and divide by 75 times the transverse; this will give the area, nearly.

To find the length of a hyperbolic curve.—Rule.—To 21 times the square of the conjugate add 9 times the square of the transverse; also, to 21 times the square of the conjugate add 19 times the square of the transverse, and multiply each of these sums by the abscissa.

To each of the two products add 15 times the product of the transverse and square of the conjugate.

Then, as the less sum is to the greater, so is the ordinate to the length of the curve, nearly.

When the transverse, the conjugate, and the abscissæ are given, to find the ordinate.—Rule.—As the transverse diameter is to the conjugate, so is the square root of the product of the two abscissæ to the ordinate required.

Note.—In the hyperbola, the less abscissa added to the axis gives the greater: and the greater abscissa subtracted from the axis, gives the less.

When the transverse and conjugate diameters, and the ordinate, are given, to find the abscissæ.—Rule.—To the square of half the conjugate add the square of the ordinate, and extract the square root of that sum.

Then, as the conjugate diameter is to the transverse, so is the square root to half the sum of the abscissæ.

To this half sum add half the transverse diameter for the greater abscissa, and subtract it for the less.

When the transverse diameter, ordinate, and abscissæ, are given, to find the conjugate.—Rule.—As the square root of the product of the two abscissæ is to the ordinate, so is the transverse diameter to the conjugate.

When the conjugate diameter, the ordinate, and the two abscissæ, are given, to find the transverse diameter.—Rule.—To the square of half the conjugate add the square of the ordinate, and extract the square root of that sum.

To this root add the half conjugate when the less abscissa is used; and subtract it when the greater abscissa is used; reserving the sum or difference.

Then, as the square of the ordinate is to the product of the abscissæ and conjugate, so is the reserved sum, or difference, to the transverse.

Mensuration of Solids.—*To find the solidity of a cube.*—Rule.—Multiply the side of the cube by itself, and that product again by the side; the last product will be the solidity of the given cube.

To find the solidity of a parallelopipedon.—Rule.—Multiply the length, breadth, and depth or altitude, continually together, or, in other words, multiply the length by the breadth, and that product by the depth or altitude, and this will give the required solidity.

To find the solidity of cylinders and prisms.—Rule.—Multiply the area of the base by the height of the cylinder or prism, and the product will give the solid content.

To find the convex surface of a cylinder.—Rule.—Multiply the circumference by the length of the cylinder; the product will be the convex surface required.

To find the convex surface of a right cone, or pyramid.—Rule.—Multiply the perimeter, or circumference of the base, by the slant height, or length of the side of the cone, and half the product will be the surface.

To find the convex surface of a frustum of a right cone, or pyramid.—Rule.—Multiply the sum of the perimeters of the two ends by the slant height or side of the frustum, and half the product will be the surface required.

To find the solidity of a cone, or pyramid.—Rule.—Multiply the area of the base by the perpendicular height, and one-third of the product will be the content.

To find the solidity of the frustum of a cone.—Rule.—Divide the difference of the cubes of the diameters of the two ends by the difference of the diameters; this quotient multiplied by ·7854 and again by one-third of the height, will give the solidity.

To find the solidity of the frustum of a pyramid.—Rule.—Add to the areas of the two ends of the frustum the square root of their product, and this sum, multiplied by one-third of the height, will give the solidity.

To find the solidity of a wedge.—Rule.—To the length of the edge of the wedge add twice the length of the back; multiply this sum by the height of the wedge, and then by the breadth of the back; one-sixth of the product will be the solid content.

To find the solidity of a prismoid.—Rule.—Add into one sum the areas of the two ends and four times the middle section, parallel to them; then, this sum multiplied by one-sixth of the height, will give the content.

Note.—The length of the middle section is equal to half the sum of the lengths of the two ends; and its breadth is equal to half the sum of the breadths of the two ends.

To find the convex surface of a sphere, or globe.—Rule.—Multiply the diameter of the sphere by its circumference.

Or, multiply 3·1416 by the square of the diameter; the product will be the convex surface required.

Note.—The convex surface of any zone or segment may be found, in like manner, by multiplying its height by the whole circumference of the sphere.

To find the solidity of a sphere or globe.—Rule.—Multiply the cube of the axis by ·5236; the product will be the solidity.

To find the solidity of a spherical segment.—Rule.—To three times the square of the radius of its base add the square of its height; then, multiply the sum by the height, and the product by ·5236.

To find the solidity of a spherical zone or frustum.—Rule.—To the sum of the squares of the radius of each end, add one-third of the square of the height of the zone; this sum, multiplied by the said height, and the product by 1·5708, will give the solidity.

To find the solidity of a spheroid.—Rule.—Multiply the square of the revolving axis by the fixed or shorter axis; the product, multiplied by ·5236, will give the content.

To find the solidity of a segment of a spheroid.—Rule 1.—*When the base is circular or parallel to the revolving axis,* multiply the fixed axis by 3, the height of the segment by 2, and subtract the one product from the other; then multiply the remainder by the square of the height of the segment, and the product by ·5236.

Then, as the square of the fixed axis is to the square of the revolving axis, so is the last product to the content of the segment.

Rule 2.—*When the base is perpendicular to the revolving axis,* multiply the revolving axis by 3, and the height of the segment by 2, and subtract the one from the other; then, multiply the remainder by the square of the height of the segment, and the product by ·5236.

Then, as the revolving axis is to the fixed axis, so is the last product to the content.

To find the solidity of the middle frustum of a spheroid.—Rule 1.—*When the ends are circular, or parallel to the revolving axis,* to twice the square of the revolving axis, add the square of the diameter of either end; then, multiply this sum by the length of the frustum, and the product again by ·2618; this will give the solidity.

Rule 2.—*When the ends are elliptical, or perpendicular to the revolving axis,* to twice the product of the transverse and conjugate diameters of the middle section, add the product of the transverse and

conjugate of either end; multiply this sum by the length of the frustum, and the product by ·2618; this will give the solidity.

To find the surface of a circular spindle.—Rule.—Multiply the length of the spindle by the radius of the revolving arc. Multiply also the said arc by the central distance, or distance between the centre of the spindle and centre of the revolving arc. Subtract this last product from the former; double the remainder; multiply it by 3·1416, and the product will give the surface of the spindle.

Note.—The same rule will serve for any segment, or zone, cut off perpendicularly to the chord of the revolving arc; but, in this case, the particular length of the part, and the part of the arc which describes it, must be used, instead of the whole length and whole arc.

To find the solidity of a circular spindle.—Rule.—Multiply the central distance, as above, by half the area of the revolving segment. Subtract the product from one-third of the cube of half the length of the spindle. Then, multiply the remainder by 12·5664, or 4 times 3·1416, and the product will be the solidity required.

To find the solidity of the frustum, or zone, of a circular spindle.—Rule.—From the square of half the length of the whole spindle, take one-third of the square of half the length of the frustum, and multiply the remainder by the said half-length of the frustum. Multiply the central distance by the revolving area, which generates the frustum. Subtract the last product from the former; and the remainder, multiplied by 6·2832, or twice 3·1416, will give the content.

To find the solidity of an elliptic spindle.—Rule.—To the square of the greatest diameter, add the square of twice the diameter at one-fourth of its length; multiply the sum by the length, and the product by ·1309, and it will give the solidity, very nearly.

To find the solidity of a frustum or segment of an elliptic spindle.—Rule.—Proceed, as in the last rule, for this, or any other solid, formed by the revolution of a conic section about an axis, namely:

Add together the squares of the greatest and least diameters, and the square of double the diameter in the middle between the two; multiply the sum by the length, and the product by ·1309, and it will give the solidity.

Note.—For all such solids this rule is exact when the body is formed by the conic section, or a part of it, revolving about the axis of the section; and it will always be very near the truth, when the figure revolves about another line.

To find the solidity of a parabolic conoid.—Rule.—Multiply the square of the diameter of the base by the altitude, and the product by ·3927.

To find the solidity of a frustum of a paraboloid.—Rule.—Multiply the sum of the squares of the diameters of the two ends by the height of the frustum, and the product by ·3927.

To find the solidity of a parabolic spindle.—Rule.—Multiply the square of the middle diameter by the length of the spindle, and the product by ·41888, (which is eight-fifteenths of ·7854,) and it will give the content.

To find the solidity of the middle frustum of a parabolic spindle.—Rule.—Add together 8 times the square of the greatest diameter, 3 times the square of the least diameter, and 4 times the product of these two diameters; multiply the sum by the length, and the product by ·05236, (which is $\frac{1}{6}$ of 3·1416;) this will give the solidity.

To find the convex surface of a cylindrical ring.—Rule.—To the thickness of the ring add the inner diameter; multiply this sum by the thickness, and the product by 9·8696, (which is the square of 3·14159,) and it will give the superficies required.

To find the solidity of a cylindrical ring.—Rule.—To the thickness of the ring add the inner diameter; then multiply the sum by the square of the thickness, and the product by 2·4674, (which is one-fourth of the square of 3·1416,) and it will give the solidity.

To find the superficies or solidity of any regular body.—Rule 1.—Multiply the tabular *surface* by the square of the linear edge, and the product will be the superficies.

Rule 2.—Multiply the tabular *solidity* by the cube of the linear edge, and the product will be the solidity.

Table of the Surfaces and Solidities of the Regular Bodies when the linear edge is 1.

No. of Sides.	Names.	Surfaces.	Solidities.
4	Tetrahedron	1·73205	0·11785
6	Hexahedron	6·00000	1·00000
8	Octahedron	3·46410	0·47140
12	Dodecahedron	20·64573	7·66312
20	Icosahedron	8·66025	2·18169

METALS AND ALLOYS, *employed in the mechanical and useful arts.* Metals are elementary bodies, being all capable of combining with oxygen, and many of them, during this combination, exhibit the phenomena of combustion. Formerly only seven metals were known, but modern discoveries have added to the number greatly. Metals are distinguished by their great specific gravity, considerable tenacity and hardness, opacity, and property of reflecting the greater part of the light which falls on their surface, giving rise to what is denominated the metallic lustre or brilliancy. Opacity is another leading property of metals; even when beat to the greatest possible thinness, they transmit scarcely any light; from the union of the two qualities density and opacity, arises that of lustre. By their opacity and the denseness of their texture, they reflect the greatest part of the light that falls on their surface. From their density they are susceptible of a fine polish, by which their lustre is increased.

Tenacity distinguishes a number of the metals, and is not possessed in any great degree by othet bodies; hence arises their malleability and ductility. Some of the metals are neither malleable not ductile. Both these qualities are greater in combinations of the metals than in the individual metals. Metals are the best conductors of caloric; their expansibilities are various, and are probably nearly in the order of their fusibilities. Mercury melts at so low a temperature, that it can be obtained in the solid state only at a very low temperature; others, as platina, can scarcely be melted by the most intense heat which we can excite. Metals may be volatilized; at the degree of 600 quicksilver may be volatilized, and zinc and arsenic at a temperature not very remote from this. Metals are the best conductors of electricity.

Table of the Properties of the Metals.

Name.	When discovered.	By whom.	Color.	Specific gravity.	Fusing point, Fahr.	Scale of ductility.	Scale of malleability.	Tenacity.	Ratio of hardness.
Gold	Known from the earliest ages.	....	Pure yellow.	19·257	5237	1	1	68·216	8

*Antimony** is of a silvery white color, brittle and crystalline in its ordinary texture. It fuses at about 800°, or at a dull-red heat, and is volatile at a white heat. Its specific gravity is 6·712. (*Hatchett, Phil. Trans.* 1803. *Brande*, 849.)

Antimony expands on cooling; it is scarcely used alone, except in combination with similar bars of other metals for producing thermo-electricity: but antimony, which in the metallic state is frequently called "regulus," is generally combined with a large portion of lead, and sometimes with tin, and other metals. See *Lead* and *Tin*.

"Antimony and tin, mixed in equal proportions, form a moderately hard, brittle, and very brilliant alloy, capable of receiving an exquisite polish, and not easily tarnished by exposure to the air; it has been occasionally manufactured into speculums for telescopes. Its sp. gr., according to *Gellert*, is less than the mean of its constituent parts."—*Aikin's Dictionary.*

Bismuth is a brittle white metal, with a slight tint of red; its specific gravity is 9·822. (*Hatchett, Phil. Trans.* 1803.) It fuses at 476°, (*Crichton,*) 507°, (*Rudberg,*) and always crystallizes on cooling. According to Chaudet, pure bismuth is somewhat flexible. A cast bar of the metal (see *Rennie*) one-tenth of an inch in diameter, supports, according to Muschenbroek, a weight of 48 pounds. Bismuth is volatile at a high heat, and may be distilled in close vessels. It transmits heat more slowly than most other metals, perhaps in consequence of its texture. (*Brande*, 861.)

* The alloys are in general arranged under those metals which constitute respectively their largest proportional parts, but in some few instances under those from which they derive their peculiar characters.

Bismuth is scarcely used alone, but it is employed for imparting fusibility to alloys, thus:

8 bismuth, 5 lead, 3 tin, constitute Newton's fusible alloy, which melts at 212° F.

2 bismuth, 1 lead, 1 tin, Rose's fusible alloy, which melts at 201° F.

5 bismuth, 3 lead, 2 tin, when combined melt at 199°.

8 bismuth, 5 lead, 4 tin, 1 type-metal, constitute the fusible alloy used on the Continent for producing the beautiful casts of the French medals, by the *clichée* process. The metals should be repeatedly melted and poured into drops until they are well mixed. Mr. Charles V. Walker substituted antimony for the type-metal, and strongly recommends this latter in preference to the first-named fusible alloy *Electrotype Manipulation*, Part II. p. 9–11, where the *clichée* process is described.

1 bismuth and 2 tin make the alloy Mr. Cowper found to be the most suitable for rose-engine and eccentric-turned patterns, to be printed from after the manner of letter-press. He recommends the thin plates to be cast upon a cold surface of metal or stone, upon which a piece of smooth paper is placed, and then a metal ring; the alloy should neither burr nor crumble; if proper, it turns soft and silky; when too crystalline, more tin should be added.

2 bismuth, 4 lead, 3 tin, }
1 bismuth, 1 lead, 2 tin, } constitute pewterer's soft solders.

All these alloys must be cooled quickly to avoid the separation of the bismuth; they are rendered more fusible by a small addition of mercury.

Copper, with the exception of titanium, is the only metal which has a red color; it has much lustre, is very malleable and ductile, and exhales a peculiar smell when warmed or rubbed. It melts at a bright-red or dull-white heat; or, according to Daniell, at a temperature intermediate between the fusing points of silver and gold = 1996° Fahr. Its specific gravity varies from 8·86 to 8·89; the former being the least density of cast copper, the latter the greatest of rolled or hammered copper. (*Brande*, 812.)

Copper is used alone for many important purposes, and very extensively for the following: namely, sheathing and bolts for ships, brewing, distilling, and culinary vessels. Some of the fire-boxes for locomotive engines, boilers for marine engines, rollers for calico-printing and paper-making, plates for the use of engravers, &c.

Copper is used in alloying gold and silver, for coin, plate, &c., and it enters with zinc and nickel into the composition of German silver. Copper alloyed with one-tenth of its weight of arsenicis so similar in appearance to silver, as to have been substituted for it.

The alloys of copper, which are very numerous and important, are principally included under the general name *Brass*. In the more common acceptation, brass means the yellow alloy of copper, with about half its weight of zinc; this is often called by engineers "yellow brass."

Copper alloyed with about one-ninth its weight of tin, is the metal of brass ordnance, which is very generally called gun-metal; similar alloys used for the *brasses* or bearings of machinery, are called by engineers *hard* brass, and also gun-metal; and such alloys, when employed for statues and medals, are called bronze. The further addition of tin leads to bell-metal, and speculum-metal, which are named after their respective uses; and when the proportion of copper is exceedingly small, the alloy constitutes one kind of pewter.

Copper, when alloyed with nearly half its weight of lead, forms an inferior alloy, resembling gun metal in color, but very much softer and cheaper, lead being only about one-fourth the value of tin, and used in much larger proportion. This inferior alloy is called pot-metal, and also cock-metal, because it is used for large vessels and measures, for the large taps or cocks for brewers, dyers, and distillers, and those of smaller kinds for household use.

Generally the copper is only alloyed with one of the metals, zinc, tin, or lead; occasionally with two, and sometimes with the three in various proportions. In many cases the new metals are carefully weighed according to the qualities desired in the alloy, but random mixtures more frequently occur, from the ordinary practice of filling the crucible in great part with various pieces of old metal, of unknown proportions, and adding a certain quantity of new metal to bring it up to the color and hardness required. This is not done solely from motives of economy, but also from an impression which appears to be very generally entertained, that such mixtures are more homogeneous than those composed entirely of new metals, fused together for the first time.

The remarks we have to offer on these copper alloys will be arranged in the tabular form, in four groups; and, to make them as practical as possible, they will be stated in the terms commonly used in the brass-foundry. Thus, when the founder is asked the usual proportions of yellow brass, he will say, 6 to 8 oz. of zinc, (to every pound of copper being implied.) In speaking of gun-metal, he would not say, it had one-ninth, or 11 per cent. of tin, but simply that it was $1\frac{1}{2}$, 2, or $2\frac{1}{4}$ oz., (of tin,) as the case might be; so that the quantity and kind of the alloy, or the *addition* to the pound of copper, is usually alone named.

Alloys of copper and zinc only.—The marginal numbers denote the ounces of zinc added to every pound of copper.

$\frac{1}{8}$ to $\frac{1}{2}$ oz. Castings are seldom made of pure copper, as under ordinary circumstances it does not cast soundly: about half an ounce of zinc is usually added, frequently in the shape of 4 oz. of brass to every pound of copper; and by others 4 oz. of brass are added to every two or three pounds of copper.

1 to $1\frac{1}{4}$ oz. Gilding-metal, for common jewelry: it is made by mixing 4 parts of copper with 1 of calamine brass; or sometimes 1 lb. of copper with 6 oz. of brass. The sheet gilding-metal will be found to match pretty well in color with the cast gun-metal, which latter does not admit of being rolled; they may be therefore used together when required.

3 oz. Red sheet-brass, made at Hegermühl, or $5\frac{1}{2}$ parts copper, 1 zinc. (*Ure.*)

3 to 4 oz. Bath metal, pinchbeck, Mannheim gold, similor, and alloys bearing various names, and resembling inferior jeweller's gold greatly alloyed with copper, are of about this proportion: some of them contain a little tin; now, however, they are scarcely used.
6 oz. Brass, that bears soldering well.
6 oz. Bristol brass is said to be of this proportion.
8 oz. Ordinary brass, the general proportion; less fit for soldering than 6 oz., it being more fusible.
8 oz. Emerson's patent brass was of this proportion, and so is generally the ingot brass, made by simple fusion of the two metals.
9 oz. This proportion is the one extreme of Muntz's patent sheathing. See 10⅔.
10⅔ oz. Muntz's metal, or 40 zinc and 60 copper. "Any proportions," says the patentee, "between the extremes 50 zinc and 50 copper, and 37 zinc 63 copper, will roll and work at the red-heat;" but the first-named proportion, or 40 zinc to 60 copper, is preferred.

The metal is cast into ingots, heated to a red-heat, and rolled and worked at that heat into ships' bolts and other fastenings and sheathing.
12 oz. Spelter-solder for copper and iron is sometimes made in this proportion; for brass work the metals are generally mixed in equal parts. See 16 oz.
12 oz. Pale-yellow metal, fit for dipping in acids, is often made in this proportion.
16 oz. Soft spelter-solder, suitable for ordinary brass-work, is made of equal parts of copper and zinc. About 14 lbs. of each are melted together and poured into an ingot-mould with cross-ribs, which indents it into little squares of about 2 lbs. weight; much of the zinc is lost. These lumps are afterwards heated nearly to redness upon a charcoal fire, and are broken up, one at a time, with great rapidity on an anvil, or in an iron pestle and mortar. The heat is a critical point; if too great, the solder is beaten into a cake or coarse lumps and becomes tarnished; when the heat is proper, it is nicely granulated, and remains of a bright-yellow color; it is afterwards passed through a sieve. Of course, the ultimate proportion is less than 16 oz. of zinc.
16 oz. Equal parts is the one extreme of Muntz's patent sheathing. See 10⅔.
16½ oz. Hamilton and Parker's patent mosaic gold, which is dark-colored when first cast, but on dipping assumes a beautiful golden tint. When cooled and broken, say the patentees, "all yellowness must cease, and the tinge vary from reddish-fawn or salmon color to a light purple or lilac, and from that to whiteness." The proportions are stated as from 52 to 58 zinc to 50 of copper, or 16½ to 17 oz. to the pound.
32 oz., or 2 zinc to 1 copper, a bluish-white brittle alloy, very brilliant, and so crystalline that it may be pounded cold in a pestle and mortar.
128 oz., or 2 oz. of copper to every pound of zinc; a hard crystalline metal, differing but little from zinc, but more tenacious; it has been used for laps or polishing disks.

Remarks on the alloys of copper and zinc.—These metals seem to mix in all proportions.

The addition of zinc continually increases the fusibility, but from the extremely volatile nature of zinc, these alloys cannot be arrived at with very strict regard to proportion.

The red color of copper slides into that of yellow brass at about 4 or 5 oz. to the pound, and remains little altered unto about 8 or 10 oz.; after this it becomes whiter, and when 32 oz. of zinc are added to 16 of copper, the mixture has the brilliant silvery color of speculum metal, but with a bluish tint.

These alloys, from about 8 to 16 oz. to the pound of copper, are extensively used for dipping, as in an enormous variety of furniture work; in all cases the metal is annealed before the application of the scouring or cleaning processes, and of the acids, bronzes, and lackers subsequently used.

The alloys with zinc retain their malleability and ductility well, unto about 8 or 10 oz. to the pound; after this the crystalline character slowly begins to prevail. The alloy of 2 zinc and 1 copper, before named, may be crumbled in a mortar when cold.

The ordinary range of good yellow brass, that files and turns well, is from about 4½ to 9 oz. to the pound. With additional zinc, it is harder and more crystalline; with less, more tenacious, and it hangs to the file like copper; the range is wide, and small differences are not perceived.

Alloys of copper and tin only.—The marginal numbers denote the ounces of *tin* added to every pound of copper.

Ancient Copper and Tin Alloys.

¾ oz. Ancient bronze nails flexible, or 20 copper, 1 tin. (*Ure.*)
1¾ oz. Soft bronze, or 9 to 1. — According to Pliny, as quoted by Wilkinson.
2 oz. Medium bronze, or 8 to 1.
2¼ oz. Hard bronze, or 7 to 1. — Ancient weapons and tools, by various analyses, or 8 to 15 per cent. tin; medals from 8 to 12 per cent. tin, with 2 parts zinc added to each 100, for improving the bronze color. (*Ure.*)
6 to 8 oz. Ancient mirrors.

Modern Copper and Tin Alloys.

1 oz. Soft gun-metal, that bears drifting, or stretching from a perforation.
1⅓ oz. A little harder alloy, fit for mathematical instruments; or 12 copper and one very pure grain tin.
1½ oz. Still harder, fit for wheels to be cut with teeth.
1½ to 2 oz. Brass ordnance, or 8 to 12 per cent. tin; but the general proportion is one-ninth part of tin.
2 oz. Hard bearings for machinery.
2½ oz. Very hard bearings for machinery. By Muschenbroek's tables it appears that the proportion 1 tin and 6 copper is the most tenacious alloy; it is too brittle for general use, and contains 2⅔ oz. to the pound of copper.

For some other alloys used in machinery, see alloys of copper, zinc, tin, and lead, p. 354
3 oz. Soft musical bells.
3½ oz. Chinese gongs and cymbals, or 20 per cent. tin.
4 oz. House bells.

4½ oz. Large bells.
5 oz. Largest bells.
7½ to 8½ oz. Speculum metal. Sometimes one ounce of brass is added to every pound as the means of introducing a trifling quantity of zinc; at other times small proportions of silver are added; the employment of arsenic was strongly advocated by the Rev. John Edwards. Lord Oxmantown, now the Earl of Rosse, says, "tin and copper, the materials employed by Newton in the first reflecting telescope, are preferable to any other with which I am acquainted; the best proportions being 4 atoms of copper to 1 of tin, (Turner's numbers;) in fact, 126·4 parts of copper to 58·9 of tin."—*Trans. Royal Soc.* 1840, p. 504.

The object agreed upon by all experimentalists appears to be the exact saturation of the copper with the tin, and the proportionate quantities *differ very materially* (*in this and all other alloys*) *according to the respective degrees of purity* of the metals: for the most perfect alloys of this group, Swedish copper and grain tin should be used.

Mr. Ross says: "When the alloy is perfect, it should be white, glassy, and flaky. When the copper is in excess, it imparts a red tint easily detected; when the tin is in excess, the fracture is granulated, and also less white." His practice is to pour the melted tin into the fluid copper when it is at the lowest temperature that a mixture by stirring can be effected; then to pour the mixture into an ingot, and to complete the combination by remelting in the most gradual manner, by putting the metal into the furnace as soon almost as the fire is lighted. Trial is made of a little piece taken from the pot immediately prior to pouring.

32 oz. of tin to 1 lb. of copper make the alloy called by the pewterers "temper," which is added in small quantities to tin for some kinds of pewter, called "tin and temper," in which the copper is frequently much less than 1 per cent.

Remarks on the alloys of copper and tin only.—These metals seem to mix in all proportions.

The addition of tin continually increases the fusibility, although when it is added cold it is apt to make the copper pasty, or even to set it in a solid lump in the crucible.

The red color of the copper is not greatly impaired in those proportions used by the engineer, namely up to about 2½ oz. to the pound; it becomes grayish white at 6, the limit suitable for bells, and quite white at about 8, the speculum metal; after this, the alloy becomes of a bluish cast.

The tin alloy is scarcely malleable at 2 oz., and soon becomes very hard, brittle, and sonorous; and when it has ceased to serve for producing sound, it is employed for reflecting light.

The tough, tenacious character of copper under the tools rapidly gives way; alloys of 1½ cut easily 2½ assume about the maximum hardness without being crystalline; after this they yield to the file by crumbling in fragments rather than by ordinary abrasion in shreds, until the tin very greatly predominates, as in the pewters: when the alloys become the more flexible, soft, malleable, and ductile, the less copper they contain.

Alloys of copper and lead only.—The marginal numbers denote the ounces of lead added to every pound of copper.

2 oz. A red-colored and ductile alloy.
4 oz. Less red and ductile; neither of these is so much used as the following, as the object is to employ as much lead as possible.
6 oz. Ordinary pot-metal, called dry pot-metal, as this quantity of lead will be taken up without separating on cooling; this is brittle when warmed.
7 oz. This alloy is rather short, or disposed to break.
8 oz. Inferior pot-metal, called wet pot-metal, as the lead partly oozes out in cooling, especially when the new metals are mixed; it is therefore always usual to fill the crucible in part with old metal, and to add new for the remainder. This alloy is very brittle when slightly warmed. More lead can scarcely be used, as it separates on cooling.

Remarks on the alloys of copper and lead only.—These metals mix in all proportions until the lead amounts to nearly half; after this they separate in cooling.

The addition of lead greatly increases the fusibility.

The red color of the copper is soon deadened by the lead; at about 4 oz. to the pound the work has a bluish leaden hue when first turned, but changes in an hour or so to that of a dull gun-metal character.

When the lead does not exceed about 4 oz. the mixture is tolerably malleable, but with more lead it soon becomes very brittle and rotten; the alloy is greatly inferior to gun-metal, and is principally used on account of the cheapness of the mixture, and the facility with which it is turned and filed.

Alloys of copper, zinc, tin, and lead, &c.—This group refers principally to gun-metal alloys, to which more or less zinc is added by many engineers; the quantity of tin in every pound of the alloy, which is expressed by the marginal numbers, principally determines the hardness.

Keller's statues at Versailles are found as the mean of four analyses, to consist of

Copper	91·40,	or about	14⅝	ounces.
Zinc	5·53	"	1	"
Tin	1·70	"	⅜	"
Lead	1·37	"	¼	"
	In 100 parts or the 16 ounces.			

1¼ to 2¼ oz. tin to 1 lb. copper used for bronze medals, or 8 to 15 per cent. tin, with the addition of 2 parts in each 100 of zinc, to improve the color.

The modern so-called bronze medals of our mint are of pure copper, and are afterwards bronzed superficially.

1½ oz. tin + zinc to 16 oz. copper. Pumps and works requiring great tenacity.

$1\frac{1}{2}$	oz. tin	2	oz. brass	16	"	For wheels to be cut into teeth.
$1\frac{3}{4}$	"	2	"	16	"	For wheels to be cut into teeth.
2	"	$1\frac{1}{2}$	"	16	"	For turning-work.
$2\frac{1}{4}$	"	$1\frac{1}{2}$	"	16	"	For nuts of coarse threads, and bearings.

The engineer who uses these five alloys recommends melting the copper alone: the small quantity of brass is then melted in another crucible, and the tin in a ladle; the two latter are added to the copper when it has been removed from the furnace; the whole are stirred together and poured into the moulds without being run into ingots. The real quantity of tin to every pound of copper is about one-eighth ounce less than the numbers stated, owing to the addition of the brass, which increases the proportion of copper.

$1\frac{7}{8}$ oz. tin, $1\frac{7}{8}$ oz. zinc, to 1 lb. of copper. This alloy, which is a tough, yellow, brassy gun-metal, is used for general purposes by a celebrated engineer; it is made by mixing $1\frac{1}{2}$ lb. tin, $1\frac{1}{2}$ lb. zinc, and 10 lbs. of copper: the alloy is first run into ingots.

$2\frac{1}{2}$ oz. tin, $\frac{1}{2}$ oz. zinc, to 1 lb. of copper, used for bearings to sustain great weights.

$2\frac{1}{2}$ oz. tin, $2\frac{1}{2}$ oz. zinc, to 1 lb. copper, were mixed by the late Sir F. Chantry, and a razor was made from the alloy; it proved nearly as hard as tempered steel, and exceedingly destructive to new files, and none others would touch it.

1 oz. tin, 2 oz. zinc, 16 oz. brass. Best hard white metal for buttons.

$\frac{1}{2}$ oz. tin, $1\frac{1}{2}$ oz. zinc, 16 oz. brass. Common ditto. (*Phillips's Dictionary.*)

10 lbs. tin, 6 lbs. copper, 4 lbs. brass, constitute white solder. The copper and brass are first melted together, the tin is added, and the whole stirred and poured through birch twigs into water to granulate it; it is afterwards dried and pulverized cold in an iron pestle and mortar. This white solder was introduced as a substitute for silver solder in making gilt buttons. Another button solder consists of 10 parts copper, 8 of brass, and 12 of spelter or zinc.

Remarks on alloys of copper, zinc, tin, lead, &c.—Ordinary yellow brass, (copper and zinc,) is rendered very sensibly harder, so as not to require to be hammered, by a small addition of tin, say $\frac{1}{4}$ or $\frac{1}{2}$ oz. to the lb. On the other hand, by the addition of $\frac{1}{4}$ to $\frac{1}{2}$ oz. of lead, it becomes more malleable and casts more sharply. Brass becomes a little whiter for the tin, and redder for the lead. The addition of nickel to copper and zinc constitutes the so-called German silver.

Gun-metal (copper and tin) very commonly receives a small addition of zinc; this makes the alloy mix better, and to lean to the character of brass by increasing the malleability without materially reducing the hardness. The standard measures for the Exchequer were made of a tough alloy of this kind. The zinc, which is sometimes added in the form of brass, also improves the color of the alloy, both in the recent and bronzed states. Lead, in small quantity, improves the ductility of gun-metal, but at the expense of its hardness and color; it is seldom added. Nickel has been proposed as an addition to gun-metal by Mr. Donkin, and antimony by Dr. Ure.

Pot-metal (copper and lead) is improved by the addition of tin, and the three metals will mix in almost any proportions: when the tin predominates, the alloy so much the more nearly approaches the condition of gun-metal. Zinc may be added to pot-metal in very small quantity, but when the zinc becomes a considerable amount, the copper takes up the zinc, forming a kind of brass, and leaves the lead at liberty, and which, in great measure, separates in cooling. Zinc and lead are also very indisposed to mix alone, although a little arsenic assists their union by "killing" the lead as in shot-metal. Antimony also facilitates the combination of pot-metal; 7 lead, 1 antimony, and 16 copper mixed perfectly well the first fusion, and the alloy was decidedly harder than 4 lead and 16 copper; and apparently a better metal. "Lead and antimony, though in small quantity, have a remarkable effect in diminishing the elasticity and sonorousness of the copper alloys."

Gold is of a deep and peculiar yellow color. It melts at a bright-red heat, equivalent, according to Daniell, to 2016° of Fahrenheit's scale, and when in fusion appears of a brilliant greenish color. Its specific gravity is 19·3. It is so malleable that it may be extended into leaves which do not exceed the one two hundred and eighty-two thousandth of an inch in thickness, or a single grain may be extended over 56 square inches of surface. This extensibility of the metal is well illustrated by gilt buttons, 144 of which are gilt by 5 grains of gold, and less than even half that quantity is adequate by giving them a very thin coating. It is also so ductile that a grain may be drawn out into 500 feet of wire. The pure acids have no action upon gold. (*Brande*, 972.)

Gold, in the pure or fine state, is not employed in bulk for many purposes in the arts, as it is then too soft to be durable. The gold foil used by dentists for stopping decayed teeth is perhaps as nearly pure as the metal can be obtained: it contains about six grains of alloy in the pound troy, or the one-thousandth part. Every superficial inch of this gold foil or leaf weighs $\frac{3}{4}$ of a grain, and is 42 times as thick as the leaf used for gilding.

The wire for gold lace prepared by the refiners for gold-lace manufacturers, requires equally fine gold, as when alloyed it does not so well retain its brilliancy. The gold, in the proportion of about 100 grains to the pound troy of silver, or of 140 grains for double-gilt wire, is beaten into sheets as thin as paper; it is then burnished upon a stout red-hot silver bar, the surface of which has been scraped perfectly clean. When extended by drawing, the gold still bearing the same relation as to quantity, namely, the 57th part of the weight, becomes of only one-third the thickness of ordinary gold-leaf used for gilding. In water-gilding, fine gold is amalgamated with mercury, and washed over the gilding metal, (copper and tin;) the mercury attaches itself to the metal, and when evaporated by heat, it leaves the gold behind in the dead or frosted state: it is brightened with the burnisher. (See *Technological Repository*, vol. ii., p. 361: 1828.) By the electrotype process, a still thinner covering of pure gold may be deposited on silver, steel, and other metals. Mr. Dent has introduced this method of protecting the steel pendulum-springs of marine chronometers and other time-pieces from rust.

Fine gold is also used for soldering chemical vessels made of platinum.

Gold alloys.—Gold-leaf, for gilding, contains from 3 to 12 grains of alloy to the oz., but generally 6

grains. The gold used by respectable dentists, for plates, is nearly pure, but necessarily contains about 6 grains of copper in the oz. troy, or one-eightieth part; others use gold containing upwards of one-third of alloy: the copper is then very injurious.

With *copper*, gold forms a ductile alloy of a deeper color, harder and more fusible than pure gold: this alloy, in the proportion of 11 of gold to 1 of copper, constitutes *standard gold;* its density is 17·157, being a little below the mean, so that the metals slightly expand on combining. One troy pound of this alloy is coined into $46\frac{29}{40}$ sovereigns, or 20 troy pounds into 934 sovereigns and a half. The pound was formerly coined into 44 guineas and a half. The standard gold of France consists of 9 parts of gold and 1 of copper. (*Brande*, 979.)

For *Gold Plate* the French have three different standards: 92 parts gold, 8 copper; also 84 gold, 16 copper; and 75 gold, 25 copper.

In England, the purity of gold is expressed by the terms 22, 18, 16 carats, &c. The pound troy is supposed to be divided into 24 parts, and the gold, if it could be obtained perfectly pure, might be called 24 carats fine.

The "Old Standard Gold," or that of the present currency, is called fine, there being 22 parts of pure gold to 2 of copper.

The "New Standard," for watch-cases, &c., is 18 carats of fine gold, and 6 of alloy. No gold of inferior quality to 18 carats, or the "New Standard," can receive the Hall mark; and gold of lower quality is generally described by its commercial value, as 60 or 40 shilling gold, &c.

The alloy may be entirely silver, which will give a green color, or entirely copper for a red color; but the copper and silver are more usually mixed in the one alloy according to the taste and judgment of the jeweller.

The following alloys of gold are transcribed from the memoranda of the proportions employed by a practical jeweller of considerable experience.*

First group.—Different kinds of gold that are finished by polishing, burnishing, &c., without necessarily requiring to be colored:

The gold of 22 carats fine, or the "Old Standard," is so little used, on account of its expense and greater softness, that it has been purposely omitted.

18 carats, or New Standard gold, of yellow tint:*

15 dwt.	0 grs. gold.
2 dwt.	18 grs. silver.
2 dwt.	6 grs. copper.
20 dwt.	0 grs.

18 carats, or New Standard gold, of red tint:*

15 dwt.	0 grs. gold.
1 dwt.	18 grs. silver.
3 dwt.	6 grs. copper.
20 dwt.	0 grs.

16 carats, or Spring gold: this, when drawn or rolled very hard, makes springs little inferior to those of steel:

1 oz.	16 dwt. gold.	or 1·12
	6 dwt. silver.	— ·4
	12 dwt. copper.	— ·12
2 oz.	14 dwt.	2 ·8

60*s.* gold of yellow tint, or the fine gold of the jewellers; 16 carats nearly:

1 oz.	0 dwt. gold.
	7 dwt. silver.
	5 dwt. copper.
1 oz.	12 dwt.

60*s.* gold of red tint, or 16 carats:

1 oz.	0 dwt. gold.
	2 dwt. silver.
	8 dwt. copper.
1 oz.	10 dwt.

40*s.* gold, or the old-fashioned jewellers' gold, about 11 carats fine; no longer used:

1 oz.	0 dwt. gold.
	12 dwt. silver.
	12 dwt. copper.
2 oz.	4 dwt.

Second group.—Colored golds; these all require to be submitted to the process of wet-coloring, which will be explained: they are used in much smaller quantities, and require to be very exactly proportioned.

Full red gold:

5 dwt. gold.
5 dwt. copper.
10 dwt.

Red gold:

10 dwt. gold.
1 dwt. silver.
4 dwt. copper.
15 dwt.

Green gold:

5 dwt.	0 grs. gold.
	21 grs. silver.
5 dwt.	21 grs.

Gray gold: (Platinum is also called gray gold by jewellers:)

3 dwt.	15 grs. gold.
1 dwt.	9 grs. silver.
5 dwt.	0 grs.

* When it is not otherwise expressed, it will be understood all these alloys are made with fine gold, fine silver, and fine copper, obtained direct from the refiners. And to insure the standard gold passing the test of the Hall, 3 or 4 grains additional of gold are usually added to every ounce.

Blue gold; scarcely used:
5 dwt. gold.
5 dwt. steel filings.
—
10 dwt.
—

Antique gold, of a fine greenish yellow color:

18 dwt. 9 grs. gold,	or	18· 9
21 grs. silver,	—	1· 3
18 grs. copper,	—	·12
20 dwt. 0 grs.		20· 0

Third group.—Gold solders: these are generally made from gold of the same quality and value as they are intended for, with a small addition of silver and copper, thus:

Solder for 22 carat gold:
1 dwt. 0 grs. of 22 carat gold.
2 grs. silver.
1 gr. copper.

1 dwt. 3 grs.

Solder for 18 carat gold:
1 dwt. 0 grs. of 18 carat gold.
2 grs. silver.
1 gr. copper.

1 dwt. 3 grs.

Solder for 60*s.* gold:*
1 dwt. 0 grs. of 60*s.* gold.
10 grs. silver.
8 grs. copper.

1 dwt. 18 grs.

Solder for 40*s.* gold; but middling silver solder is more generally used:
1 dwt. fine gold.
1 dwt. silver.
2 dwt. copper.
—
4 dwt.

Dr. Hermstadt's imitation of gold, which is stated not only to resemble gold in color, but also in specific gravity and ductility, consists of 16 parts of platinum, 7 parts of copper, and 1 of zinc, put in a crucible, covered with charcoal powder, and melted into a mass.

Gold alloyed with platinum is also rather elastic, but the platinum whitens the alloy more rapidly than silver.

Lead appears to have been known in the earliest ages of the world. Its color is bluish white; it has much brilliancy, is remarkably flexible and soft, and leaves a black streak on paper: when handled it exhales a peculiar odor. It melts at about 612°, and by the united action of heat and air, is readily converted into an oxide. Its specific gravity, when pure, is 11·445; but the lead of commerce seldom exceeds 11·35. (*Brande*, 833.)

Lead is used in a state of comparative purity for roofs, cisterns, pipes, vessels for sulphuric acid, &c. Ships were sheathed with lead and with wood from before the Christian era to 1450, after which wood was more commonly employed, and in 1790 to 1800 copper sheathing became general; of late years, lead with a little antimony has likewise been used, also Muntz's sheathing, an alloy of copper and zinc and galvanized sheet-iron. The most important alloys are those employed for printers' type, namely, about

3 lead, 1 antimony, for the smallest, hardest, and most brittle types.
4 lead, 1 antimony, for small, hard, brittle types.
5 lead, 1 antimony, for types of medium size.
6 lead, 1 antimony, for large types.
7 lead, 1 antimony, for the largest and softest types.

The small types generally contain from 4 to 6 per cent. of tin, and sometimes also 1 to 2 per cent. of copper; but as old metal is always used with the new, the proportions are not exactly known.

Stereotype plates contain about 4 to 8 parts of lead to one of antimony.

Baron Wetterstedt's patent sheathing for ships consists of lead with from 2 to 8 per cent. of antimony; about 3 per cent. is the usual quantity. The alloy is rolled into sheets.

Similar alloys, and those of lead and tin in various preparations, are much used for emery-wheels and grinding-tools of various forms by the lapidary, engineer, and others. The latter also employs these readily fused alloys for temporary bearings, guides, screw-nuts, &c.

Organ-pipes consist of lead alloyed with about half its quantity of tin to harden it. The mottled or crystalline appearance so much admired shows an abundance of tin.

Shot-metal is said to consist of 40 lbs. of arsenic to one ton of lead.

In casting sheet-lead, the metal was poured from a swing-trough upon a long and nearly horizontal table, covered with a thin layer of coarse damp sand, previously levelled with a metal rule or strike. The thickness of the fluid metal was determined by running the strike along the table before the lead cooled, the excess being thus swept into a spill-trough at the lower end of the table; but the sheet-lead now more commonly used is cast in a thick slab, and reduced between laminating rollers; it is known as "milled lead."

The metal for organ-pipes is prepared by allowing the metal to escape through a slit in the trough, as it is slid along a horizontal table, so as to leave a trail of metal behind it; the thickness of the metal is regulated by the width of the slit through which it runs, and the rapidity of the traverse; a piece of cloth or ticken is stretched upon the casting-table. The metal is planed to thickness, bent up, and soldered into the pipes.

Lead pipes are cast as hollow cylinders and drawn out upon triblets; they are also cast of indefinite

* By others, 4 grains of brass are added to the solder; it then fuses beautifully and is of good color. Zinc is sometimes added to other gold solders to increase their fusibility; the zinc (or brass, when used) should be added at the last moment, to lessen the volatilization of the zinc.

length without drawing. A patent was taken out for casting a sheath of tin within the lead, but it has been abandoned.

Lead shot are cast by letting the metal run through a narrow slit, into a species of colander at the top of a lofty tower; the metal escapes in drops, which, for the most part, assume the spherical form before they reach the tank of water into which they fall at the foot of the tower, and this prevents their being bruised. The more lofty the tower, the larger the shot that can be produced; the good and bad shot are separated by throwing small quantities at a time upon a smooth board nearly horizontal, which is slightly wriggled; the true or round shot run to the bottom, the imperfect ones stop by the way, and are thrown aside to be remelted; the shot are afterwards riddled or sifted for size, and churned in a barrel with black-lead.

Mr. Joseph Manton took out a patent for amalgamating the surface of leaden shot with mercury. One pound of mercury was added to every cwt. of shot; they were churned together in a revolving barrel nearly full of water, until the shot assumed a silvery coat. These shot were stated to foul the barrel of the gun in a less degree than others, and also to be less injurious to the game after it had been killed.

Mercury is a brilliant white metal, having much of the color of silver, whence the terms *hydrargyrum argentum vivum*, and *quicksilver.* It has been known from very remote ages. It is liquid at all common temperatures; solid and malleable at —40° F., and contracts considerably at the moment of congelation. It boils and becomes vapor at about 670°. Its specific gravity at 60° is 13·5. In the solid state its density exceeds 14. The specific gravity of mercurial vapor is 6·976. (DUMAS, *Ann. de Ch. et Ph.* xxxiii., *Brande*, 928.)

Mercury is used in the fluid state for a variety of philosophical instruments, and for pressure gages for steam-engines, &c. It is sometimes, though rarely, employed for rendering alloys more fusible; it is used with tin-foil for silvering looking-glasses, and it has been employed as a substitute for water in hardening steel. Mercury forms amalgams with bismuth, copper, gold, lead, palladium, silver, tin, and zinc.

Mercury is commonly used for the extraction of gold and silver from their ores by amalgamation, and also in water-gilding. See *Gold.*

Nickel is a white, brilliant metal, which acts upon the magnetic needle, and is itself capable of becoming a magnet. Its magnetism is more feeble than that of iron, and vanishes at a heat somewhat below redness, 630°, (Faraday.) It is ductile and malleable. Its specific gravity varies from 8·27 to 8·40 when fused, and after hammering from 8·69 to 9. It is not oxidized by exposure to air at common temperatures, but when heated in the air it acquires various tints, like steel; at a red heat it becomes coated by a gray oxide. (*Brande*, 802.)

Nickel is scarcely used in the simple state; Mr. Brande mentions, however, that he has seen a Bavarian coin that had been struck in it; but it is principally used together with copper and zinc, in alloys that are rendered the harder and whiter the more nickel they contain; they are known under the names of albata, British plate, electrum, German silver, pakfong, teutanag, &c.: the proportions differ much, according to price; thus the

Commonest	are 3 to 4 parts nickel, 20 copper, and 16 zinc.
Best	are 5 to 6 parts nickel, 20 copper, and 8 to 10 zinc.

About two-thirds of this metal is used for articles resembling plated goods, and some of which are also plated, (see *silver;*) the remainder is employed for harness, furniture, drawing and mathematical instruments, spectacles, the tongues for accordions, and numerous other small works.

The *white copper* of the Chinese, which is the same as the German silver of the present day, is composed, according to the analysis of Dr. Fyfe, of

31·6	parts of nickel,	40·4	of copper,	25·4	of zinc, and	2·6	of iron.	
17·48	"	"	53·39	"	13·0	"		*Frick's Imitative Silver.*

The white copper manufactured at Sutil, in the duchy of Saxe Hildburghausen, is said by Keferstein to consist of copper 88·000, nickel 8.753, sulphur, with a little antimony, 0·750, silex, clay, and iron, 1·75. The iron is considered to be accidentally introduced into these several alloys, along with the nickel, and a minute quantity is not prejudicial.

Iron and steel have been alloyed with nickel; the former, (the same as the meteoric iron which always contains nickel,) is little disposed to rust, whereas the alloy of steel with nickel is worse in that respect than steel not alloyed.

Palladium is of a dull-white color, malleable and ductile. Its specific gravity is about 11·3, or 11·86 when laminated. It fuses at a temperature above that required for the fusion of gold. (*Brande*, 998.)

"Palladium is a soft metal, but its alloys are all harder than the pure metal. With silver it forms a very tough malleable alloy, fit for the graduations of mathematical instruments, and for dental surgery, for which it is much used by the French; with silver and copper, palladium makes a very springy alloy, used for the points of pencil-cases, inoculating lancets, tooth-picks, or any purpose where elasticity and the property of not tarnishing are required; thus alloyed it takes a high polish. Pure palladium is not fusible at ordinary temperatures, but at a high temperature it agglutinates so as to be afterwards malleable and ductile."—*W. Cock.*

This useful metal was discovered by Dr. Wollaston, in 1803, and it has recently been found in some abundance in the gold ores of the Minas Geraës district; the process now employed for its separation was discovered by Mr. P. N. Johnson. Palladium is calculated thoroughly to fulfil many of the purposes to which platinum and gold are applied in the useful arts, and from its low specific gravity, it may be obtained at about half the price of an equal *bulk* of platinum, and at one-eighth that of gold; and it equally resists the action of mineral acids and sulphuretted hydrogen.—*London Journal of Science for* 1840.

Palladium was used in the construction of the balances for the United States' Mint.

Platinum is a white metal, extremely difficult of fusion, and unaltered by the joint action of heat

and air. It varies in density from 21 to 21·5, according to the degree of mechanical compression which it has sustained; it is extremely ductile, but cannot be beaten into such thin leaves as gold and silver (*Brande*, 4th Ed. p. 822.)

The particles of the generality of metals, when separated from the foreign matters with which they are combined, are joined into solid masses by simple fusion; but platinum being nearly infusible when pure, requires a very different treatment, which was introduced by Dr. Wollaston, and is now conducted in the following manner by Messrs. Johnson and Cock, of London, the celebrated metallurgists.

The platinum is first dissolved chemically, and it is then thrown down in the state of a precipitate; next it is partly agglutinated in the crucible into a spongy mass, and is then compressed whilst cold in a rectangular mould by means of a powerful fly-press or other means, which, in operating upon 500 ounces, converts the platinum into a dense block about 5 inches by 4, and 2½ inches thick. This block is heated in a smith's forge, with two tuyeres meeting at an angle, at which spot the platinum is placed amidst the charcoal fire; when it has reached the welding point, or almost a blue heat, it receives one blow under a heavy *drop*, or a vertical hammer, somewhat like a pile-driving engine; it then requires to be reheated, and it thus receives a fresh blow about every 20 minutes, and in a week or ten days it is sufficiently welded or consolidated on all sides to admit of being forged into bars, and converted into sheets, rods, or wires by the ordinary means.

The motive for operating upon so great a quantity is for making the large pans for concentrating sulphuric acid, in only two or three pieces, which are soldered together with fine gold. In France, 2,000 ounces are sometimes welded into one mass, so that the vessels may be absolutely entire, a practice which is considered in this country to be unnecessarily costly. For small quantities the treatment is the same, but in place of the drop, the ordinary flatter and sledge-hammer are used.

Platinum is exceedingly tough and tenacious, and "hangs to the file worse than copper," on which account, when it is used for the graduated limbs of mathematical instruments, the divisions should be cut with a diamond point, and which is the best instrument for fine graduations of all kinds, and for ruling grounds, or the lined surfaces for etching.

Platinum is employed in Russia for coin. This valuable metal is used in various chemical and philosophical apparatus, in which resistance to fusion or to the acids is essential.

The alloys of platinum are scarcely used in the arts: that with a small quantity of copper is employed in Paris for dental surgery. For alloys of platinum and steel, see *Quarterly Journal of the Royal Inst.*, vol ix., p. 328. The alloy of equal parts of steel and platinum is therein highly spoken of as a mirror.

"Dr. Von Eckart's alloy contains platinum 2·40, silver 3·53, and copper 11·71. It is highly elastic, of the same specific gravity as silver, and not subject to tarnish; it can be drawn to the finest wire from ⅛th of an inch diameter, without annealing, and does not lose its elasticity by annealing. It is highly sonorous, and bears hammering red-hot, rolling and polishing."

Mr. Ross added to silver one-fourth of its weight of platinum, and he considers that it took up one-tenth its weight. The alloy became much harder than silver, capable of resisting the tarnishing influences of sulphur and hydrogen, and was fit for graduations.

An alloy of platinum with ten parts of arsenic is fusible at a heat a little above redness, and may therefore be cast in moulds. On exposing the alloy to a gradually increasing temperature in open vessels, the arsenic is oxidized and expelled, and the platinum recovers its purity and infusibility.—*Turner's Chemistry.*

Tin also so greatly increases the fusibility of platinum, that it is hazardous to solder the latter metal with tin solder, although gold is so used.

Platinum, as well as gold, silver, and copper, are deposited by the electrotype process: and silver plates thus platinized are employed in Smee's Galvanic Battery.

Rhodium is a white metal, very difficult of fusion; its specific gravity is about 11: it is extremely hard. When pure, the acids do not dissolve it. (*Brande*, 1001.)

Rhodium was discovered in 1803, by Dr. Wollaston, and has been long employed for the nibs of pens, which have been also made of ruby, mounted on shafts of spring gold; these kinds have had to endure for the last 7 or 8 years the rivalry of "Hawkins' everlasting Pen," of which latter, the author from many months' constant use can speak most favorably. "The everlasting pen," says the inventor, "is made of gold, tipped with a natural alloy, which is as much harder than rhodium as steel is harder than lead; will endure longer than the ruby, yields ink as freely as the quill, is as easily wiped, and if left unwiped is *not corroded*." See also *Mec. Mag.*, 1840, p. 554. Mr. Hawkins employs the natural alloy of iridium and osmium, two scarce metals, discovered by Tennant amongst the grains of platinum; the alloy is not malleable, and is so hard as to require to be worked with diamond powder. The metals rhodium, iridium, and osmium, are not otherwise employed in the arts than for pens, although steel has been alloyed with rhodium. See also the *Quarterly Journal, Royal Inst.*, vol. ix.

Silver is of a more pure white than any other metal; it has considerable brilliancy, and takes a high polish. Its specific gravity varies between 10·4, which is the density of cast silver, and 10·5 to 10·6, which is the density of rolled or stamped silver. It is so malleable and ductile, that it may be extended into leaves not exceeding a ten-thousandth of an inch in thickness, and drawn into wire much finer than a human hair. Silver melts at a bright-red heat, estimated by Mr. Daniell at 1873° of Fahrenheit's scale, and when in fusion appears extremely brilliant. (*Brande*, 953.)

Silver is but little used in the pure unalloyed state, on account of its extreme softness, but it is generally alloyed with copper in about the same proportion as in our coin, and none of inferior value can receive the "Hall mark." Diamonds are set in fine silver, and in silver containing 3 to 12 grs. of copper in the ounce; the work is soldered with pure tin.

The sheet metal for plated works is prepared by fitting together very truly, a short stout bar of copper and a thinner plate of silver; when scraped perfectly clean, they are tied strongly together with

binding wire, and united by partial fusion without the aid of solder. The plated metal is then rolled out, and the silver always remains perfectly united, and of the same proportional thickness as at first. Additional silver may be burnished on hot, when the surfaces are scraped clean, as explained under gold; this is done either to repair a defect, or to make any part thicker for engraving upon, and the uniformity of surface is restored with the hammer. In addition to its use for articles of luxury, the important service of copper plated with silver for the parabolic reflectors of lighthouses must not be overlooked; these are worked to the curve with great perfection by the hammer alone.

Plated spoons, forks, harness, and many other articles, are made of iron, copper, brass, and German silver, either cast or stamped into shape; the objects are then filed and scraped perfectly clean; and fine silver, often little thicker than paper, is attached with the aid of tin solder and heat; the silver is rubbed close upon every part with a burnisher.

The electrotype process is also used, under Elkington & Co.'s patent, for plating several of the metals with silver, which it does in the most uniform and perfect manner; the silver added is charged by weight at about three times the price of the metal; the German silver, or albata, is generally used for the interior substance, as when the silver is partially worn through, the white alloy is not so readily detected as iron or copper.

Silver alloys.—Mr. Brande says, "The alloy with *copper* constitutes plate and coin; by the addition of a small proportion of copper to silver, the metal is rendered harder and more sonorous, while its color is scarcely impaired. Even with equal weights of the two metals, the compound is white; the maximum of hardness is obtained when the copper amounts to one-fifth of the silver. The *standard silver* of this country consists of $11\frac{2}{20}$ pure silver, and $\frac{18}{20}$ copper, or 11·10 silver, and 0·90 copper. A pound of troy, therefore, is composed of 11 oz. 2 dwts. pure silver, and 18 dwts. of copper. Its density is 10·3; its calculated density is 10·5, so that the metals dilate a little on combining. The French silver coin is constituted of 9 silver and 1 copper." (*Brande.*) The French *billon* coin is 1 silver and 4 copper. (*Kelly.*)

"For *silver plate*, the French proportions are $9\frac{1}{2}$ parts silver, $\frac{1}{2}$ copper, and for trinkets, 8 parts silver, 2 copper."

Silver solders are made in the following proportions:

Hardest silver solder, 4 parts fine silver, and 1 part copper; this is difficult to fuse, but is occasionally employed for figures.

Hard silver solder, 3 parts sterling silver, and 1 part brass wire, which is added when the silver is melted, to avoid wasting the zinc.

Soft silver solder for general use, 2 parts fine silver, and 1 part brass wire. By some few, $\frac{1}{8}$ part of arsenic is added, to render the solder more fusible and white, but it becomes less malleable; the arsenic must be introduced at the last moment, with care to avoid its fumes.

Silver is also soldered with tin solder, (2 tin, 1 lead,) and with pure tin.

Silver and mercury are used in the plastic metallic stopping for teeth.

Tin has a silvery-white color, with a slight tint of yellow; it is malleable, though sparingly ductile. Common tin-foil, which is obtained by beating out the metal, is not more than 1-1000th of an inch in thickness, and what is termed *white Dutch metal* is in much thinner leaves. Its specific gravity fluctuates from 7·28 to 7·6, the lightest being the purest metal. When bent it occasions a peculiar crackling noise, arising from the destruction of cohesion amongst its particles.

When a bar of tin is rapidly bent backwards and forwards several times successively, it becomes so hot that it cannot be held in the hand. When rubbed it exhales a peculiar odor. It melts at 442°, and by exposure to heat and air is gradually converted into a protoxide. (*Brande.*)

Pure tin is commonly used for dyers' kettles; it is also sometimes employed for the bearings of locomotive carriages and other machinery. This metal is beaten into very large sheets, some of which measure 200 by 100 inches, and are of about the thickness of an ordinary card; the small-sized foil is stated not to exceed one-thousandth of an inch in thickness. The metal is first laminated between rollers, and then spread one sheet at a time upon a large iron surface or anvil, by the direct blows of hammers with very long handles; great skill is required to avoid beating the sheets into holes. The large sheets of tin-foil are only used for silvering looking-glasses by amalgamation with mercury. See *Mr. Farrow's apparatus, Trans. Soc. of Arts*, vol. 49, p. 146. Tin-foil is also used for electrical purposes. The amalgam used for electrical machines, is 7 tin, 3 zinc, and 2 mercury.

Tin is drawn into wire, which is soft and capable of being bent and unbent many times without breaking; it is moderately tenacious, and completely inelastic. Tin tube is extensively used for gas fittings, and many other purposes; it has been recently introduced in an ingenious manner for the formation of very cheap vessels, for containing artists' and common colors, besides numerous other solid substances and fluids, required to be hermetically sealed, with the power of abstracting small quantities.

Tin plate is an abbreviation of tinned iron plate; the plates of charcoal iron are scoured bright, pickled, and immersed in a bath of melted tin covered with oil, or with a mixture of oil and common resin; they come out thoroughly coated. Tinned iron wire is similarly prepared; there are several niceties in the manipulations of each of these processes which cannot be noticed in this place.

Tin is one of the most cleanly and sanatory of metals, and is largely consumed as a coating for culinary vessels, although the quantity taken up in the tinning is exceedingly small, and which was noticed by Pliny.

Tin imparts hardness, whiteness, and fusibility to many alloys, and is the basis of different solders, pewters, Britannia metal, and other important alloys, all of which have a low power of conducting heat.

Pewter is principally tin; mostly lead is the only addition, at other times copper, but antimony, zinc, &c., are used with the above, as will be separately adverted to. The exact proportions are unknown even to those engaged in the manufacture of pewter, as it is found to be the better mixed when it contains a considerable portion of old metal, to which new metal is added by trial.

In order to regulate the quality of pewter wares, the Pewterers' Company published in 1772 "A Table of the Assays of Metal, and of the Weights and Dimensions of the several sorts of Pewter Wares," and they threatened with expulsion from their guild, any who departed from the regulations given in this now scarce and disregarded pamphlet.

The assay is made by casting a small button of the metal to be tried in a brass mould, which is so proportioned that the button, if pure tin, weighs exactly 182 grains; all the metals added to the tin being heavier than the latter: the buttons or assays are the heavier the less tin they contain, and at page 14 of the pamphlet the following scale is given:

Assay of pure tin				182	grains.
Ditto of fine or plate metal	1½	grains heavier	than tin, or	183½	"
Ditto of trifling metal	3½	"	"	185½	"
Ditto of ley metal	16½	"	"	198½	"

and it may be added, although an unauthorized addition, that equal parts of tin and lead are about fifty grains heavier than tin, or 232 grains.

Some pewters are now made nearly as common as the last proportion: when cast they are black, shining and soft; when turned, dull and bluish. Other pewters only contain 1-5th or 1-6th of lead; these when cast are white, without gloss, and hard; such are pronounced very good metal, and are but little darker than tin. The French legislature sanctions the employment of 18 per cent. of lead with 82 of tin, as quite harmless in vessels for wine and vinegar.

The finest pewter, frequently called "tin and temper," consists mostly of tin, with a very little copper, which makes it hard and somewhat sonorous, but the pewter becomes brown-colored when the copper is in excess. The copper is melted, and twice its weight of tin is added to it, and from about ½ to 7 lbs. of this alloy, or the "temper," are added to every block of tin weighing from 360 to 390 pounds.

Antimony is said to harden tin and to preserve a more silvery color, but is little used in pewter. Zinc is employed to cleanse the metal rather than as an ingredient; some stir the fluid pewter with a thin strip, half zinc and half tin; others allow a small lump of zinc to float on the surface of the fluid metal whilst they are casting, to lessen the oxidation.

Britannia metal, or white metal, is said to consist of 3½ cwt. of block tin, 28 lbs. antimony, 8 lbs. copper, and 8 lbs. brass; it is cast into ingots and rolled into very thin sheets. This manufacture was introduced in about the year 1770, by Jessop and Hancock.

Tin solders are very much used in the arts, and according to Dr. Turner,

1 tin	3 lead,	the coarse plumber's solder,	melts at about	500 F.
2 "	1 "	the ordinary or fine tin solder	" " "	360 F.

Zinc.—A bluish-white metal, with considerable lustre, rather hard, of a specific gravity of about 6·8 in its usual state, but, when drawn into wire, or rolled into plates, its density is augmented to 7 or 7·2. In its ordinary state at common temperatures, it is tough, and with difficulty broken by blows of the hammer. It becomes very brittle when its temperature approaches that of fusion, which is about 773°; but at a temperature a little above 212°, and between that and 300°, it becomes ductile and malleable, and may be rolled into thin leaves, and drawn into moderately fine wire, which, however, possesses but little tenacity. When a mass of zinc, which has been fused, is slowly cooled, its fracture exhibits a lamellar and prismatic crystalline texture.—*Brande*, 770.

Zinc, which is commercially known as *spelter*, although it is always brittle when cast, has of late years taken its place amongst the malleable metals; the early stages of its manufacture into sheet, foil, and wire, are stated to be conducted at a temperature somewhat above that of boiling water; and it may be afterwards bent and hammered cold, but it returns to its original crystalline texture when re-melted. It has been applied to many of the purposes of iron, tinned-iron, and copper; it is less subject to oxidation from the effects of the atmosphere than the iron, and much cheaper, although less tenacious, ductile, or durable than the copper. The sheet metals when bent lengthways of the sheet, (or like a roll of cloth,) are less disposed to crack than if bent sideways. In this respect zinc and sheet-iron are the worst: the risk is lessened when they are warmed.

Zinc is applied as a coating to preserve iron from rust.

Zinc mixed with one-twentieth its weight of speculum metal, may be melted in an iron ladle, and made to serve for some of the purposes of brass, such as common chucks. The alloy is sufficient to modify the crystalline character, but reserves the toughness of the zinc; it will not, however, bear hammering, either hot or cold. Four atoms of zinc and one of tin, or 133·2 and 57·9, make a hard, malleable, and less crystalline alloy.

Biddery ware, manufactured at Biddery, a large city, 60 miles N. W. of Hyderabad in the East Indies, and also at Benares, is said by Dr. Heyne to consist of copper, 16 oz.; lead, 4 oz.; and tin, 2 oz., melted together: and to every 3 oz. of this alloy, 16 oz. of spelter or zinc are added. The metal is used as an inferior substitute for silver, and resembles some sorts of pewter.

The foregoing alloys are mostly derived from actual practice, and although it has been abundantly shown that alloys are most perfect, when mixed according to atomic proportions, or by multiples of their chemical equivalents, yet this excellent method is little adopted, owing to various interferences.

For example, it is in most cases necessary, from an economic view, to mix some of the old alloys, (the proportions of which are uncertain,) along with the new metals. In most cases also unless the fusion and refusion of the alloys are conducted with considerably more care than ordinary practice ever attains, or really demands, the loss by oxidation completely invalidates any nice attempts at proportion; and

which proportions can be alone exactly arrived at, when the combined metals are nearly or quite pure.

Hardness, fracture, and color of alloys.—The object of this division of our article is to explain, in a general way, some of the peculiarities and differences amongst alloys, in the manner of a supplement to the list; prior to entering on the means of melting the metals, without which process alloys cannot be made: yet notwithstanding that the list contains the greater number of the alloys in ordinary use, and many others, it is merely a small fraction of those which might be made, for, says Dr. Turner, "It is probable that each metal is capable of uniting in one or more proportions with every other metal, and on this supposition the number of alloys would be exceedingly numerous."*

It is also stated by the same distinguished authority, that "Metals appear to unite with one another in every proportion, precisely in the same manner as sulphuric acid and water. Thus there is no limit to the number of alloys of gold and copper." The same might be said of many other metals, and when the alloys compounded of three, four, or more metals, are taken into account, the conceivable number of alloys becomes almost unlimited. "It is certain, however, that metals, have a tendency to combine in definite proportion; for several atomic compounds of this kind occur native." "It is indeed possible that the variety of proportions in alloys is rather apparent than real, arising from the mixture of a few definite compounds with each other, or with uncombined metal; an opinion not only suggested by the mode in which alloys are prepared, but in some measure supported by observation."†

It appears to be scarcely possible to give any sufficiently general rules by which the properties of alloys may be safely inferred from those of their constituents; for although, in many cases, the working qualities and appearance of an alloy, may be nearly a mean proportional between the nature and quantities of the metals composing it; yet in other and frequent instances the deviations are excessive, as will be seen by several of the examples referred to.

Thus, when lead, a soft and malleable metal, is combined with antimony, which is hard, brittle, and crystalline, in the proportions of from twelve to fifty parts of lead to one of antimony, a flexible alloy is obtained, resembling lead, but somewhat harder, and which is rolled into sheets for sheathing ships. Six parts of lead and one of antimony are used for the large soft printers' types, which will bend slightly, but are considerably harder than the foregoing; and three parts of lead and one of antimony are employed for the smallest types, that are very hard and brittle, and will not bend at all: antimony being the more expensive metal, is used in the smallest quantity that will suffice.‡ The difference in specific gravity between lead and antimony constantly interferes, and unless the type metal is frequently stirred, the lead, from being the heavier metal, sinks to the bottom, and the antimony is disproportionally used from the surface.§

In the above examples, the differences arising from the proportions appear intelligible enough, as when the soft lead prevails, the mixture is much like the lead; and as the hard, brittle antimony is increased, the alloy becomes hardened, and more brittle: with the proportion of four to one, the fracture is neither reluctant like that of lead, nor foliated like antimony, but assumes very nearly the grain and color of some kinds of steel and cast-iron. In like manner when tin and lead are alloyed, the former metal imparts to the mixture some of its hardness, whiteness, and fusibility, in proportion to its quantity; as seen in the various qualities of pewter, in which however copper, and sometimes zinc or antimony, are found.

The same agreement is not always met with; as nine parts of copper, which is red, and one part of tin, which is white, each *very* malleable and ductile metals, make the tough, rigid metal used in brass ordnance, from which it obtains its modern name of gun-metal, but which neither admits of rolling nor drawing into wire; the same alloy is described by Pliny as the soft *bronze* of his day. The continual addition of the tin, the *softer metal*, produces a gradual increase of hardness in the mixture; with about one-sixth of tin the alloy assumes its maximum hardness consistent with its application to mechanical uses; with one-fourth to one-third tin it becomes highly elastic and sonorous, and its brittleness rather than its hardness is greatly increased.

When the copper becomes two, and the tin one part, the alloy is so hard as not to admit of being cut with steel tools, but crumbles under their action; when struck with a hammer, or even suddenly warmed, it flies into pieces like glass, and clearly shows a structure highly crystalline, instead of malleable. The alloy has no trace of the red color of the copper, but it is quite white, susceptible of an exquisite polish, and being little disposed to tarnish it is most perfectly adapted to the reflecting speculums of telescopes and other instruments, for which purpose it is alone used.

Copper, when combined *in the same proportions* with a different metal, also light-colored and fusible, namely two parts of copper with one of zinc, (which latter metal is of a bluish-white, and *crystalline*, whereas tin is very ductile,) makes an alloy of entirely opposite character to the speculum metal; namely, the soft yellow brass, which becomes by hammering very elastic and ductile, and is very easily cut and filed.

Again, the same proportions, namely, two parts of copper and one of lead, make a common inferior

---

* Dr. Turner's Chemistry, Seventh Edition, 1841, p. 558. † Ibid., p. 559.

‡ In this alloy the antimony fulfils another service besides that of imparting hardness: antimony somewhat expands on cooling, whereas lead contracts very much, and the antimony therefore, within certain limits, compensates for this contraction, and causes the alloy to retain the full size of the moulds.

Sometimes from motives of economy the neighboring parts of machinery are not wrought accurately to correspond one with the other, but lead is poured in to fill up the intermediate space, and to make contact. As around the brass nuts in the heads of some screw-presses, in the guides or followers for the same, and some other parts of either temporary or permanent machinery. Antimony is quite essential in all these cases to prevent the contraction the lead alone would sustain, and which would defeat the intended object, as the metal would otherwise become smaller than the space to be filled.

§ A little tin is commonly introduced into types, and likewise copper in minute quantity; iron and bismuth are also spoken of; the last is said to be employed on account of its well-known property of expanding in cooling, so as to cause the types to swell in the mould, and copy the face of the letter more perfectly; but although I find bismuth to have been thus used, it appears to be neither common nor essential in printing types.

metal, called pot-metal, or cock-metal, from its employment in those respective articles. This alloy is much softer than brass, and hardly possesses malleability; when, for example, the beer-tap is driven into the cask, immediately after it has been scalded, the blow occasionally breaks it in pieces, from its reduced cohesion.

Another proof of the inferior attachment of the copper and lead, exists in the fact that if the moulds are opened before the castings are almost cold enough to be handled, the lead will ooze out, and appear on the surface in globules. This also occurs to a less extent in gun-metal, which should not, on that account, be too rapidly exposed to the air; or the tin *strikes to the surface*, as it is called, and makes it particularly hard at those parts, from the proportional increase of the tin. In casting large masses of gun-metal, it frequently happens that little hard lumps, consisting of nearly half tin, work up to the surface of the runners or pouring places, during the time the metal is cooling.

In brass, this separation scarcely happens, and these moulds may be opened whilst the castings are red-hot, without such occurrence; from which it appears that the copper and zinc are in more perfect chemical union, than the alloys of copper with tin, and with lead.

Malleability and ductility of alloys.—The malleability and ductility of alloys are in a great measure referable to the degrees in which the metals of which they are respectively composed possess these characters.

Lead and tin are malleable, flexible, ductile, and inelastic, whilst cold, but when their temperatures much exceed about half way towards their melting heats, they are exceedingly brittle and tender, owing to their reduced cohesion.

The alloys of lead and tin partake of the general nature of these two metals; they are flexible when cold, even with certain additions of the brittle metals antimony and bismuth, or of the fluid metal mercury; but they crumble with a small elevation of temperature, as these alloys melt at a lower degree than either of their components, to which circumstance we are indebted for the tin solders.

Zinc, when cast in thin cakes, is somewhat brittle when cold, but its toughness is so far increased when it is raised to about 300° Fahr. that its manufacture into sheets by means of rollers is then admissible; it becomes the malleable zinc, and retains the malleable and ductile character, in a moderate degree, even when cold, but in bending rather thick plates it is advisable to warm them to avoid fracture; when zinc is remelted it resumes its original crystalline condition.*

Zinc and lead will not combine without the assistance of arsenic, unless the lead is in very small quantity; the arsenic makes this and other alloys very brittle, and it is besides dangerous to use. Zinc and tin make, as may be supposed, somewhat hard and brittle alloys, but none of the zinc alloys, except that with copper to constitute brass, are much used.

Gold, silver, and copper, which are greatly superior in strength to the fusible metals above named, may be forged either when red-hot or cold, as soon as they have been purified from their earthy matters, and fused into ingots; and the alloys of gold, silver, and copper are also malleable, either red-hot or cold.†

Fine, or pure gold and silver, are but little used alone; the alloy is in many cases introduced less with the view of depreciating their value than of adding to their hardness, tenacity, and ductility; the processes which the most severely test these qualities, namely, drawing the finest wires and beating gold and silver leaf, are not performed with the pure metals, but gold is alloyed with copper for the red tint, with silver for the green, and with both for intermediate shades. Silver is alloyed with copper only, and when the quantity is small its color suffers but slightly from the addition, although all its working qualities are greatly improved, pure silver being little used.

The alloys of similar metals having been considered, it only remains to observe that when dissimilar metals are combined, as those of the two opposite groups—namely, the fusible lead, tin, or zinc, with the less fusible copper, gold, and silver—the malleability of the alloys when cold is less than that of the superior metal; and when heated barely to redness, they fly in pieces under the hammer; and therefore, brass, gun-metal, &c., when red-hot, must be treated with precaution and tenderness. Muntz's patent metal, which is a species of brass and is rolled red-hot, appears rather a contradiction to this; but in all probability this alloy, like the ingots of cast-steel, requires at first a very nice attention to the force applied. It will be also remembered the action of rollers is more regular than that of the hammer; and soon gives rise to the fibrous character, which, so far as it exists in metals, is the very element of strength when it is uniformly distributed throughout their substance. This will be seen by the inspection of the relative degrees of cohesion possessed by the same metal when in the conditions of the casting, sheet, or wire, and to which quality or the tenacity of alloys we shall now devote a few lines.

Strength or cohesion of alloys.—The strength or cohesion of the alloys, is in general greatly superior to that of any of the metals of which they are composed.

All nice attempts at proportion, are, however, entirely futile, unless the metals are perfectly pure; for example, it is a matter of common observation that for speculums, a variable quantity of from seven and a half to eight and a half ounces of tin is required for the exact saturation of every pound of copper, and upon which saturation the efficiency of the compound depends; bells of exactly similar quality sometimes thus require the dose of tin to vary from three and a half to five ounces to the pound of copper, according to the qualities of the metals.

Fusibility of alloys.—In concluding this slight view of some of the general characters of alloys, it remains to consider the influence of heat, both as an agent in their formation, and as regards the degree in which it is required for their after fusion; the lowest available temperature being the most desirable in every such case.

"Metals do not combine with each other," says Dr. Turner, "in their solid state, owing to the influence

* It is considered that most of the sheet zinc contains a very little lead.

† Gold alloyed with copper alone is not very malleable when hot.

of chemical affinity being counteracted by the force of cohesion. It is necessary to liquefy at least one of them, in which case they always unite, provided their mutual attraction is energetic. Thus, brass is formed when pieces of copper are put into melted zinc; and gold unites with mercury at common temperatures by mere contact."

The agency of mercury in bringing about *triple* combinations of the metals, both with and without heat, is also very curious and extensive. Thus, in *water-gilding*, the silver, copper, or gilding metal, when chemically clean, are rubbed over with an amalgam of gold containing about eight parts of mercury; this immediately attaches itself, and it is only necessary to evaporate the mercury, which requires a very moderate heat, and the gold is left behind. *Water-silvering* is similarly accomplished.

Cast-iron, wrought-iron, and steel, as well as copper and many other metals, may be tinned in a similar manner. An amalgam of tin and mercury is made so as to be soft and just friable; the metal to be tinned is thoroughly cleaned either by filing or turning, or if only tarnished by exposure, it is cleaned with a piece of emery-paper or otherwise, without oil, and then rubbed with a thick cloth moistened with a few drops of muriatic acid. A little of the amalgam then rubbed on with the same rag, thoroughly coats the cleaned parts of the metal by a process which is described as *cold-tinning*; other pieces of metal may be attached to the tinned parts by the ordinary process of tin-soldering.

In making the tinned-iron plates, the scoured and cleaned iron plates are immersed in a bath of pure melted tin; covered with pure tallow, the tin then unites with every part of the surfaces; and in the ordinary practice of tinning culinary vessels of copper, pure tin is also used. The two metals, however must then be raised to the melting heat of tin; but the presence of a little mercury enables the process to be executed at the atmospheric temperature, as above explained.

In Mr. Mallett's recently patented "processes for the protection of iron from oxidation and corrosion, and for the prevention of the fouling of ships," one proceeding consists in covering the iron with zinc.

The ribs or plates for iron ships are immersed in a "cleansing bath" of equal parts of sulphuric or muriatic acid and water, used warm; the works are then hammered, and scrubbed with emery or sand, to detach the scales and to thoroughly clean them; they are then immersed in a "preparing bath" of equal parts of saturated solutions of muriate of zinc and sal-ammoniac, from which the works are transferred to a fluid "metallic bath," consisting of 202 parts of mercury and 1292 parts of zinc, both by weight;* to every ton weight of which alloy is added about one pound of either potassium or sodium, (the metallic bases of potass and soda,) the latter being preferred. As soon as the cleaned iron works have attained the melting heat of the triple alloy, they are removed, having become thoroughly coated with zinc.

The affinity of this alloy for iron is, however, so intense, and the peculiar circumstances of surface as induced upon the iron presented to it by the preparing bath are such, that care is requisite lest by too long an immersion the plates are not partially or wholly dissolved. Indeed, where the articles to be covered are small, or their parts minute, such as wire, nails, or small chain, it is necessary before immersing them to permit the triple alloy to dissolve or combine with some wrought-iron, in order that its affinity for iron may be partially satisfied, and thus diminished. At the proper fusing temperature of this alloy, which is about 680° Fahr., it will dissolve a plate of wrought-iron of an eighth of an inch thick in a few seconds.

The palladiumizing process.—The articles to be protected are to be first cleansed in the same way as in the case of zincing; namely, by means of the double salts of zinc and ammonia, or of manganese and ammonia; and then to be thinly coated over with palladium, applied in a state of amalgam with mercury.

In the opinion of eminent chemists and metallurgists, *all* the metals, even the most refractory, which nearly or quite refuse to melt in the crucible when alone, will gradually run down when surrounded by some of the more fusible metals in the fluid state; in a manner similar to the solution of the metals in mercury, as in the amalgams, or the solutions of solid salts in water. The surfaces of the superior metals are, as it were, dissolved, washed down, or reduced to the state of alloys, layer by layer, until the entire mass is liquefied.

Thus nickel, although it barely fuses alone, enters into the composition of German silver by aid of the copper, and whilst it gives whiteness and hardness, it also renders the mixture less fusible. Platinum combines very readily with zinc, arsenic, and also with tin and other metals; so much so, that it is dangerous to melt either of those metals in a platinum spoon, or to solder platinum with common tin solder, which fuses at a very low temperature; although platinum is constantly soldered with fine gold, the melting point of which is very high in the scale. Again, the circumstances that some of the fusible bismuth alloys melt below the temperature of boiling water, or at less than half the melting heat of tin, their most fusible ingredient, show that the points of fusion of alloys, are equally as difficult of explanation or generalization as many other of the anomalous circumstances concerning them.

This much, however, may be safely advanced, that the alloys, without exception, are more easily fused than the superior metal of which they are composed; and extending the same view to the *relative* quantities of the components, it may be observed that the hard solders for the various metals and alloys are in general made of the self-same material which they are intended to join, but with small additions of the more fusible metals. The solder should be, as nearly as practicable, equal to the metal on which it is employed, in hardness, color, and every property except fusibility; in which it must excel just to an extent that, when ordinary care is used, will avoid the risk of melting, at the same time, both the object to be soldered and likewise the softer alloy or solder by which it is intended to unite its parts.

It would appear as if every example of soldering in which a more fusible alloy is interposed, were also one of superficial alloying. Thus, when two pieces of iron are united by copper, used as a solder

* Being in the proportion of one atom of mercury to forty atoms of zinc.

it seems to be a natural conclusion that each surface of the iron becomes alloyed with the copper; and that the two alloyed surfaces are held together from their particles having been fused in contact, and run into one film. It is much the same when brass or spelter solder is used, except that triple alloys are then formed at the surfaces of the iron, and so with most other instances of soldering.

And in cases where metallic surfaces are coated by other metals, the latter being at the time in a state of fusion, as in tinned-iron plates and silvered copper; may it not also be conceived, that between the two exterior surfaces which are doubtless the simple metals, a thin film of an alloy compounded of the two does in reality exist? And in those cases in which the coating is laid on by the aid of mercury, and without heat, the circumstances are very similar, as the fluidity of mercury is identical with the ordinary state of fusion of other metals, although the latter require higher temperatures than that of our atmosphere.

' When portions of the same metal are united by partial fusion, and without solder, as in the process described as *burning together*, and more recently known as the "*autogenous*" mode of soldering, no alloy is formed, as the metals simply fuse together at their surfaces.

Neither can it be supposed that any formation of alloy can occur where the one metal is attached to the other by the act of burnishing on with heat, as in making gilt wire, but without a temperature sufficient to fuse either of the metals. The union in this case is probably mechanical, and caused by the respective particles or crystals of the one metal being forced into the pores of the other, and becoming attached by a species of entanglement, similar to that which may be conceived to exist throughout solid bodies. This process, almost more than any other in common use, requires that the metals should be perfectly or chemically clean; for which purpose they are scraped quite bright before they are burnished together, so that the junction may be next approaching to that of solids generally.

And, lastly, when metals are deposited upon other metals by chemical or electrical means, the addition frequently appears to be a detached sheath, and which is easily removed; indeed, unless the metal to be coated is chemically clean, and that various attendant circumstances are favorable, the sound and absolute union of the two does not always happen, even when carefully aimed at.

METALLURGY. A word derived from the Greek, signifying the art of working metals, or the art by which metals are produced from their ores.

Metals constitute a well-known class of substances, distinguished by characteristics which every one recognizes. They are considered as elementary matter by chemists, because chemistry has failed, up to the present time, to resolve any one of them into more simple forms of matter; they may, therefore, be regarded as an aggregation of elementary atoms, held together by the force of cohesion. Metals are popularly recognized as heavy matter, of great tenacity; of a peculiar metallic lustre, which it is difficult to describe, but which is easily recognized. With one exception, namely, quicksilver, all the metals are solid at ordinary temperatures; they are all capable of liquefaction, and even volatilization, at higher temperatures, the degree of heat being a different one in every instance. Metals, as a class, are characterized by a higher specific gravity than almost all other matter; they are distinguished by opacity, from which rule only gold and silenium are excepted. The capacity of conducting heat and electricity is possessed by metals to a high degree of perfection.

Malleability is the property of metals to change their form permanently, under a certain pressure. The most important considerations for our present purposes are, the chemical qualities, the fusibility of metals, their affinity for other matter, and their affinity among themselves.

Fusibility.—The degree of heat at which metals assume the solid or the fluid state is their fusibility.

Mercury melts at	39°	Silver melts at	1860°
" boils "	600°	Gold " "	1983°
Tin melts "	420°	Cast-iron " "	2700°
Lead " "	600°	Platinum " "	4561°
Zinc " "	666°		

The affinity of the metals for oxygen forms a very important item in our investigations. The oxides of mercury, silver, gold, platinum and the platinum metals, part with their oxygen by the mere application of heat. The following oxides of metals retain their oxygen at any temperature; they require the addition of carbon or hydrogen in order to expel their oxygen: lead, copper, bismuth, antimony, chromium, arsenic, nickel, cobalt, iron, tin, zinc. Most of these oxides may be deprived of their oxygen by carbon only, others by carbon and hydrogen, and some may be reduced by hydrogen only. Hydrogen reduces all these oxides, but with most of them the point of reduction is so low as to leave the metal in the form of a fine powder, which oxidizes as soon as it is exposed to the atmosphere. Iron, copper, nickel, chromium, and other metals cannot be reduced by hydrogen, on account of the low heat by which the process is accomplished. Antimony, arsenic, tin, zinc, lead, mercury, and all the alkaline metals may be reduced by hydrogen. The facility with which metals oxidize is also of importance in metallurgical operations. Lead, copper, bismuth, antimony, chromium, and arsenic do not decompose water at any temperature, but are easily oxidized by atmospheric air. Nickel, cobalt, iron, tin, zinc, manganese, decompose water easily at a red heat. All the terrifiable metals, such as aluminum, and we may add silicon, are easily oxidized at a higher heat, and their oxides readily reduced in the presence of carbon, and of such other metals as these metals can combine with. The alkaline metals oxidize most readily under all conditions, and their oxides are easy of reduction in the presence of other metals, such as lead, antimony, and others with which the alkaline metals may combine. Besides the combination of the metals with oxygen, their union with other matter, such as sulphur, phosphorus, carbon, &c., is of high interest. Most of the metals combine readily with sulphur, such as iron or lead; others are not so easily disposed to enter into that combination, as zinc and gold. The affinity of sulphur for the metals and carbon, and the mode and conditions under which these combinations may be separated, forms a very important part of the metallurgist's knowledge. Of the same importance as the sulphur combinations are those of phosphorus; which combinations are in most cases more

difficult of separation than all other or similar compounds. Of equal importance to the smelter of metals, is the relation of the metals among themselves; it is not so much the nature and qualities of these combinations, as the conditions under which the metals combine and separate, which interest him.

The art of smelting consists in the knowledge of the nature of metals, their fusibility and relation to other matter. It is not so much the specific qualities of metals which interest the metallurgist, as the mode of manufacturing the metals from their native ores. To produce metal from ore, the first condition is to expose the ore to such a high heat as will melt the metal. Gold, mercury, and the platinum metals may be produced in this way to a certain extent. All or most of the metals in nature are combined with other matter, such as oxygen, sulphur, phosphorus; to remove the oxygen, we add to the ore matter which has a greater affinity for oxygen than the metal, at or near that degree of heat by which the metal melts: carbon is the most generally in use, hydrogen serves in some cases, and metals in others. Metals and sulphur, or other matter, may be roasted, and the metal resolved into an oxide; but if such process is not practicable, the sulphuret or phosphuret, &c., is melted along with another metal, such as sulphuret of lead or copper with metallic iron, where always that condition is complied with, namely, that the newly formed metal is more fusible than the newly formed sulphuret. Metallic ores are in most cases a mechanical mixture of the metal in its pure state, as gold ores; or a mixture of the oxide of metal and other matter, such as is the case in clay—iron—stone: or the ores are a chemical combination of one sulphuret of metal with other sulphurets of metal, as copper-pyrites in connection with iron-pyrites, to which, frequently, silex or clay is added in admixture. The prevailing principle in all metallurgical operations is, with but few exceptions, the transformation of all ores into metallic oxides, and the reduction of these oxides by carbon. Where the metallic oxides are incorporated with matter, such as silex, alumina, or lime, which cannot be reduced at those temperatures and under those conditions by which the metals melt and are reduced themselves, that matter would prevent the agglutination of the metallic globules, and permit but a small portion of the metal to separate from it, even if all other conditions of the reducing process are fulfilled; this foreign matter forms an inclosure to the metallic particles. This inclosure is to be destroyed, which, in many cases, can be done by heat simply; such is the case with some copper ores, where a certain portion of iron is present. In other cases it requires the addition of such matter to the ore which will combine with the impurities of it, melt with it, and liberate the metal. This latter part of the science of metallurgy is the most difficult to obtain, and exerts the most influence upon the practical results of the operation. This branch of our investigation it is beyond the limits of this article to explore fully, we can furnish but a faint outline of the principles involved.

The formation of fusible slags is accomplished by smelting an oxide of one metal together with the oxide of another, or these oxides together with silex. These combinations are subject to the laws of affinity developed by chemistry. They depend upon the quantity of the oxides, their degree of oxidation, their relative position in the scale of affinity, and the conditions under which the oxides meet. The most prevalent in these combinations are the silicates, or a vitrification of a metallic oxide with silex. Either mixed to a silicate, or one mixed to the other, are frequently found the carbonates, chlorides, sulphates, fluates, and other salts, which form in all cases a more or less fusible slag. The nature of the operation requires the formation of a fusible slag as most advantageous to the process. In practice, this principle is frequently modified, on account of the quality of the metal to be produced, or, more generally, for reasons of economy. Silex and alumina are the most pervading admixtures to metallic ores; these are vitrified by all the alkalies and alkaline earths, by protoxides of metals, and the oxides of metals. The fusibility of these combinations is in the following order: alkalies, alkaline-earths, protoxides, and peroxides. A mixture of various oxides or alkalies is more fusible than that of but one alkali or oxide, with silex or alumina; the greater the number of these vitrifying elements, the more fusible and homogeneous is the slag; the greater the affinity between the composing parts of a slag, the easier it melts. The laws involved in this question may be abstracted from chemistry, always, however, with due regard to the temperature by which the operation is performed.

Preparatory metallurgical operations.—Some metallic ores may be made to yield their metal by merely crushing and washing the ore—such are the gold and platinum ores. Other ores may be smelted without any preparation or addition of fluxes; to this class belong a large portion of the copper ores, some iron ores, and most of the lead ores. Some ores require simple roasting, others stamping and roasting, before they are ready for the smelting furnace. Almost all the ores, to be smelted, require the addition of fluxes to make the operation profitable. The manipulations in the smelt-works are divided into the preparation of fuel, preparation of ore, and smelting. The first we consider as too extended for the limits of this article, (see Iron,) and confine the subject to the description of the two latter processes. Preparation of ore is again divided into dressing, roasting, crushing, and washing of ore.

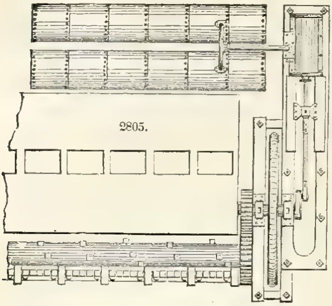
Dressing of ore.—An imperfect picking or sorting of ore is generally performed in the mines; but as a distinct separation and classification cannot be expected in this place, valuable ores are once more picked and cleaned above-ground with greater care than it could be done in the mine. Iron ores, and such ores which cannot bear such expense, are used directly from the mine, without further sorting. Gold ores are necessarily assorted before they are brought to the mill; the same operation is performed on silver ores. If there are pieces among the ore which contain no metal at all, they are thrown away; also such as are so poor as not to pay the expenses of the subsequent operations.

Stamping of ore.—If the mixture of metallic ore and impurities is very intimate, and are the impurities of such a nature as to make smelting difficult, they are moved to the stamping-mill, where the ores are crushed, broken into a more or less fine sand, and washed. Crushing is performed by machinery called a stamping-mill.

In Fig. 2805 a mill of this kind is represented in plan, and in Fig. 2806 in elevation. The machine represented in the engravings has been erected in Virginia during the last year.

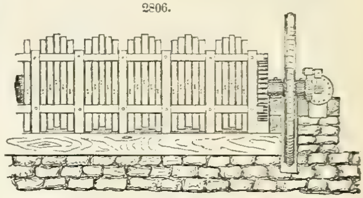
For the crushing of gold ore there are 30 stampers connected with the engine, which is of 40 horse-power. These stampers are scantlings of white-oak wood, 6 feet long, and 6 × 6 inches thick. Each wooden stamper is provided at its lower end with a cast-iron pestle, (stamper-head,) weighing from 2

to 2¼ cwts. each. These stamper-heads are made of the finest and hardest kind of cast-iron, such iron as chilled rollers are made of, and are cast in heavy iron chills, so as to harden the whole surface of the head. These heads are fastened to the wooden helve by a wrought-iron tang of two inches square iron, cast in into the head and sunk into the centre of the wood, where it is secured by wrought-iron



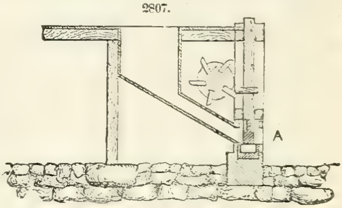
2805.

2806.



hoops laid around the lower end of the helve. The 30 stampers are divided into 3 sets of 5 each; these 5 stampers work into one trough—that is, the whole length of the trough is divided into 6 compartments, of which each forms a set or battery. Each battery has its own feeding apparatus; this is a large, wooden, fixed hopper, as shown in Fig. 2807. Into this hopper the ore is carried as it comes from the hive. It discharges the ore in the middle of the battery or set of five stampers, the middle stamper drawing as much ore as, with the assistance of the two stampers on each side, it can crush. The bottom of each trough is provided with a cast-iron plate; the stampers, however, never touch this plate. Upon this bed-plate a bed of quartz is laid, and kept so that always from 2 to 4 inches high of partly crushed quartz is in the bottom of each battery. This bottom of rocky matter protects the iron bottom, the stampers, and the whole machinery against premature destruction. Each battery is inclosed by a trough made of cast-iron plates, reaching about 7 inches high above the bottom plate.

2807.



The woodwork to which these plates are fastened is higher, and reaches up to 12 or more inches. Each battery is provided with two sieves, or grates, shown by A; these are made of sheet-iron, or sheet-copper, pierced with holes, or they are made of brass-wire gauze, tweeled, in which wire and spaces are each about $\frac{1}{20}$ of an inch. Round holes punched in plates ought to be $\frac{1}{12}$ or $\frac{1}{16}$ of an inch in diameter. These sieves are 8 inches square, fastened vertically at each end of the trough, about 4 inches or 3½ inches above the bottom. The size and form of the holes in the sieves decide the size of the grains of sand made, for all grains which cannot pass these holes are returned to the stamps.

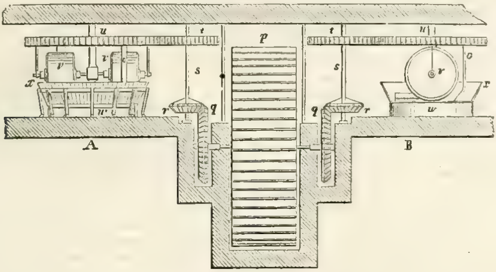
This stamping-machine crushes and washes the ore in the mean time, each stamper receiving 2½ gallons of water per minute. Where ores are stamped dry, the breast-plate and sieves at each battery can be dispensed with. The yield of the machine is about 1000 bushels of quartz converted into fine sand fit for amalgamation in 12 hours, each pestle making from 90 to 100 strokes per minute, having 10 or 11 inches lift. The water in the trough ought to be always high enough to prevent splashing, and loss of good mineral. There is a diversity of opinion respecting the construction of stamping-machines, many machines being now built entirely of cast-iron. We are not aware that any superior results have been achieved by cast-iron machines. It is against the practice and principles of mechanics to build machines which work by concussion of an almost inelastic material such as cast-iron. Wooden machines of this kind are, in the first place, cheaper, and, if well built, are more durable and of greater effect than cast-iron structures.

Gold ores are stamped to liberate the metallic gold inclosed by rocky matter. Lead ores, copper ores, silver ores, &c., are stamped to wash off the gangue. Rocky matter is of a smaller specific gravity than the metallic ores generally are, particularly the sulphurets. When an ore is pulverized, and a current of water passed through the trough containing it, the sand and clay, limestone, &c., will pass off readily in coarse grains, because its gravity is greatly diminished in water: such grains are carried off by the slightest current. Metallic substances more heavy than quartz or rocky matter, will not move until reduced to a certain size, when the particles will follow the current by adhesion, or be so inconsiderable as to be carried off by the wash water. The current of water issuing from the stamps will carry the rocky matter further than the metallic granules, and if the water and sand from the stamps is led into a long wooden trough, the lightest particles will be found furthest off the stamps, and the heaviest matter nearest to the mill. The size of the grains is regulated in the mill, chiefly by the height of the grating or sieve above the bottom of the trough or stamper-bed; further by the size of the

holes in the sieve; by the amount of water; by the lift of the stamps, weight of stamps, and particularly by the kind of bottom used. If the bottom is too hard or thin, the mill stamps coarsely; and if the rock bottom is too thick, it stamps too fine.

Other means of grinding or crushing ore are millstones, of considerable weight and size. In Fig. 2808 a mill of this kind is represented. A vertical shaft, to which a cross shaft and two millstones of 4 or 5 feet diameter are appended, revolves slowly around itself, making from 3 to five revolutions per minute. This shaft carries with it the two head-stones, which revolve around the vertical axis, and in the mean time around their own axis, running upon a third millstone, which is laid horizontal, and fixed upon the floor of the millhouse. These stones are of hard material, either of granite, gneiss, trap, or some other tenacious hard rock. Such mills are chiefly used for grinding clay, fire-clay, or kaolin in por

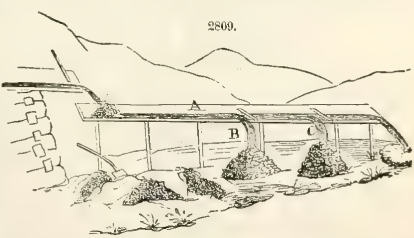
2808.



celain manufactories. Similar mills are exclusively employed in North Carolina for crushing gold ores, also to some extent in Virginia; they are there entirely constructed of iron, or at least the facing, or grinding part of it is made of cast-iron; and are here called Chilian-mills. These mills show one advantage to the stamper-mills; that is, they may be made to grind the ore very fine; and where that is necessary, as it is with many gold ores, these mills are advantageous. But there is one serious drawback to these machines: they require much power in proportion to their effect, and much room. A strong mill of this kind requires from 4 to 6 horse-power, with which it will grind from 40 to 50 bushels of ore in 12 hours, that is, ten bushels to a horse-power. One horse-power will drive one stamper in a stamp-mill, and that stamper will crush at least 30 bushels in the same time,—a consideration which is of importance where wages, power, and time are valuable. Other crushing apparatus, such as common mills, in the form of grist-mills, crushing rollers, and similar machinery, are not in use in this country, at least not to any extent.

Washing of ores.—Ores which contain a considerable amount of clay, lime, sand, and other impurities which may be injurious to the smelting operation, are washed in an abundance of water, so as to carry off the light particles and retain the heavy metallic matter. The simplest form of a washing apparatus, such as is used for washing impure iron ores, is represented in Fig. 2809. A is a long wooden trough of from 20 to 50 feet long, 12 inches wide in the bottom, and 6 or 8 inches high. This trough is a little inclined to the horizon, so as to afford a gentle current. At the upper end a strong current of water is let into it, from a weir or an elevated reservoir, which flows down the channel at a rapid rate. At the entrance of the water a laborer throws in, at intervals, a shovelfull of unclean ore, under the current from the spout of the pool. The water in falling upon the ore moves first the small and light particles, which are carried downwards to the valves B and C. The light, floating particles are carried over these valves, and are discharged at the end of the trough. The heavier particles near the bottom are carried to the valves and pass through these, the coarse through the opening B, and the smaller through C, forming heaps below, from which the remaining light impurities flow off. This apparatus is simple, effective, and may be applied in all instances where washing is to be done. Various modes and machines are used in Europe to remove the earthy matter from the ore by washing. Complicated sifting machines are employed, the grilles or step-washings of Hungary, percussion-tables, shaking-tables, German-chests, sleeping-tables, swing-sieves, and a host of other machines, all of which are of no use to us; these machines work too slow, absorb too much labor, and are not advantageous to our modes of working. The above wash apparatus, properly modified in particular cases, is all-sufficient for washing any kind of ore, and purifying it so far as necessary.

2809.



Roasting of ores.—This process is sometimes performed on the ores when brought from the mine, as

is the case with iron ore, or it is performed after the ores are crushed, which is the way of working silver ores in North Carolina. The principle involved in this operation is to drive off all that volatile matter from the ore which may be dissipated by heat; such as water, carbon, sulphur, phosphorus, chlorine, arsenic, zinc, &c. The consequence of this operation, if well performed, is in all cases, with but few exceptions, the oxidation of the remaining metals to their highest degree; a condition in which the ores are most easily worked, and reduced by carbon to the metallic state. Roasting is performed in this country almost exclusively in the open air; experiments made on roasting ovens met in but few instances with success. There is no doubt but that roast ovens are more economical in the use of fuel than heaps in the open air, but the ovens require more labor; and as fuel is cheap with us, labor high, the reverse of what they are in Europe, it appears to be natural to follow those modes of working which tend to lessen cost, and do the work in the cheapest way. In Fig. 2810 a roast-heap is represented in section. These heaps are often round, but in most cases are mounds of from 25 to 50 and more feet long. The operation consists in spreading over an area of a certain length, and from 8 to 20 feet wide sticks of fire-wood, which may be of an indifferent kind and form. The spaces between the sticks are filled up by small wood, chips, or any kind of fuel, providing, however, sufficient spaces for the access of air from below. The coarser pieces of ore are now spread over this grating of wood, and a layer of from 8 to 12 inches levelled over it; on this ore fine charcoal, braise, is spread about 2 inches thick. Instead of fine charcoal, mineral coal slack may be used to advantage, or wood chips, or in fact any fuel free of injurious matter, such as sulphur, phosphorus, &c. Ore is now piled again upon this coal, and the operation of laying coal and ore in successive layers repeated until that height of the heap is reached which is calculated to be most advantageous in this particular instance. One inch thick of coal is generally considered sufficient for one foot high of ore, exclusive of the foundation of wood. The ore is broken into uniform sizes, of from 2 to 3 inches thick. Fire is kindled in the lower parts of the heap, which to conduct to advantage requires considerable skill, sagacity, and industry. The chief object in this operation being the dissipation of volatile matter, it is evident that the melting of any particles of the ore is to be prevented, for from such melted ore no degree of heat will separate the injurious matter effectually. The conducting of the degree of heat in the roasting heap is therefore an operation liable to injure the ore instead of benefiting it. Ores which melt readily, such as impure iron ores, silver and lead ores, pyrites of all kinds, require more than common watchfulness to insure success in the operation.

2810.

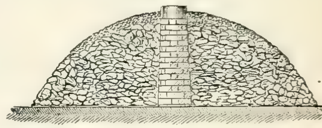


Fig. 2811 represents the section of a reverberatory furnace for roasting schliech of lead ore in Germany These ores contain much sulphuret of zinc, and resemble our silver ores in Virginia and North

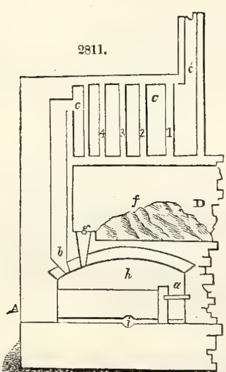
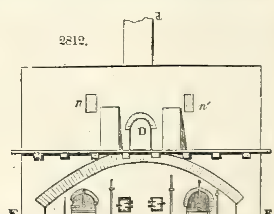
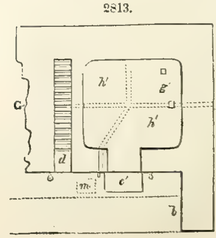
2811.



2812.



2813.



Carolina, for which reasons we allude particularly to this furnace. Fig. 2812 is the drawing of an elevation of that furnace, showing it to be a double furnace; and Fig. 2813 is the plan of half the furnace, or one single furnace. In these several figures, *a* is the furnace or fireplace; *b*, a chimney leading to

the condensing chambers *c c*, in which the evaporated metals, as zinc, arsenic, &c., are conducted; *d* is the stack for the escape of the burnt gases and smoke; *e'* is the charging door; *f* the drying chamber for expelling the water from the ore; *g* is the hopper or charging orifice; *h* the hearth of the furnace; *i* channels for the escape of moisture from the ground; *n n'* are openings leading to the condensing chambers. In each of these furnaces nearly half a ton of ore is charged at a time, which takes from 6 to 12 hours work to be roasted; much zinc delays the process. About two thirds of a cord of wood is required to perform one heat. If well constructed and properly managed, these furnaces work exceedingly well, but require a great deal of labor.

As remarked before, roasting ovens are more economical in the use of fuel than heaps in the open air; this advantage, however, is balanced by our having generally cheap fuel. These ovens are liable to do imperfect work; the access of air, which is the chief oxidizing agent, is not so freely admitted as in heaps. In ovens the advantageous access of watery vapors is out of the question, which, as in the case of heaps, are derived from the ground in such quantities and in such conditions as to be most advantageous to the operation. Watery vapors afford in roasting the triple advantage of being a powerful oxidizing element, in the mean time carrying off sulphur in the form of sulphuretted hydrogen, and assisting in keeping the heat more uniform than it can be done without these vapors. The roasting in heaps may be more expensive in some cases; it certainly is more correct in principle than roasting in ovens.

Roasting in reverberatory furnaces may be considered an advantageous operation where sulphur, arsenic, and such volatile matter is to be expelled which cannot well be removed in the yard by roasting in heaps. These furnaces apply particularly where arsenic is to be driven off; but as no arsenical ores are smelted in the Union, there is little use for reverberatory roast-ovens. At the copper smelt-works roasting is done to a certain extent in the reverberatory, but it is not practised in any other instance. This furnace suffers under the same disadvantage as the roast-oven; the work performed by it is expensive, because of the labor it requires to stir and shovel the ore.

Blast machines are auxiliaries in metallurgical operations. We refer to the article on "IRON" for information.

Assay of ores is a very important operation in smelt-works. Assaying is not only performed here to ascertain the quantity of metal contained in the ore; it is employed both for that purpose and for assaying the metal to inquire what kind of metals and how much of each is contained in the samples produced in the smelting-furnace. Assays of gold ores are generally made by pounding the rock, converting it into a very fine powder, and washing the debris of rock away, which latter operation is performed in a sheet-iron pan. The remaining gold, after washing, is either taken up, amalgamated by quicksilver, and the quicksilver expelled by heat, or, if the quantity is large, say one grain or more, it is weighed in its native state. Experienced gold-washers will judge very near correctly how much one bushel of ore will contain in gold by making one or more pan-washes.

Assays for ascertaining the quantity of a certain kind of metal in a specimen of ore, are in this instance chiefly made in the dry way. If an ore is to be assayed for its contents in gold or silver, the ore is finely powdered, sieved, and mixed with its three or fourfold weight of litharge. This litharge must be free from any other metal but lead; the common shop litharge is not quite safe in this respect, and in case a correct assay is required, it is advisable to dry and roast sugar of lead; the litharge derived from it may be considered pure. The fine litharge and fine ore are well mixed, to which a very little carbonate of soda may be added. If not much gold or silver is expected, but little lead is reduced in this process, which is regulated by the quantity of carbon mixed with it. In most cases, half an ounce of lead will contain all the gold and silver in the ore; one grain of charcoal produces 30 grains of lead; if we want, therefore, 240 grains, or one half ounce of lead, we mix 8 grains of fine charcoal powder with the above mixture of ore and litharge. The mixture is put in a dry and warm crucible, covered by a little common salt, and a slab to prevent the falling in of coal, and then exposed to a rapid heat in an air-furnace. One half hour's heat will finish the operation; the crucible is cooled, broken, and the button of lead removed, washed, and cupelled. This button of lead, of half an ounce weight, requires a cupel of half an ounce; better if one ounce. The cupel is a flat crucible, made of bone-ashes, which, when the lead is heated in it, and in the mean time oxidized, it absorbs the oxide of lead, just as a sponge absorbs water; but this cupel will not absorb any metal in the metallic state. Gold and silver have but little affinity for oxygen, and in heating the alloy of lead and other metals, all other metals will be oxidized and absorbed by the cupel, while gold and silver remain in their pure condition. When, in exposing the cupel in a muffle, or in a crucible, to a white heat, all the lead and other metal is oxidized and absorbed, a bright globule of gold or silver, or a mixture of both, remains; in the latter case the globule is analyzed in the humid way, to ascertain the quantity of either metal, gold or silver.

Next to the assays of gold or silver ores, are those of copper. These ores are pounded, roasted, and mixed with from 75 to 100 per cent. of black flux. Black flux is prepared in mixing the powders of equal parts of saltpetre and crude tartar together, heating this mass gently, and stirring it with a red-hot iron; the burnt powder is again pounded, sifted, and kept in a glass-stoppered bottle for occasional use. The well-pounded and roasted ore is intimately mixed with its flux, put into a crucible, and heated to a bright white heat in the shortest time. The resulting button of copper is broken out of the cooled crucible and washed; it is crude copper, and requires to be refined. This button is pounded in case it is brittle; if not, it is melted in its original form, along with half its weight of black flux, to which a little common salt or saltpetre is added; the first, however, is preferable. While this crucible is melting, another is heated, in which a flux composed of black flux, common salt, and saltpetre, is contained; when the copper is thoroughly melted, and the second crucible hot, the flux melted, the copper is cast from the first into the latter. By these means, metal and flux is mixed without running the risk of losses, which inevitably follow if the crucibles are not shaken, or if they are stirred by an iron rod. If the copper after this second assay is not fine, the process of refining is repeated once more, by which time fine copper is obtained. In this operation, some copper remains always in the scoriæ; the latter

may be gathered together from all the smeltings and melted along with some black flux, which will produce a small button of crude copper; this is added to the first after it is refined, or added by approximating its value in copper. This last grain contains generally a great deal of iron, and looks like iron.

Other ores than those mentioned are commonly not assayed in the smelt-works. Iron, lead, zinc, &c., are of too little value; they cannot bear these expenses. Tin we are not yet smelting, and in so far have no need of assaying it.

Assaying forms a very important branch of the smelting establishment. In this country, owing to the youth of metallurgical operations, most of the smelt-works are connected with the mines; from this rule the copper smelt-works are only excepted. For these reasons, the assay necessary to ascertain the value of ore, in order to establish its price, is not in extensive use. When smelt-works shall be carried on in their proper form, assaying of ore will be more generally executed. At present the assays of ore are only used to ascertain the value of ore specimens, by which assays, as they allude but to a small and in most cases a selected part of the ore, many illusory prices of ore are furnished, which deceive the unwary. All assays made in the dry way are incorrect; they always furnish a smaller amount of metal than the large operation; if, however, the assays are conducted with uniform precision, the loss in each case will be the same, and may be represented by a per-centage of the whole. The second feature of the utility of the dry assay is its affording indications of the amount and nature of the foreign admixtures to the ore: it furnishes a guide to the smelter at the furnace. Experiments as to the mode of smelting an ore to the best advantage, can be made in the crucible with less expense and greater facility than in the smelting furnace. A third advantage arising from the assay laboratory is the analysis of the manufactured metal in respect to its purity and contents of precious metals.

Assay in the humid way.—The chemical analysis of ore, or the assay in the humid way, is not of much practical use to the metallurgist. If this assay is well performed, it furnishes an exact table of the contents of an ore, of slags, and of metals; but it requires more science and experience than commonly is at the disposal of the practical man, to make that use of an analysis which frequently is expected from it. The humid analysis furnishes the facts, the elements for the science of metallurgy; but the application of these facts is subject to more difficulties than at a superficial glance appear: it is moreover a means of inducing young, speculative minds to a waste of time and money which may be better employed than in chemical analysis. This department belongs to the scientific chemist: it is of no use in the smelting-house. There is no doubt but the humid analysis furnishes the most correct estimate of the contents of an ore, slag, and metal, but in all instances it is advisable to verify these results by the dry assay, for there are innumerable instances where the portions of metal obtained in the analysis cannot be yielded by the ore in the most perfect smelting operations. The assay comes nearer to the practical result than the analysis. We cannot deny that the analysis furnishes principles upon which improvements are and may be executed, but these principles and facts are only useful in the hands of a scientific and experienced metallurgist.

The manufacture of metals.—In this part of our labors we shall omit the allusion to iron, because a valuable contribution is furnished under the proper head; we shall further limit ourselves to those metals which are actually manufactured, or are likely to be manufactured in the United States.

Gold.—*Germ.* gold; *Fr.* Or; *Lat.* Aurum. Gold is found almost over the whole globe, but in most cases in small quantities compared with other metals. At the present time California affords the largest amount of this metal in the world. Virginia, North Carolina, South Carolina, Georgia, and Alabama, in the United States, afford gold in considerable quantity. The production of California amounted in the year 1850 to about $40,000,000 worth of this metal; the other States of the Union together about $2,000,000. Next to the United States, the largest amount of gold is furnished by Russia, from the Ural Mountains. It is found extensively in the South American States, near the Equator, in Africa, Asia, and Europe. Gold is chiefly found in its native condition, in a metallic state, alloyed with silver, and sometimes with tellurium, as is the case in Virginia and North Carolina. In California it is found chiefly in alluvial ground, bedded upon rock in most cases; it is also found inclosed in quartz rock, apparently in veins ramifying the rocks of an extensive mountain range. This California gold is obtained chiefly in large grains, and often in lumps of several pounds weight. In the other States of the Union the gold is in very minute fragments, often invisible to the eye if not aided by a lens, only to be detected by crushing and grinding the rock and washing off the debris. This gold is apparently derived from the decomposition of iron and copper pyrites, chiefly the first; which assertion cannot be objected to, because it is founded in principle that almost all iron pyrites contain gold, that the gold ores of that region are rocks which are colored by iron, and that this iron is evidently derived from the decomposition of the pyrites. Pyritous ores of this kind are worked which contain no visible gold, or which do not yield gold at the first crushing and washing, but which furnish gold in a succession of amalgamations, performed after regular intervals of exposure to the air in a fine powder. Gold is also furnished by the silver ores of North Carolina and Virginia.

A splendid yellow color and brilliant metallic lustre characterizes gold distinctly from other metals; its specific gravity being 19·3 to water, is another quality easily appreciated by the senses. It is preeminently ductile, which qualifies it for an extensive use in the arts. One grain of gold may be drawn into a wire 500 feet long; silver may be coated with gold, of which the thickness is only the twelve-millionth part of an inch, and still the microscope cannot detect the slightest indication of an interruption of the gold coating. Pure gold requires more heat for melting than either silver or copper, but as all native gold is alloyed with some other metal, it may be considered more fusible than those metals. If, in cupelling gold, the hot globule shines with a greenish light, we may consider the gold not much adulterated; if it contains 10 per cent., or from there to one-third of silver, the color of the gold is in the hot cupel white as silver. Pure gold is not very volatile, and may be exposed to a strong heat for a long time without loss of metal; but if gold is alloyed with volatile metal, such as lead, zinc, and antimony, it is liable to be carried off by their vapors. Gold has a considerable cohesion, which

inclines it to crystallization. Its crystal form is an octahedron; it is often found in fragments of crystals imbedded in quartz, of which fine specimens are found in California, and also in the gold region of the Southern States. In melting gold along with pure borax it assumes a whitish color, as if adulterated with silver; in melting it again with saltpetre, or common salt, it recovers its rich yellow color.

The geological position of gold is in the primitive rock. It is found in granite, disseminated in grains and spangles through the mass of rock. In the United States gold is chiefly found in the stratified transition series; in California it appears to be disseminated through this rock, imbedded in quartz. Most of the gold, the California gold exclusively, is found in alluvial soil. In the Southern gold region this source is much exhausted, and the gold is here obtained from regular, well-developed veins, running parallel with the general direction of the rock strata, southwest by northeast. The plane of inclination of these veins is also parallel with the plane of inclination of the general formation. It appears from this that the gold-bearing veins are of a simultaneous origin with the rock; at least, they have been introduced when the rock was in a plastic condition. In Virginia and North Carolina the gold-bearing veins are a ferruginous talcose slate, often inclined to mica slate. In North Carolina this slate is found to be very hard in many instances, showing a compact solid mass of rock, apparently the same slate, but having been under the influence of a considerable heat, it is hardened. In Virginia this slate is more soft, the fissures open more readily, and the whole vein shows the appearance of soft slate. This slate is impregnated with small quartz veins, from one-eighth to one-half an inch, and often two inches thick. Where these quartz veins are thin and in great numbers, the ore is always found to be richest in gold. This feature of the ore is well developed throughout Virginia, and at Goldhill, North Carolina. The vein-stone of the gold-bearing veins is strongly impregnated with oxide of iron, showing evidences that this iron is derived from pyrites, because the oxide appears in dots or flowers, and groups of dots. Many of these veins have been traced to that depth where the pyrites are not oxidized; here they appear in their perfect crystal form, and are profusely distributed through the slate. The oxidation of these pyrites appears to depend on the penetrability of the rock by atmospheric agents; where the slate is soft we find it oxidized to the depth of from 50 to 150 feet; where the slate is hard, as is the case at the Sawyer mine, North Carolina, the oxidation reaches hardly ten or twenty feet deep, and is in many places, such as bluffs, not developed at all. At the latter spots the pyrites are in their original form, untouched by oxygen. Where the pyrites are not oxidized the extraction of gold is connected with considerable more expense than it is from soft slate and oxidized pyrites. The crushing of the hard slate is in the first place more expensive; the sulphur of the pyrites destroys a large portion of quicksilver in amalgamation, and the gold cannot be all extracted; the largest portion of it remains inclosed by the sulphuret of iron, which can only be liberated by destroying that envelope.

When we consider the great extension of the Southern gold formation, which is at least 500 miles long; the breadth of the gold-bearing strata in which the veins are imbedded, and which is from 5 to 20 miles wide; further consider the depth of these veins, which may be assumed to be 2000 feet, the body of gold ore in these regions is certainly to be regarded as an important source of national wealth. There is, however, one drawback to the rapid extraction of gold from these deposits—the ores are all, without exception, pyritous in greater depth, and to work these sulphurets to advantage no progress has been made up to this time. Various experiments tending to accomplish this purpose, and affording means of extraction, have been tried, but none of these succeeded so far as to work the poorer class of ores. At Goldhill, N. C., where the ores yield from $1.50 to $3 of gold in 100 pounds or one bushel of ore, the pyritous ores are ground, amalgamated, and a certain portion of gold extracted. The crushed ore, now a fine sand, is exposed to the influence of the atmosphere for one year, after which the process of grinding and amalgamating is repeated, and another portion of gold, almost equal to the first, is extracted. An exposure of another year furnishes another crop of gold, which operation may be repeated four or five times without extracting all the metal from the sand. This way of working is tedious, expensive, and will not answer where the ores yield but 25 cents to the bushel. The process of roasting these ores by artificial fire is too expensive, and all processes which require much labor are out of the question. Here is a promising field for American ingenuity and industry.

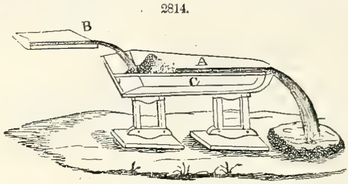
The extraction of gold is performed in California, and also in some parts of the Southern States, simply by washing the alluvial soil, removing the sand, clay, and debris of rock; after these operations the gold, as specifically the heaviest matter, will remain in the vessel in which the washing has been performed. This washing may be done to advantage in a tin pan or a sheet-iron pan. Such a pan is filled with sand containing the gold and immersed in water; in stirring it gently by hand the clay and light sand flow off, and, after some of the earthy matter is removed, the pan is shaken so as to bring the heavier gold to the bottom of it; the superstratum of sand is now removed, and the gold found in the bottom of the pan. Where water is abundant, a more effective machine than the pan is employed. This machine is called a rocker. It is represented in Fig. 2814.

This is a machine made of wood, about 6 feet long, 26 inches high, and 16 inches wide in the trough. A is a grating of flat iron bars, set edgeways, leaving an open space of about ½ an inch between each bar. By B a strong current of water is let upon this grating, which flows off at the opposite end of the machine. The machine rests upon two gently curved frames, which admit of a rocking motion upon two planks laid on the ground. This apparatus is set in a rocking motion by a boy, two wooden springs on each side of it limiting that motion, and forcing the rocker back at each vibration. The machine represents in its motion a worn-out cradle, which is used beyond gentle rocking. A laborer supplies the rocker with sand at B, by means of a shovel; the sand which passes through the grating, and also the gold, falls into the trough C, in which quicksilver is kept in case the gold is fine; it forms here an amalgam of gold. The light sand from C is swept off by the water which passes through the grating. The cradle is more or less inclined towards the discharge of the charges, according to the kind of material to be washed. These operations are quite effective; secure, for coarse gold; the fine and floating gold is lost.

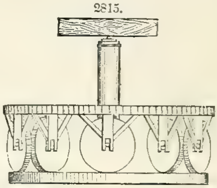
Gold inclosed in rocky matter cannot be washed with success in the foregoing described manner; the rock must be crushed, and is, in this operation, transformed into more or less fine sand. The bulk of this sand is removed by washing, and the rest, with the gold, reserved for amalgamation. The crushing is performed in the stamp-mill, Fig. 2808; the sand, including gold, conducted over hides, which retain the gold, and the sand is floated away. The gold and sand from the hides are removed, when the latter are filled, to an amalgamating machine, which combines the gold with quicksilver, and admits the sand to flow off. Instead of hides, woollen blankets are also used for gathering the gold, and there is a diversity of opinions as to the merits of either. Blankets, it is contended, are more expensive than hides, but they have the advantage of working more uniform. Hides are cheaper, but they lose their hairs or wool very soon, and are then not fit to do good work. Hides of short, curly wool are selected; these are spread on the ground, and over these the water, sand, and gold are led in a broad sheet. In other instances shaking-tables are suspended at the discharge of the stampers, which gather the gold and some sand. Shaking-tables are wooden platforms of 8 or 10 feet long, and from 3 to 4 feet wide, made of 2-inch plank well joined together, and the whole smoothly planed. Around the edges of the table are projecting ribs, which prevent the water from flowing over the edges. In suspending this table, a little inclined to the horizontal, leading the sand and water over it in a broad sheet, and applying a gentle shaking motion to it, the gold will sink to the bottom and move gently down the plane; it is arrested at the lowest end of the table by a projection on the table. In either of the above cases the gold is brought to the amalgamating machine for amalgamation.

Most of the gold-mining establishments are provided with Chilian mills for crushing the ore. We furnish a description of it in its simplest form in Fig. 2808, in which form most of these machines are erected. Still, there are some machines of this kind in North Carolina, which work by four or five runners or crushers in one trough.

2814.

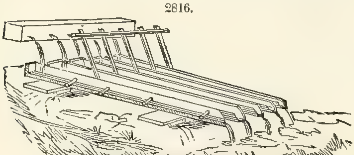


2815.

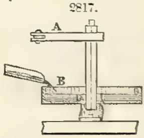


In Fig. 2815 is such a machine represented as it is in operation at Goldhill. It is a cast-iron circular trough of about 16 feet diameter, 10 inches wide, and 6 inches deep; the trough is firmly fixed upon the floor of the mill. In this trough five travellers or head-stones are moving, of 3 feet diameter and 6 inches thick, rounded on the edge, made of cast-iron. These travellers are fixed to the revolving-shaft in the centre, and are moved by it. The circular trough is supplied with coarsely broken ore and a constant current of water, which latter washes off all the light impurities, and leaves the gold in the trough. At the close of every day's work the trough is supplied with some quicksilver, which is worked in it for $\frac{1}{4}$ or $\frac{1}{2}$ hour's time, in which time it absorbs the gold, and is then removed as amalgam. The water from these mills is generally conducted into other machines, in which some of the fine gold which passes from the first machine is gathered. In most cases a shallow round basin, of about 4 feet diameter, is appended, in which a rake moves around with a vertical axis, gently stirring the sediment which may settle from the passing water. It retains only the heavy particles. In other instances, Sullivan bowls (a small machine which derived its name from the inventor, residing in North Carolina) are appended; these gather the heavy parts which may escape the previous machines.

2816.



2817.



A Sullivan bowl is represented in Fig. 2817. A vertical wooden shaft of about 18 inches long and 2 inches square carries on the lower part a shallow vessel or bowl B, about 2 inches deep and 18 inches in diameter. This bowl is formed of a wooden bottom and sheet-iron periphery. This bowl receives the water from the other machines at or near its circumference, and discharges at the centre. By the lever A, the machine is set in a rocking motion, caused by a crank connected with the same. This machine gathers a great deal of fine gold, but it is an expensive machine, because they work but little water, and it requires many machines to do the work of a small establishment.

The gold from the various machines, mixed with some sand and other impurities, is carried to the Chilian mill for amalgamation, in case there is no other machine for doing that work. This is an imperfect machine for amalgamation, and causes losses in quicksilver and gold. In most cases separate

machines are used for amalgamation: in North Carolina the cradle is generally employed. The cradle is made from the trunk of a tree, hollowed out so as to form a round trough, closed at one end and open at the other, as represented in Fig. 2816.

Here is a battery of 5 cradles represented: as many as that are frequently connected and moved by a little boy. A cradle is from 10 to 12 feet long, hollowed out of a trunk of at least 24 inches diameter. The bottom part is thicker than the sides. The first cradle in the drawing shows a section. We see here three or more grooves carved in the bottom; in each of these grooves from 3 to 4 pounds of quicksilver are put. At the farthest end sand is shovelled in and water led upon it, the cradles being a little inclined towards the discharge. A gentle current of water will have a tendency to wash sand and every thing else down the trough, the trough being, in the mean time, in a rocking motion, which assists the water in washing off every thing. The quicksilver in the grooves is also in constant motion, by which the heavy granules of gold gliding down on the bottom are arrested by it, while the lighter matters, as sand, &c., are not attracted, and pass over the mercury. These machines are very effective, but work slow, and lose much of the fine suspended gold. Other amalgamating machines have recently been put in operation; their efficacy is, however, not settled, and we hesitate to describe them In North Carolina the German barrel amalgamation has been introduced within a few months, but we are not informed of the results. In Virginia, amalgamating machines of novel patterns have been tried, but we are not acquainted with their effects.

All amalgamating machines suffer under a common evil,—they cannot work all the water as it issues from the crushing machines to advantage. In all instances half the golden contents of the ore are lost. This is owing partly to the clayish condition of the ore, which clay incloses particles of gold and carries it off, and partly to the extreme division of the gold in the ores of these regions, particularly in North Carolina. This minute division causes the gold to be suspended in water, and in that condition it is carried away by the current. A good amalgamating apparatus, which will work the water directly from the crushing machines, rub off clay and other matter from the particles of gold, so as to make it adhere to the quicksilver, and which does not lose any quicksilver, is still a desideratum in the Southern gold-mining districts.

Gold, gathered by quicksilver, forms a white amalgam. In the amalgamating machines a surplus of quicksilver is used to secure the fluidity of the mercury; for if it gets slimy, or still worse, plastic, like clay, it will not absorb any more gold with facility. The fluid amalgam is pressed through a soft leather or a piece of close canvas, to remove the superfluous mercury; after which a solid amalgam, called quick, remains in the bag. The quicksilver which passes through the bag retains always some gold in solution, the quantity of which varies according to the stuff through which it has been squeezed. The amalgam thus obtained contains from 30 to 70 per cent. of gold, according to the mode of working and the quality of the ore. The quick from the Chilian mills generally contains but from 30 to 40 per cent. of gold, while that from stampers contains seldom less than 40, and in most cases from 50 to 60 per cent. of gold. This circumstance appears to speak in favor of the stamps; the difference in the contents of gold, in the amalgam, is owing to its division; the finer the gold the less of it the amalgam contains. The dry amalgam is distilled in an iron retort, lined with clay; a red heat will drive off the mercury, which is condensed by leading it into cold water. The gold remains in the retort in the form of a powder, which is collected, melted in a crucible along with some saltpetre, and cast into iron moulds, forming square bars of about one pound weight each. One pennyweight of gold of the Virginia mines is generally worth from 90 to 92 cents. North Carolina gold contains more silver than the first, and a pennyweight is seldom more than 90, and in the majority of cases, from 80 to 90 cents to the pennyweight. California gold ranges from 75 to 90 cents.

In Virginia and North Carolina gold ores are mined, crushed, and amalgamated, which yield but the 150,000th part of gold to the bulk of ore, and these ores are worked with profit. The Russel Mining Co., in North Carolina, which operates 12 or more Chilian mills, works ore which yields 10 cents of gold to the bushel, or 100 pounds of ore, with profit. The Louisa Mining Co., which employs stampers for crushing, shows that ores which yield 7 cents in the bushel may be worked, and pay expenses and profit. There are inexhaustible stores of gold ores in the Southern States; it requires nothing but industry to make its production profitable.

Silver.—Argent, *Fr.;* silber, *Germ.;* argentum, *Lat.* Native silver is frequently found; it appears crystallized, but chiefly in irregular concretions, often in the form of fine hairs. Generally it is combined, or alloyed, with gold, quicksilver, antimony, arsenic. It appears as sulphuret in connection with the sulphurets of most other metals.

Pure silver is the brightest of the metals, of a beautiful white color and rich lustre. Its specific gravity is 10·47. It is a little more fusible than gold, but in practice we find generally the reverse, which is owing to the alloys of the two metals, which have a more softening influence upon gold than upon silver. Silver is exceedingly malleable, but not so much as gold; it crystallizes very readily when exposed for some time to the influence of heat in a melted state, but not so when alloyed to other metals. This latter quality of silver has been made available in practice, in refining lead for silver. If silver bearing lead is exposed to a melting heat, the silver will not crystallize along with some lead. Lead crystallizes more readily in this case, and these crystals may be removed from the fluid mass by an iron dipper pierced with small holes. The crystals of lead, thus freed from the largest part of their silver, are melted and converted into pigs and sold. After repeated melting and crystallization, the remaining fluid is rich in silver, and is now refined in the common way.

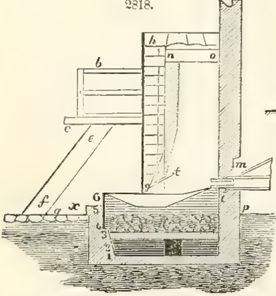
Silver ores are of great variety: there is antimonial silver, found in Mexico and Europe; sulphuret of silver, almost everywhere; also the mixtures of sulphuret of silver, with other metallic sulphurets; chloride, carbonate, and tellurate of silver are curiosities of little practical value. Most of the silver, and in the United States exclusively, is derived from the sulphuret of lead, from galena. In the Union we have but one establishment which manufactures silver to some extent; it is the Washington Mining Co., in North Carolina. As the production of silver from its ore is generally conducted on the same

principles, and as the operation at the Washington mine may be considered one of the most difficult cases, on account of the composition of its ore, we will describe the operation in this instance.

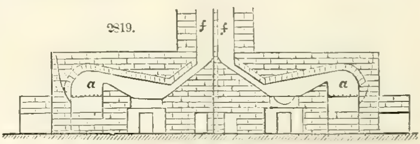
The ore at this establishment consists chiefly of brown sulphuret of zinc, which is largely mixed with galena, copper, and iron pyrites; it contains silver, gold, and other metals. The ore as it comes from the mine is broken into coarse fragments, and roasted in heaps in the open air, in the manner described before. The roasting is performed altogether by wood and wood charcoal. After the first roasting the piles are picked over for such ore which is well roasted, and that which is too much roasted. This is brought to the stampers, crushed into a fine powder, and washed, so as to carry off all the oxidized zinc and quartz. If the ore, after its being crushed, is found to be imperfectly roasted, it is returned to the yard and once more subjected to roasting. That part of the ore which is rejected in the yard is piled and roasted along with some fresh ore from the mine. In this way it may happen that some of the ore is exposed to several heats. The roasting operation is not considered to be finished until all the sulphuret of zinc is destroyed; that is, until the zinc is deprived of its sulphur and converted into oxide of zinc, in which form it may be washed away by the water at the stamping-mill.

The finely powdered ore consists now chiefly of galena, or, in case the roasting operation is well performed, of oxide of lead, oxide of iron, oxide of copper, silver, and other matter. This ore is brought to the smelting-furnace, called a high-furnace, and here smelted along with some fluxes by charcoal. In Fig. 2818 such a furnace is represented; it is a solid work of masonry, calculated to retain its heat if once thoroughly heated. The fire is urged by cylinder bellows, driven by a steam-engine; the air to the furnace is supplied at the tuyere *m*. In consequence of the alternate charges of coal and ore, the basin or hearth *g* is regularly supplied with metal, which is removed at certain intervals of time, so as to afford room for fresh metal and cinder. In this manner about one ton of lead is obtained in 12 hours, which is removed and put aside for refining. The composition of the ore, which makes its perfect roasting difficult, renders it necessary to make large additions of iron ore to the posts of ore. The iron oxide, which is reduced in presence of carbon in the furnace, will absorb the sulphur from the other metals in case there is any sulphur left after roasting. This circumstance renders the operation tedious and slow. It cannot be avoided but by perfect roasting, which may be considered practically impossible in this instance. The presence of zinc is what renders the operation tedious and expensive. If the zinc is not removed to a large extent, it will, in smelting the ore, carry off by evaporation much of the other metals, gold and silver not excepted. The sulphurets of zinc and lead are very fusible if in contact. In roasting the ore these two sulphurets will invariably melt together, which causes the roasting process to be either very expensive or imperfect. All experience with a similar ore in other parts of the world are confirmatory as to this operation being expensive.

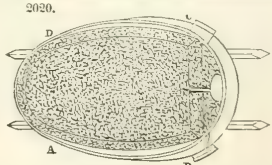
2818.



2819.



2020.

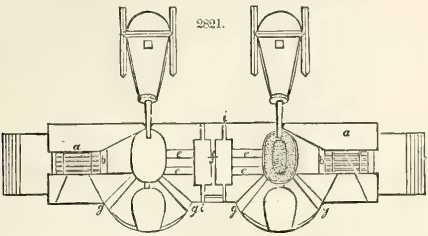


The lead from these blast-furnaces is transferred to the refining-furnace. Formerly the English refining-furnace was used as it is represented in Fig. 2819, in a longitudinal section. Here is a double, or two furnaces represented, which, as is shown, are reverberatory furnaces. The fireplace *a* throws the flame over the hearth or cupel into a chimney, which is provided with a sliding door at *f f* to shut off the draft and prevent the fumes of metal from escaping through the stack. The cupel is formed of several layers of bone-ashes, mixed with wood-ashes; this mass is rammed into an iron hoop when in a moistened condition. The form of this cupel is represented in Fig. 2820; from above it is a concave egg-shaped dish, of about 5 inches thick, the largest diameter being 4 feet, the smallest 2 feet. When the furnace and cupel are heated, the lead, previously melted in an iron pot, is cast into it; and now the bellows, which are represented in Fig. 2821, are set to work, a gentle current of air is thrown over the hot surface. The action of the blast is here twofold: it oxidizes the lead and forms litharge of it, and drives by its force the melted litharge to the opposite side of the blast, or the tap-hole, where it flows out and falls into an iron basin, from whence it is carried back to the smelting-furnace. The level of the lead is in this way gradually reduced if not kept up to a certain height; this is done by casting in melted lead, which is always ready melted in an iron pot. This process is carried on until a certain quantity of lead has been concentrated so far that a little more than one weight of lead is combined with an equal weight of silver; this rich lead is taken out and refined in a properly prepared cupel. If sufficient rich lead is ready to make from 500 to 1000 ounces of silver, it is refined in a new cupel,

and the silver melted into a cake. The operation is carried on as before, with the only difference, that no fresh lead is added.

The Washington mine has more recently introduced the German refining-furnace represented in Fig. 2822, with what success we are not aware. This furnace is larger than the above English furnace, the cupel being at least 6 feet diameter. The drawing shows a section of the furnace, in which the fire-place *y*, the tuyeres *n n*, and the door *q*, into which the lead is charged, are shown. In Fig. 2823 is a ground plan of the furnace shown. Here is the flue *x* visible, which leads to the stack, and which serves in the mean time to clear off from the surface of the melted lead some of the scum. The cupel of this furnace is made entirely of wood-ashes, which are the refuse ashes from the soap-works, and in this respect the furnace has an advantage over the English furnace. The floor or hollow surface of it is well pounded by wooden mallets, to make it solid and smooth. About four tons of lead are charged for one heat; it is carefully laid upon the bottom, and at first gently heated, so as not to injure the fresh bottom

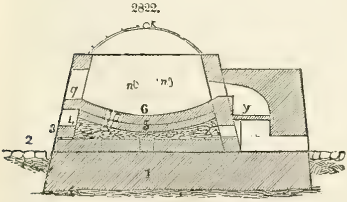
2821.



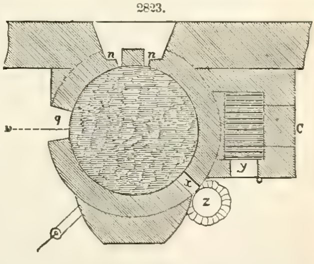
and dome. When the lead is melted, and all ebullition ceases, the blast is thrown in at the tuyeres *n n* by setting the bellows at playing on the surface of the melted metal. At first no litharge is made, but a dirty froth of oxydized metals is raked off, to facilitate which formation of froth, fine charcoal dust is thrown on the surface. When all the impurities of the lead are removed in this way, the formation of litharge begins, which flows off at the flue *x*. The separation of the litharge from the lead must be assisted by a hook, because the blast is generally not strong enough to move the fluid oxide of lead over the large surface of the molten mass. The cupellation of four tons of metal lasts from 18 to 20 hours. Towards the end of the operation some silver is carried off with the litharge, which portion of litharge is therefore carefully preserved, to be remelted by itself or along with other ore. The silver is, in this operation, obtained pure in the first heat; it is melted into the form of a cake in a cavity prepared for its reception in the centre of the hearth.

In all these refining operations there is an inevitable loss of metal, disappearing in the form of fumes, through the chimney. This loss is variable, and may be modified by the skill of the workman and the purity of the lead; it amounts on an average to from 4 to 7 per cent. of the lead melted.

2822.



2823.



The extraction of silver from its ores by amalgamation is not practised in the United States; this process requires rich ores and cheap quicksilver. In the old States of the Union there is no prospect of seeing this process executed; but in California, where rich silver ores and mercury ores abound, there may be a probability of its being executed; still it is a tedious, expensive operation, which, at the rate of wages paid in the United States, will not yield much profit. Amalgamation is a process not adapted to our social condition; it is too laborious to secure success in ordinary cases of common or average ore. For these reasons we do not furnish a description of this operation. In our condition there is no way of working silver ores profitably but by smelting the ore and refining the lead; or, in some instances, the new process introduced last year into European establishments may answer our purposes.

Some of the silver smelt-works of Germany have been in a condition of working poor ores, which, in many instances, have not covered the expenses of smelting or amalgamation, which must be extreme cases, considering German industry and perseverance. A process has been introduced within a short time, which promises to advance the interest of the metallurgy of silver greatly. The operation is as follows. Silver ores which may be poor or contain more or less silver, are coarsely broken or stamped, and then

carried to a reverberatory furnace; here the ore is heated to redness, calcined, and in that state from 2 to 5 per cent. of common salt is added to the ore; the whole kept in that degree of heat, and stirred by iron bars for some hours. The object of this operation is to transform the silver contained in the ore into chloride of silver, which is so much more easy, as silver has a predominating affinity for chlorine. If the operation of heating is perfected, the red-hot ore is drawn from the furnace and thrown hot into a boiling concentrated solution of common salt. The hot salt solution will dissolve the chloride of silver, and it is kept in solution so long as that solution is boiling-hot; it is therefore necessary to filtrate it in this condition. To the hot and filtrated solution a little muriatic acid is added, and then some coarse pieces of crude copper; which latter precipitates all the silver in a metallic state, in the form of a fine powder: this is gathered and melted in a crucible; it is pure silver. This process is, to all appearances, simple, and is in fact so; but it requires an expert chemist to execute the operation. If there is only copper, iron, and silver present in the ore, the operation is simple; but if there is gold, lead, or quicksilver in the ore, the case is not so easily managed; for the gold will not pass with the silver into the solution, and the chlorides of lead and quicksilver, which are soluble in the same manner as chloride of silver, are precipitated by the same means. The application of this process to our Southern ores is difficult, but it may be an extremely useful process in applying it to the argentiferous stamp-work of the Lake Superior copper ores.

The silver ores of the Southern gold region, such as are smelted at the Washington mines, yield from 200 ounces to 300 ounces of silver in a ton of lead; the ore itself contains on an average 8 per cent. of lead; the other matter is zinc, iron, copper, tin, and chiefly sulphur. The silver is worth $1.80 the ounce, because it is alloyed with a large portion of gold, which raises its value to double the value of pure silver.

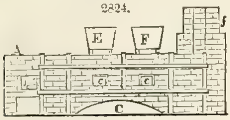
Copper.—Germ. Kupfer; *Fr.* Cuivre; *Lat.* Cuprum. Copper was known to the ancients long before iron; most of the metallic instruments of the era preceding ours were made of copper, alloyed with tin and other metals. The ancient nations on the old continent, as well as the inhabitants of America before European invasion, understood the art of hardening copper as well as we now understand hardening steel. This art is now lost, and we doubt its utility if it were recovered. Copper is profusely distributed all over the globe; its ores are found everywhere. Native copper is particularly found in this country and in Russia. The ores of copper are chiefly sulphurets, of which the yellow sulphuret, or copper pyrites, forms nine-tenths of all the ore used in the smelt-works. Besides this ore, there is the gray sulphuret; there are carbonates, arseniates, phosphates, silicates, oxides of copper, and others; all these ores are of more interest to the mineralogist than to the metallurgist. The bulk of ore, particularly in this country, are the yellow pyrites; besides which, the native copper forms an important source of metal to the smelter. The whole amount of copper produced in the world annually is about 33,000 tons, of which Europe produces 25,000 tons; the rest is American copper.

In the United States there are four large copper smelt-works, and some smaller. At Boston, New York, Baltimore, and Pittsburg are smelt-works, working on the English plan; smaller furnaces are in Missouri, Wisconsin, and Michigan. At present most of the smelt-works are stopped for want of ore. If all the furnaces in the Union could be kept in operation, we should produce more copper than we want, and have some for export; for the smelt-works have a capacity of 18,000 tons. The works along the Atlantic coast depend chiefly upon ores from Cuba; Pittsburg and Boston are supplied from Lake Superior. All the States along the Atlantic coast furnish copper ores, but there must be causes which prevent a regular supply to the smelt-works. Our ores are not particularly rich, still there are mines in New Jersey, Pennsylvania, Virginia, and all the Southern States, which will pay handsomely if carried on properly. There is a deposit of native copper in Virginia which will furnish stamp-work equal to Lake Superior. The chief difficulty in our copper-mining business is, that some of these mines have been carried on by ignorant persons; in other cases, swindlers have abused the confidence of the community. If copper-mining in either of the Atlantic States is carried on with discrimination, industry, and not over-sanguine expectations, there is no doubt as to its being a safe and paying business. Many of our copper mines would be, and could be carried on by farmers, or the owners of the soil, it their knowledge of mining and preparation or concentration of the ore were sufficient to make the operation profitable. In these respects the smelt-works can assist a great deal in developing the resources of the country, if they will furnish such instructions to the owners of the mines as will facilitate their operation; for it must be presumed the smelt-works are more qualified to furnish practical information on that subject than any other person or persons can do. Ores do not come now on consignment, because the owner of the ore does not like to run the risk of a sale which appears to him arbitrary. Our Atlantic smelt-works have to exert themselves in developing the sources of ore, and export copper, or they are to stop operations. Lake Superior promises to furnish 6000 tons of copper this year; this will supply nearly the demand of the Union; there is, therefore, little or no choice for the Atlantic works, but to smelt for export. Here are means, that is, ore and fuel, to go into competition with Europe: it requires some industry to make these means available.

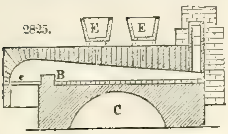
The smelting of copper ores in all of our smelt-works is carried on in furnaces resembling the English furnaces at Swansea. The operation of smelting is also similar to the English process, all of which elaborate descriptions are furnished in Ure's Dictionary of Manufactures and Mines. The operation of smelting is divided chiefly into preparing, or washing and crushing of the ore, calcining, smelting and refining. The washing of these ores is performed at the mines, and also the crushing or concentration, and does not differ from similar operations performed on other ores. The furnaces used in the various operations at the smelt-works are all of the reverberatory kind, and fired by bituminous coal, or by wood. Fig. 2824 shows a calcining-furnace in elevation, Fig. 2825 the same furnace in section, and Fig. 2827 shows the ground-plan of the furnace. A is the fire-place, B is the hearth, C an arch into which the ore is drawn; E E are stationary hoppers, or feeders, and *b b b b* four work-doors. The ore in this calcining operation is not fused; it is heated merely to such a degree of heat as will evaporate sulphur and arsenic, and oxidize the metallic ores. These calcined ores are exposed to a second heat,

either in the same furnace, or, as in most cases, in a separate or smelting-furnace. Such a furnace is represented in Figs. 2832, 2833, showing the plan and section of it; here A B is the hearth, C the fire-place, L the hopper, and K M a receiving-pot filled with water, in which the copper is granulated. In the second operation, or smelting, some copper is produced along with the matt or slag, which is separated and treated in a peculiar way. The matt, which contains but little copper, is returned to the calcined ore, and smelted along with it. In this operation fluxes are added in case the ore does not contain sufficient flux for smelting. Iron forms the best flux, and for these reasons: copper pyrites, which always contain more or less iron pyrites, are the most profitable ores in the smelting operation. Other fluxes are the metallic oxides of manganese, lead and tin, besides which, lime, fluor-spar, or other fluxes are used.

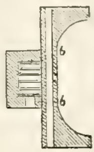
2824.



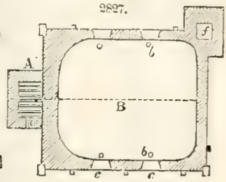
2825.



2826.



2827.



The copper obtained in the first smelting operation is impure, and classes not higher than a rich matt or melted ore; its granules consist of copper, iron, sulphur, &c. This matt or coarse metal is once more calcined in the calcining-furnace, and then subjected to another smelting, by which operation a more refined metal is obtained. The latter product is, however, not yet fine copper; it is matt, which contains 60 per cent. of copper; it is granulated and roasted as before, and once more smelted, by which a richer matt is obtained. These alternate operations of roasting and smelting are repeated from seven to eight times before fine copper is obtained. The cause of this delay, or repetition of calcining, is found in the great affinity of copper for sulphur and arsenic, which it requires repeated fire and cooling to expel successfully.

The refining of copper is done in the smelting-furnace, or a refining-furnace kept for the purpose. The melting of the pigs is conducted slowly, so as to calcine the copper, in case any impurities are left in the fine copper. When the copper is melted, its surface is covered by finely broken charcoal, which operation is repeated as the charcoal consumes. This refining process lasts for 20 hours, and longer, for one heat of from 8 to 9 tons, after which time the copper is ladled out by means of iron ladles coated with clay.

The Germans, and all other European nations, also the new copper smelt-works in Baltimore, smelt their copper ores in furnaces similar to those represented in Figs. 2828 to 2831. The operation is similar to that of smelting lead, silver, or iron ores. In these furnaces, which are about 15 feet high, and 3 feet wide, are two tuyeres C C, and a cinder tap-hole in the line G H. The copper is tapped into the basin *i*, where it is chilled on the surface and forms rosettes, or it is cast into pigs for refining. The latter process is performed in reverberatory furnaces, similar to those described.

The native copper occurring at Lake Superior, in Virginia, and elsewhere, contains a large portion of silver, which at present is lost; to extract this silver by liquation is expensive, and injurious to the quality of the metal; to do it by amalgamation is expensive, and hardly would pay the trouble. There are, however, ores which contain more than one per cent. of silver to the copper, and we may assume the whole body of copper contains the half of one per cent.; this would amount, on the 6000 tons of Lake Superior copper to be furnished this year, to at least $60,000 worth of silver, which silver is now entirely lost. We recommend for the extraction of this silver the process alluded to above.

Copper is one of the most useful metals, particularly in its alloys with tin, zinc, and other metals. The native metal is frequently found to be crystallized in concrete, irregular masses, ramifying the rock in which it is found; it is also found in grains, disseminated through the rock. It is less fusible than silver, of a specific gravity of 8·94. It is highly tenacious, and its fracture fibrous.

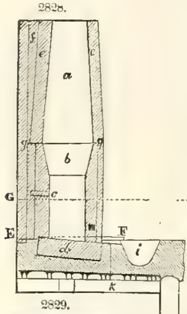
Lead.—Germ. Blei; *Fr.* Plomb; *Lat.* Plumbum. This metal is, like gold, silver, and copper, known since time immemorial. It is one of the metals the most easily obtained from its ores. The chief ore from which lead is smelted is galena or sulphuret of lead, which contains when pure 86·66 parts of metal, and the remainder sulphur. The United States and Spain are at present the contending parties in the lead market, and there is a prospect of our final supremacy. The amount of lead manufactured throughout the world may be about 100,000 tons annually, of which our Mississippi lead region furnished last year 20,000 tons, Spain 31,000 tons, and England 39,000 tons.

The metallurgy of lead is very simple, particularly in this country, where an abundance of good galena is found, as in Missouri, Iowa, Illinois, Arkansas, Virginia, California, and more or less in all the States of the Union. Very little or no lead is smelted from other ores but galena. In the Northwestern States, Illinois, Wisconsin, and Missouri, are the principal lead smelt-works; the operation as it is conducted in these places is very much the same as in other parts of the Union.

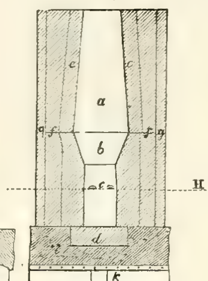
Lead is smelted in the above-named States in reverberatory furnaces and in blast-furnaces. The reverberatory furnaces resemble those in which copper is smelted, of which Figs. 2832, 2833, show a

vertical and horizontal section. About one ton of ore, along with one ton of slag from the previous heats, forms one charge. The whole is thoroughly heated by closed doors and suffocated combustion, so as to produce carbonic oxide gas in the furnace, for reducing as much lead from the slags and ore as possible. When in this way most of the lead is extracted, the doors of the furnace are opened, more heat is given, and the mass, ore and slags, thoroughly melted, with the addition of some pure quicklime, which is occasionally thrown into the melting mass, and well stirred along with the ore. Most of the lead is yielded by the ore in this operation, still there is more than 25 per cent. of it lost in the slags; these are resmelted in a blast-furnace. Reverberatory furnaces are heated by dry wood, and produce in 24 hours from three to four tons of metal.

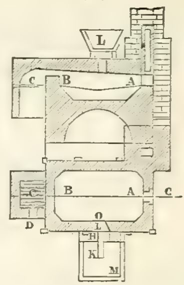
2828.



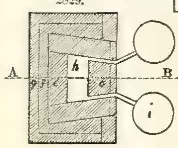
2830.



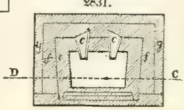
2832.



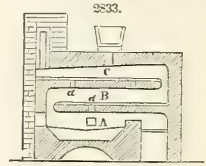
2829.



2831.



2833.



More general than the foregoing are the blast-furnaces for smelting lead. These are furnaces resembling a cupola in which iron is smelted, more than any thing else; they are generally built in a rough manner in appearance, but the inside of the furnace coincides with a cupola; it is generally from six to eight feet high; the blast is introduced by the nozzle *h* to the tuyere *y*. The lead, in gathering in the bottom *f*, is frequently tapped, so as to have but little metal in the furnace at a time. The cinder, or slag, is kept as high as the tuyere, and if it reaches too high some of it is tapped at a tap-hole in the front of the furnace. One blast-furnace will produce in 24 hours about two tons of lead, for which it consumes 6000 lbs. of galena, 25 bushels of charcoal, and about a quarter of a cord of wood. In this operation, as in the reverberatory, a great deal of metal is lost, which in most cases amounts to 20 per cent. or more. The slags contain most of this loss, still a large portion of it is destroyed by evaporation. The blast-furnace has the advantage over the reverberatory so far as regards economy, but it does not furnish so much metal in the same time as the latter.

The slags from the blast-furnace, the reverberatory, and the slags from the old Scotch furnaces, now no longer in use, are gathered, broken into coarse lumps of about two inches, and are then subjected to another smelting in the slag-furnace. The slag-furnace is similar to the above blast-furnace, but it is lower; its extreme height is only four feet, and in many instances it is only three feet high. The slags are here smelted by charcoal, with the addition of some lime and iron ore, by which about two-thirds of the lead contained in the slags is obtained; one-third of the metal in the slags, or 10 per cent. of the ore, is therefore irrecoverably lost. These furnaces are the same in principle as that represented in the above drawing; the work in it differs somewhat from the smelting of ore. The lead and slags flow here continually, the first into a basin nearest the tap-hole in which it gathers; the latter flows from this basin into a somewhat distant reservoir of water, where it is cooled and thrown away. A slag-furnace will smelt in 24 hours about two tons of metal; this, however, depends upon the richness of the slags; it will make more if the slags are rich, and will make less if poor.

The conditions of the lead business are not very encouraging at present; the profits are so small that the smelting of lead is reduced to an occupation which hardly pays the trouble of carrying it on. If an Illinois smelter, who carries on one furnace, can make ten dollars a day, he does very well. When we consider the risk of bad debts, accidents, and stoppages for want of ore or hands, we find that the smelting of lead pays worse than any other trade.

Zinc.—This metal was known to the ancients, who melted oxide of zinc, called galmei by the Germans, together with copper, and formed brass of it. A similar process is performed with the red oxide of zinc in New Jersey. The Chinese have known this process longer than historical reports reach. The most abundant ores of zinc are the sulphurets, blende; these are found in Virginia and North Carolina

in inexhaustible quantities, along with galena, silver, and the sulphurets of iron and copper. Another ore is the oxide of zinc, calamine, which is combined with carbonic acid, or silex, or both of these matters. Large deposits of this kind of ore are found in New Jersey, Pennsylvania, and some of it along the northwestern lakes.

Zinc is a brittle metal, of a bluish white color and considerable lustre; it is soon tarnished with an insoluble coating of protoxide of zinc. Its fracture is crystalline and short, and its malleability not remarkable. American zinc, manufactured by the New Jersey Company, is remarkable for its tenacity. Fine wires may be drawn of it, which possess great strength, a beautiful silvery lustre, and fine appearance. The specific gravity of zinc is 6·9 to 7·3; it melts at about 700°, and soon burns with a bluish-white light, forming bright white flowers of zinc, a flocculent matter resembling cotton-wool, or snow-flakes—it is oxide of zinc.

In the United States not much zinc is manufactured in its metallic state at present; the low price of the European zinc will not admit of working our own ores. Some zinc is manufactured in New Jersey, but the quantity is small in comparison to that imported. Considerable use, however, is made of the red oxide for the manufacture of brass. An important business could be done in the Southern States by working the silver blende for zinc, and extracting the silver in the mean time, either before or after the zinc is manufactured from it. The Silesian process of working zinc ore is the best adapted for working this kind of ore, for which reason we shall describe this operation in preference to other processes.
